2. Rows one to four favour Perforce for this workload. Row five favours git. Row six favours git.
3. For a 300-person studio where everyone sits in one building with a fast local network, row five is worth little and rows one to four are worth a great deal.

4. For a distributed open-source project with 4,000 contributors on five continents who have never met, the weighting inverts completely.
5. Neither team is confused. They are optimizing different things, and the correct engineering answer is “it depends on the workload”, which is an unsatisfying sentence that happens to be true.

■ 37.10.4 PLAIN – what is really happening inside

1. The locking problem deserves precision, because it is the clearest structural limit of the distributed model.
2. A lock is a statement that everyone must agree on, at the same time. “Only Priya may edit `level3.blend` right now.”
3. Agreement at the same time requires a single place that answers the question. That is exactly what a distributed system does not have.
4. So the absence of file locking in git is not laziness or a missing feature. It is a direct consequence of the architecture. You cannot have both.
5. Git LFS adds a lock command, and it works by contacting the LFS server. That is the same admission: to lock, you must centralize something.
6. The binary merge problem is different and is about file formats. Git merges text line by line. A `.psd`, a `.fbx` or a `.docx` has no lines, so there is nothing to merge.
7. Git will happily store binary files and version them. It just cannot combine two divergent edits, and it cannot compress them well, so the repository grows roughly linearly with every binary change.
8. The size problem compounds because git history is immutable. A 500 MB file committed once by mistake in 2019 is in every clone forever, unless someone rewrites history and every clone is re-made.

■ 37.10.5 TECHNICAL – the engineer’s version

1. Honest comparison across the main systems still in use in 2026.

System	Model	Typical domain
Git	distributed	source code, everywhere
Perforce P4	centralized	games, chips, film
Subversion	centralized	legacy enterprise
Mercurial	distributed	some large monorepos
Plastic SCM	centralized+	Unity game teams

2. Perforce, founded 1995 by Christopher Seiwald, remains the standard in game development, semiconductor design and visual effects. It received the 2019 CEDEC Award for Engineering, an award from the Japanese game industry, which tells you where its users are.
3. Perforce’s exclusive checkout is implemented with the `+l` file type modifier, which makes the server grant a write lock to one client at a time.
4. Perforce’s other decisive feature for these teams is the **client workspace view**, a mapping that lets a user sync one subdirectory of a 5 TB depot. Git has partial workarounds, sparse-checkout and partial clone, but they are less complete and less familiar.
5. Where experts disagree: some argue git plus LFS plus sparse-checkout now covers the game studio case and Perforce persists mainly through inertia and tooling lock-in. Others argue locking and workspace views are structural and git will never match them. Both positions are held by serious practitioners and the disagreement is genuine.

6. Scaling work on the git side is real and ongoing. Microsoft's VFS for Git, released in 2017 as GVFS, and later Scalar, merged into git itself in version 2.38 in October 2022, exist to make very large repositories usable.
7. Mitigations for the size problem, all mainstream as of 2026.

Technique	Reduces	Cost
Git LFS	clone size	needs LFS server
partial clone	clone size	fetches on demand
shallow clone	clone size	loses history
sparse-checkout	working tree	not history
commit-graph file	traversal time	none, local
multi-pack index	lookup time	none, local

8. Note which column those mitigations sit in. The last two are free local speedups. The first three all trade offline capability or history for size. That trade is the theme of this section.
9. `git maintenance start`, added in git 2.31, March 2021, schedules background packing, commit-graph writing and prefetching, and is the modern replacement for manually running `git gc`.

■ 37.10.6 WORDS – remember these

1. File locking — one person at a time may edit a file — a server-granted exclusive write lock, unavailable in a purely distributed model.
2. Binary file — a file with no lines to compare — content without a text structure, so it cannot be three-way merged or delta-compressed well.
3. Monorepo — one repository holding many projects — a single history covering multiple products, common at very large companies.
4. Sparse checkout — having only part of the project in your folder — a cone-mode pattern list restricting which paths are materialized.
5. Source of truth — the copy everyone agrees is correct — an external convention plus server permissions, not a property of git itself.
6. Depot — Perforce's name for the server-side store — the centralized repository from which client workspaces are mapped and synced.

37.11 Git is not GitHub

■ 37.11.1 PLAIN – in simple words

1. This confuses more beginners than anything else in the subject, so it goes in plainly.
2. **Git** is a program on your computer. You install it. It makes and reads files in a `.git` directory. It is free software, first released in 2005.
3. **GitHub** is a company that runs servers. You make an account. It stores copies of repositories and adds features around them. It launched on 10 April 2008 and Microsoft bought it in 2018.
4. Git does not need GitHub. GitHub needs git.
5. You can use git for thirty years and never make a GitHub account.
6. You can host repositories on GitLab, on Bitbucket, on a Raspberry Pi in a cupboard, on a USB stick, or on a company server. Git does not care.
7. The names are similar because GitHub chose a name based on git. That naming choice has cost the world a great deal of confusion.
8. Here is the sharpest possible test, and the reader lived it: during the outage, git kept working and GitHub did not.

9. That is not a coincidence. It is the boundary made visible.

■ 37.11.2 PLAIN – a picture in your head

1. Git is a **word processor**. GitHub is a **print shop and a noticeboard**.
2. The word processor runs on your laptop. It works on a train. It never asks anyone's permission.
3. The print shop takes your document, keeps a copy, lets others read it, lets people leave notes on it, and runs a checking machine over it.
4. If the print shop closes, your word processor is unaffected and your document is still on your laptop.
5. If your laptop dies, the print shop still holds the copy you dropped off.
6. Neither one is the other. They cooperate through one narrow channel: you carrying documents in and out.

Where this comparison breaks:

7. A print shop holds a dumb copy. A GitHub repository is a real git repository and could replace yours entirely, which is why it feels authoritative.
8. And some things blur the line deliberately. GitHub Actions can commit to your repository. The GitHub web editor makes real commits. But those are GitHub running git on its own machines, which does not change the boundary.

■ 37.11.3 PLAIN – a worked example

1. The division of labour, feature by feature.

Feature	Git	GitHub
commit, branch, merge	yes	no
full local history	yes	no
pull requests	no	yes
code review comments	no	yes
issues and projects	no	yes
CI via Actions	no	yes
access control, teams	no	yes
releases page	no	yes
hosting a remote	partly	yes

2. The partly in the last row: git includes `git daemon` and can serve over SSH, so a plain server with git installed is a perfectly good remote. It simply has no web interface.
3. During the reader's outage, the left column all worked and the right column all failed, because every item in the right column is an HTTPS request to a server in that unreachable direction.
4. The clearest evidence in that session: plain git operations behaved as described in 37.8, and GitHub API calls failed. Same laptop, same minute, different dependency.

■ 37.11.4 PLAIN – what is really happening inside

1. What git actually is: a set of programs, mostly C, plus some shell and Perl. On a typical install it is a git binary and a directory of helper executables, around a hundred subcommands.
2. It speaks two wire protocols for talking to other repositories: the smart HTTP protocol and the SSH protocol, plus the older `git://` daemon protocol on port 9418. Chapter 40 covers all three.

3. What GitHub actually is: a large web application and API, backed by many servers that hold bare git repositories, wrapped in authentication, permissions, a review system, an issue tracker and a CI system.
4. When you `git push` to GitHub, `git` on your laptop opens a connection, runs the standard protocol, and a program on GitHub's side receives the pack. That receiving program is `git-receive-pack`, part of `git`.
5. So the push path is pure `git` at both ends. GitHub's own features do not participate.
6. When you open a pull request, none of that happens. Your browser or the `gh` command makes an HTTPS API call to GitHub. There is no `git` protocol involved and nothing is written to your `.git`.
7. That is why one worked offline and the other did not. They are different systems reached by different means.
8. The honest version: people say "push to GitHub" and "my code is on GitHub" as if GitHub were where the code lives. Your code lives on your disk. GitHub has a copy, which is extremely useful and is not the original.

■ 37.11.5 TECHNICAL - the engineer's version

1. Git the software: created 2005, maintained by Junio Hamano since 26 July 2005, licensed under GPL version 2, current release 2.55.0 dated 29 June 2026. Written mainly in C.
2. GitHub the service: launched 10 April 2008 by Tom Preston-Werner, Chris Wanstrath, P. J. Hyett and Scott Chacon. Microsoft announced acquisition on 4 June 2018 for 7.5 billion US dollars in stock. The deal closed on 26 October 2018.
3. Alternatives, all of which speak the same `git` protocols: GitLab from 2011, Bitbucket from 2008, Gitea, Forgejo, Sourcehut, AWS CodeCommit, Azure Repos, and a plain SSH account on any Linux box.
4. Interface boundary in one table.

Thing you do	Protocol	Offline
<code>git clone</code> , <code>fetch</code> , <code>push</code>	<code>git</code> over HTTPS/SSH	needs net
<code>git commit</code> , <code>log</code> , <code>merge</code>	none	works
open a pull request	GitHub REST/GraphQL	needs net
<code>gh pr list</code>	GitHub REST/GraphQL	needs net
view Actions run	GitHub web/API	needs net

5. The `gh` command line tool is a GitHub client, not a `git` client. It has nothing to do with the `git` binary and fails independently of it. During the reader's outage this distinction was visible directly.
6. GitHub-specific concepts that do not exist in `git` at all: pull request, fork relationship, issue, label, milestone, review, required status check, branch protection rule, `mergeStateStatus`, Actions workflow, release, Gist.
7. Git concepts GitHub merely displays: `commit`, `tree`, `blob`, `tag`, `branch`, `ref`, `merge`, `rebase`, `cherry-pick`, `reflog`. GitHub cannot show you a `reflog`, because a `reflog` is local to a working repository.
8. Chapter 40 covers remotes, transports, authentication, tokens and scopes, and the exact division of labour when a push both moves refs and triggers a GitHub workflow.

■ 37.11.6 WORDS - remember these

1. Git — the version control program on your machine — a distributed VCS implemented as a suite of C programs, GPLv2, first released 2005.

2. GitHub — a company hosting git repositories with extra features — a web service owned by Microsoft since 2018, offering pull requests, issues and CI.
3. Forge — the general word for a code hosting service — GitHub, GitLab, Bitbucket, Gitea and similar, all built around bare git repositories.
4. Pull request — a request to merge, with discussion — a forge feature, not a git feature, implemented over the forge's own API.
5. git-receive-pack — the program on the server that accepts a push — the receiving half of git's push protocol, run by the hosting service.
6. API — a way for programs to talk to a service — here, GitHub's REST and GraphQL interfaces over HTTPS, entirely separate from the git protocol.

37.12 Getting started properly

■ 37.12.1 PLAIN - in simple words

1. There are exactly two ways a git repository comes to exist on your machine.
2. **git init** makes a new empty one, here, now, from nothing. No network.
3. **git clone <url>** copies an existing one, including all its history, and sets up a remote called origin pointing back at where it came from.
4. That is the complete list. Everything else is one of these two, possibly done by a tool on your behalf.
5. Before your first commit, tell git who you are. It records a name and an email address in every commit, permanently.
6. That email does not have to be real or reachable. Nothing sends mail to it. It is a label. But it is baked into the commit hash and cannot be quietly changed later without changing every hash after it.
7. Then create a `.gitignore` file listing things git should not track: build outputs, dependency folders, editor files, secrets.
8. And learn one hard fact early, because it catches everybody: `.gitignore` does **not** untrack a file that is already tracked.

■ 37.12.2 PLAIN - a picture in your head

1. `git init` is starting a new notebook. Blank, yours, immediate.
2. `git clone` is photocopying someone's finished notebook, cover to cover, including their crossings-out, and writing their address inside your front cover so you can find them again.
3. `.gitignore` is a note on the front of the notebook saying "do not copy receipts into this book".
4. And here is the catch that the note cannot fix: if you already glued a receipt onto page 4, the note does nothing. The receipt is on page 4. It will be on page 4 in every photocopy anyone ever makes.
5. To stop tracking it you must deliberately remove it, and even then it stays in the old pages, because old pages are never edited.

Where this comparison breaks:

6. A photocopy is a dead copy. A clone is fully alive: it can commit, branch and serve as the source for further clones.
7. And unlike a notebook, you can start with `git init` and later attach a remote, which is the normal path for a project that begins locally.

■ 37.12.3 PLAIN – a worked example

1. The full first-time setup, exactly as it should be typed.

```
git config --global user.name "Shikhar Singh"
git config --global user.email "you@example.com"
git config --global init.defaultBranch main
git config --global pull.rebase false
git config --global core.autocrlf input    # false on Windows
```

2. Then a new project from nothing:

```
mkdir myproject && cd myproject
git init
printf 'node_modules/\n*.log\n.env\n' > .gitignore
git add .
git commit -m "Initial commit"
```

3. That commit exists now, fully, with no account and no network.
4. Now the .gitignore trap, demonstrated with real output from a sandbox. A secret file was committed by mistake, then added to .gitignore.

```
$ git ls-files
.gitignore
app.py
config.env          <- still tracked

$ printf 'CHANGED\n' >> config.env
$ git status --short
 M config.env       <- git is still watching it
```

5. The .gitignore had no effect at all, because ignore rules apply only to files git is not already tracking.
6. The fix, and its limit:

```
$ git rm --cached config.env
$ git commit -m "stop tracking config.env"
$ git ls-files
.gitignore
app.py          <- now untracked

$ git show HEAD~2:config.env
secret-key      <- STILL IN HISTORY, forever
```

7. Read that last line carefully. The secret is out of the current commit and still recoverable from an old one. If it was a real credential, it is compromised and must be rotated. Removing it from history requires rewriting every commit after it, and every clone must be remade.

■ 37.12.4 PLAIN – what is really happening inside

1. `git init` creates the `.git` directory, writes a default config, writes HEAD containing `ref: refs/heads/main`, and installs the sample hooks. It contacts nothing.
2. Note that `refs/heads/main` does not exist yet at that point. HEAD points at a branch that has no file. That is the “unborn branch” state, and it is why `git status` on a fresh repository says “No commits yet”.
3. `git clone` does more. It creates the directory, runs `init`, adds the `[remote "origin"]` config, fetches everything, writes the remote-tracking refs, creates a local branch matching the remote’s default, and checks it out.

4. Real output, so you can see how little it says:

```
$ git clone /tmp/gitdemo/server.git clonedemo
Cloning into 'clonedemo'...
done.
$ git branch -a
* main
  remotes/origin/HEAD -> origin/main
  remotes/origin/feature/offline-work
  remotes/origin/main
```

5. Notice `remotes/origin/HEAD -> origin/main`. That records which branch the server said was its default, so `git checkout` of a bare remote name works.
6. `.gitignore` mechanics: on `git add` and on `git status`, git checks each **untracked** path against the ignore rules. Tracked paths skip the check entirely. That is the whole reason for the trap in 37.12.3.
7. Ignore rules come from several files, most specific first: the path's nearest `.gitignore`, then parent directories, then `.git/info/exclude`, then the file named by `core.excludesFile`.
8. `.gitignore` is committed and shared. `.git/info/exclude` is private and never leaves your machine. Use the second for editor droppings that only you produce.

■ 37.12.5 TECHNICAL – the engineer's version

1. Settings worth changing on day one, with what each does.

Setting	Value	Effect
<code>user.name</code>	your name	commit author
<code>user.email</code>	your address	commit author
<code>init.defaultBranch</code>	main	branch on init
<code>pull.rebase</code>	false or true	pull behaviour
<code>push.default</code>	simple	push safety
<code>core.autocrlf</code>	input or false	line endings
<code>fetch.prune</code>	true	drop dead refs
<code>rerere.enabled</code>	true	reuse conflict fixes
<code>diff.algorithm</code>	histogram	better diffs

2. `init.defaultBranch` was added in git 2.28, July 2020. Before that the default was `master`, hard-coded. Git still defaults to `master` if you do not set it, and prints a hint saying so.
3. `push.default = simple` has been the default since git 2.0 in 2014. It pushes the current branch to its upstream of the same name and refuses otherwise, which prevents accidental mass pushes.
4. `core.autocrlf` matters only across operating systems. On Windows, `true` converts to CRLF on checkout and back to LF on commit. On macOS and Linux, `input` or `false`. Better still, commit a `.gitattributes` with `* text=auto` and stop thinking about it.
5. `rerere` stands for “reuse recorded resolution”. With it on, git remembers how you resolved a conflict and applies the same resolution if it sees the same conflict again. It is invaluable during a long rebase.
6. Verify what is set and from where:

```
$ git config --list --show-scope --show-origin
system file:/etc/gitconfig filter.lfs.required=true
global file:/root/.gitconfig user.name=Shikhar
global file:/root/.gitconfig user.email=shikhar@example.com
```

7. `git check-ignore -v --no-index <path>` tells you which rule in which file at which line number is ignoring a path. Without `--no-index` it deliberately ignores tracked files, which is itself a source of confusion.

```
$ git check-ignore -v --no-index config.env
.gitignore:1:config.env config.env
```

8. For removing a secret from all history the current recommended tool is `git filter-repo`, which replaced the much slower `git filter-branch`. The git project has discouraged `filter-branch` since version 2.24, November 2019. Either way, every existing clone becomes invalid and the credential must be rotated regardless.
9. `.gitignore` pattern rules follow `gitignore(5)`: `#` is a comment, a trailing `/` matches directories only, a leading `/` anchors to the `.gitignore`'s own directory, `**` matches across directories, and a leading `!` negates an earlier rule. A negation cannot re-include a file if its parent directory is itself excluded, which is the most common pattern bug.

■ 37.12.6 WORDS – remember these

1. `init` — start a new empty repository here — create a `.git` directory with default config, `HEAD` and hooks, contacting nothing.
2. `Clone` — take a full copy of an existing repository — `init` plus a remote plus a full fetch plus a checkout of the default branch.
3. `.gitignore` — a list of things git should not track — patterns matched against untracked paths only, per `gitignore(5)`, committed and shared.
4. `Untracked file` — a file git knows nothing about — a working tree path with no index entry, eligible for ignore rules.
5. `Tracked file` — a file git is watching — a path present in the index, immune to `.gitignore` until removed with `git rm --cached`.
6. `Unborn branch` — `HEAD` points at a branch with no commits yet — the state after `git init`, before the first commit creates the ref.
7. `rerere` — git remembering how you solved a conflict before — reuse recorded resolution, enabled with `rerere.enabled true`.

37.98 Common wrong ideas

1. Wrong: git needs a server. Right: git needs a directory. `git init`, `git add`, `git commit`, `git branch` and `git merge` all work on a machine that has never been connected to anything.
2. Wrong: `origin` is the real repository. Right: `origin` is a nickname for a URL stored in `.git/config`. It has no authority in git's data model. Rename it, remove it, or have twenty of them.
3. Wrong: `origin/main` tells you where the remote's main branch is. Right: it tells you where it was the last time a fetch, pull or push succeeded on this machine. It is a file on your disk and it never expires.
4. Wrong: cloning downloads the current version of the project. Right: cloning downloads every commit, every version of every file, every branch and every tag, then checks out one of them into your folder.
5. Wrong: git and GitHub are the same thing. Right: git is a program from 2005 that runs on your computer. GitHub is a company from 2008, owned by Microsoft since 2018, that hosts copies and adds pull requests, issues and CI.

6. Wrong: a commit is saved to the cloud. Right: a commit writes objects and one ref into `.git` on your own disk. Nothing leaves your machine until you push.
7. Wrong: `git pull` is the safe way to get up to date. Right: `git pull` is `git fetch` plus a merge or rebase that changes your branch. `git fetch` alone updates your knowledge and changes nothing of yours.
8. Wrong: adding a file to `.gitignore` removes it from the repository. Right: ignore rules apply only to untracked files. An already-tracked file keeps being tracked until `git rm --cached`, and stays in history forever.
9. Wrong: “ahead 3, behind 2” is a live comparison with the server. Right: it is arithmetic between two local refs, one of which is a cache that may be weeks old. Run `git fetch` before believing it.
10. Wrong: a shallow clone is just a smaller clone. Right: a shallow clone has no old history, so `git log`, `git blame` and `git bisect` cannot see past the cut, and deepening requires the network.

37.99 Chapter summary in 20 lines

1. Version control solves six problems: history, undo, blame, parallel work, backup and collaboration. Only the last two need another computer.
2. Dated folders fail because they record copies without recording reasons or relationships, and because two people cannot use them at once.
3. The lineage runs SCCS 1972, RCS 1982, CVS from 1986 and 1990, Subversion from 2000 with 1.0 in February 2004, then git in April 2005.
4. In a centralized system the history lives on a server and your machine holds a working copy, so a commit is a network operation.
5. In a distributed system every clone is a complete repository, so a commit is a local file write. This is why the reader kept committing during the outage.
6. Git exists because BitMover ended the kernel’s free BitKeeper licence in April 2005. Torvalds started on 3 April and git was self-hosting on 7 April.
7. His stated goals were speed, simple design, strong support for non-linear development, fully distributed operation, and handling the Linux kernel.
8. A `.git` directory holds objects, refs, HEAD, config, index, hooks, logs, info, description and sometimes packed-refs. That is the entire repository.
9. A branch is a 41-byte file containing a commit hash. That is why branching is instant, free and offline.
10. In a real clone of the git project, `.git` was 316 MiB against a 60 MiB working tree, holding 418,900 objects and 85,263 commits.
11. Compression is why: about 7,877 MiB of raw object content stored in about 302 MiB, a ratio near 26 to 1, via zlib and pack deltas.
12. Shallow and partial clones trade history or content for size, and both reintroduce the network into operations that were previously local.
13. `origin` is a nickname for a URL in `.git/config`. It is a convention, not a standard, it carries no authority, and a repository may have zero remotes.
14. `origin/main` is a local file recording where you last saw the remote’s main. It is a memory, not a measurement, and it never expires by itself.
15. Only `fetch`, `pull` and `push` update remote-tracking refs. `git reflog show origin/main --date=iso` tells you how stale yours is.
16. Local commands touch only objects, refs, index and working tree. Remote commands synchronize two object databases. The split has no fuzzy middle.

17. During the outage, authoring was fully available and coordination was fully unavailable: no fetching others' work, no pull requests, no CI results.
18. The costs of the distributed model are a harder mental model, no file locking, no useful merging of binaries, large clones, and no built-in truth.
19. That is why game studios, chip designers and visual effects houses still buy Perforce, founded 1995, for its exclusive checkout and workspace views.
20. Git is a program on your computer. GitHub is a company that hosts copies. During the outage git worked and the GitHub API did not. That is the line.

What a Commit Actually Is

38.0 What this chapter gives you

1. You will be able to say what content-addressed storage is: the name of a thing is worked out from the thing itself, so equal content always gets equal names.
2. You will be able to explain what a hash function is, name the five properties that matter, and say why SHA-1 gives 160 bits printed as 40 hexadecimal characters.
3. You will be able to state honestly that SHA-1 was broken in public on 23 February 2017 by Google and CWI Amsterdam, say what git did about it, and say why git's use of it was never purely a security control.
4. You will be able to name git's four object types, blob, tree, commit and tag, describe the exact bytes each one stores, and rebuild any object's hash by hand with one shell command.
5. You will be able to draw the complete object graph of a small repository, every blob, every tree, every commit and every arrow, and say exactly which objects are created and which are reused when one file changes.
6. You will be able to explain why history is a directed acyclic graph and not a line, what a merge commit with two parents looks like inside, and why the tip hash seals everything behind it.
7. You will be able to say what a branch really is, a small text file holding 40 hexadecimal characters, and why that makes branching almost free.
8. You will be able to read and repair the state of HEAD, including detached HEAD, and recover work that looked lost after a hard reset by using the reflog.
9. You will be able to use the plumbing commands that show the machinery: `git cat-file`, `git rev-parse`, `git hash-object`, `git ls-tree`, `git count-objects`, `git verify-pack` and `git rev-list`.
10. You will be able to explain the reader's own observation that `origin/main` was `0a95cc8`, and why a rebased branch inevitably came out with a different hash.

38.1 Content-addressed storage, the central idea

■ 38.1.1 PLAIN – in simple words

1. Normally you give a thing a name and then put content inside it. A folder called `notes` holds whatever you put in it today.
2. Git does the opposite. You give it content, and git works out the name from the content.
3. The name is a long string of letters and digits, produced by feeding every byte of the content through a fixed piece of arithmetic.
4. This is called **content-addressed storage**. The address of a thing is computed from the thing.
5. Two consequences follow, and they are the whole reason git works the way it does.

6. First, the same content always gets the same name. So git can never store the same content twice. It looks up the name, finds it already there, and stops.
7. Second, if anyone changes the content even by one bit, the name no longer matches. So changing content without being noticed is not possible.
8. Everything else in this chapter is a consequence of those two sentences.

■ 38.1.2 PLAIN - a picture in your head

1. Think of a very strange left-luggage office at a railway station.
2. You hand over a bag. The clerk does not give you a numbered ticket chosen from a pile.
3. Instead the clerk weighs the bag, measures it, catalogues every object inside it, and turns all of that into one long code.
4. That code is your ticket. It describes the bag rather than pointing at a shelf.
5. If you hand in an identical bag tomorrow, you get the identical ticket. The clerk says “I already have that one” and stores nothing new.
6. If somebody opens your bag and removes one sock, then re-runs the measurement, they get a different code. Your old ticket no longer matches anything. The swap is visible.

Where this comparison breaks:

7. A real clerk could be lazy and reuse a code for two nearly identical bags. A hash function cannot be lazy. It is arithmetic, and it runs the same way every time.
8. A real bag can be measured many ways. Git measures exactly one way, over exactly the bytes, in exactly one order, so the answer is never a matter of judgement.
9. And a left-luggage ticket does not tell you what is in the bag. A git hash does not either, but it is enough to prove that the bag you get back is the bag you handed in.

■ 38.1.3 PLAIN - a worked example

1. Here is a real repository built for this chapter. Four files were created, three of them holding exactly the same line of text.
2. The command `git ls-tree -r HEAD` lists every file with the name git gave to its content.

```
100644 blob 6fe3e87371433ed417646e3cb2354cfb9cff08d3    a/one.txt
100644 blob c9330452ddba7055160034759c594f78381fd24d    a/other.txt
100644 blob 6fe3e87371433ed417646e3cb2354cfb9cff08d3    b/two.txt
100644 blob 6fe3e87371433ed417646e3cb2354cfb9cff08d3    c/three.txt
```

3. Three files, three different paths, one identical name: 6fe3e87...
4. Now count how many pieces of file content git actually stored:

```
6fe3e87371433ed417646e3cb2354cfb9cff08d3 blob 22
c9330452ddba7055160034759c594f78381fd24d blob 18
```

5. Two. Not four. The three identical files share one stored copy of 22 bytes.
6. Nobody asked for that. Nobody ran a de-duplication tool. It falls out of naming things by their content.
7. Now rename `a/one.txt` to `a/renamed.txt` and commit. The listing changes, but the stored content list does not change at all.

```
100644 blob c9330452ddba7055160034759c594f78381fd24d    a/other.txt
100644 blob 6fe3e87371433ed417646e3cb2354cfb9cff08d3    a/renamed.txt
100644 blob 6fe3e87371433ed417646e3cb2354cfb9cff08d3    b/two.txt
100644 blob 6fe3e87371433ed417646e3cb2354cfb9cff08d3    c/three.txt
```

8. The file name lives in the directory listing, not in the content. Renaming is free.

■ 38.1.4 PLAIN – what is really happening inside

1. When you run `git add file.txt`, git reads every byte of the file.
2. It puts a small header in front of those bytes. The header is the word `blob`, a space, the length in bytes, and a zero byte.
3. It runs the header plus the content through the hash function. Out comes a 160-bit number.
4. It prints that number as 40 hexadecimal characters. That is the object's name.
5. It then looks on disk for a file at `.git/objects/` plus the first two characters, a slash, then the other 38 characters.
6. If that file already exists, git does nothing more. The content is already stored, by definition, because the name proves it.
7. If it does not exist, git compresses the header plus content with `zlib` and writes it there.
8. Reading works in reverse. Given a name, git knows the path, reads the file, decompresses it, and hands back the bytes.
9. Because the file is named after its own content, git can check itself at any time. Re-hash the content, compare with the file name, and any difference is damage or tampering.

■ 38.1.5 TECHNICAL – the engineer's version

1. Git implements a content-addressable object store. The key space is the output of a cryptographic hash over `<type> <size>\0<content>`.
2. The store is also a **Merkle tree**, the structure Ralph Merkle described in his 1979 doctoral work: a tree in which every parent node contains the hash of its children.
3. That is why one hash at the top, the commit hash, transitively covers every byte in the tree below it.
4. Loose objects live at `.git/objects/ab/cdef...`. The two-character sub-directory exists because early filesystems degraded badly with hundreds of thousands of entries in one directory.
5. Here is a real loose object, on disk, byte for byte:

```
00000000 78 01 4b ca c9 4f 52 30 34 61 f0 cc 2b 29 ca 4f
00000010 29 4d 2e c9 cc cf d3 e3 02 00 54 63 07 5f
```

6. That file is 30 bytes. The leading `78 01` is a `zlib` header (RFC 1950, May 1996, by Jean-loup Gailly and Mark Adler). Decompressed it is 22 bytes:

```
b'blob 14\x00Introduction.\n'
```

7. So the stored object is `blob`, space, 14, a NUL byte, then the 14 bytes of file content. The hash is taken over all 22 of those bytes.
8. Deduplication is exact-match only. Git does not find near-duplicates at store time. Similarity is exploited later, inside packfiles, and that is a separate mechanism covered in 38.11.

Property of the store	Value in git
Key derivation	SHA-1 of header+content
Key length	160 bits, 40 hex chars
Loose object path	objects/xx/38-char-rest
Object compression	<code>zlib</code> deflate, RFC 1951
Duplicate handling	write skipped if key exists

9. The honest version: content addressing gives integrity, not secrecy. Anyone with the object store can read every byte. Encryption is a separate concern that git does not provide.

■ 38.1.6 WORDS – remember these

1. Content-addressed storage — the name comes from the content — key space is the image of a hash function over the stored bytes.
2. Blob — a stored piece of file content — a git object of type blob holding raw bytes with no name and no permissions.
3. Deduplication — storing one copy of identical things — exact-match coalescing by hash key at write time.
4. Merkle tree — a tree where each parent names its children by hash — hash tree, described by Ralph Merkle in 1979, giving transitive integrity.
5. zlib — the squeezing format git uses on disk — DEFLATE stream in a zlib wrapper, RFC 1950 and RFC 1951, both May 1996.

38.2 Hashing, and the honest truth about SHA-1

■ 38.2.1 PLAIN – in simple words

1. A **hash function** takes any amount of data and produces a short fixed-size number that stands for it.
2. Five things matter about it.
3. It is **deterministic**: the same input always gives the same output, on any machine, in any year.
4. It has a **fixed size** output: one byte in or one gigabyte in, the answer is the same length.
5. It has the **avalanche effect**: change one bit of input and about half the output bits flip. There is no gentle drift.
6. It is **one-way**: given the output you cannot work backwards to the input, other than by guessing.
7. It is **collision resistant**: it should be impractical to find two different inputs with the same output.
8. Git used SHA-1, which produces 160 bits. Printed four bits per character in hexadecimal, that is 40 characters.
9. The honest version: the fifth property, collision resistance, is broken for SHA-1. That is not a rumour, it is a demonstrated public fact from 2017.

■ 38.2.2 PLAIN – a picture in your head

1. Think of a machine that turns any document into a 40-character summary code.
2. Feed it a shopping list, get a code. Feed it the complete works of a novelist, get a code of exactly the same length.
3. Change one comma anywhere in the novel and the code changes beyond recognition, not slightly.
4. You cannot run the machine backwards. Given a code, there is no way to get the novel out of it.
5. Collision resistance is the promise that nobody can make two different documents that produce the same code.
6. That promise held for SHA-1 for about twenty-two years. Then it did not.

Where this comparison breaks:

7. A summary suggests something readable. A hash output is not readable and carries no meaning at all. It is only a label.
8. Also, a real summary of a longer document loses information gently. A hash loses nearly all information at once. From 160 bits you can prove a match, but you can never reconstruct anything.

■ 38.2.3 PLAIN – a worked example

1. Here are real SHA-1 values computed in the sandbox used to write this chapter, on an Intel Xeon at 2.10 GHz.
2. Determinism. The same five letters, hashed three times:

```
$ printf 'hello' | shasum
aaf4c61ddcc5e8a2dabede0f3b482cd9aea9434d
aaf4c61ddcc5e8a2dabede0f3b482cd9aea9434d
aaf4c61ddcc5e8a2dabede0f3b482cd9aea9434d
```

3. Avalanche. Change the last letter from o to p:

```
hello -> aaf4c61ddcc5e8a2dabede0f3b482cd9aea9434d
hellp -> d4baaad7a68a379b1e133e0fea0603051b0124ca
```

4. Of the 40 hexadecimal characters, only 3 happen to be equal. Of the 160 bits, 85 differ. The ideal for a good hash is 80. It is behaving correctly.
5. Fixed size. One byte in, and one million bytes in:

```
1 byte -> 86f7e437faa5a7fce15d1ddcb9eaeaea377667b8
1,000,000 B -> bef3595266a65a2ff36b700a75e8ed95c68210b6
```

6. Both answers are 40 characters. The length of the input is invisible in the output.
7. Now the git-specific part. Git does not hash the file. It hashes a header plus the file. Here is the proof, done by hand:

```
$ printf 'Introduction.\n' | wc -c
14
$ printf 'blob 14\0Introduction.\n' | shasum
0e2a325c7de3369b164d48fcb823bca9c2cec4e
$ git hash-object docs/intro.md
0e2a325c7de3369b164d48fcb823bca9c2cec4e
```

8. Identical. `shasum` and `git` agree, because `git`'s rule is exactly “hash the header plus the content”.

■ 38.2.4 PLAIN – what is really happening inside

1. SHA-1 works on the input in blocks of 64 bytes.
2. It keeps five 32-bit working registers, 160 bits in total, initialized to fixed constants written into the specification.
3. For each block it mixes the block into those registers through 80 rounds of addition, rotation and bit logic, then adds the result back into the running state.
4. When the input runs out, it appends a single 1 bit, then zero bits, then the original bit length as a 64-bit number, and processes the final block.
5. The five registers, printed end to end, are the answer.
6. The reason a one-bit change scatters the output is that the mixing is designed so every input bit influences every register within a few rounds.
7. A **collision** means two different inputs that end with the same five registers. Because inputs are unlimited and outputs are only 160 bits, collisions must exist. The question is only whether anyone can find one.
8. In 2017 somebody did, on purpose, with two files chosen in advance to be different in a way that mattered.

■ 38.2.5 TECHNICAL – the engineer’s version

1. SHA-1 is specified in FIPS PUB 180-1, published by the United States National Institute of Standards and Technology in 1995. It replaced SHA-0 from FIPS PUB 180 in 1993, which had a design flaw.
2. Output is 160 bits. Internal state is five 32-bit words. Block size is 512 bits. Rounds per block: 80.
3. On 23 February 2017 researchers at CWI Amsterdam and Google announced **SHAttered**, the first public SHA-1 collision: two different PDF files with the identical SHA-1 digest.
4. The published cost was approximately 2 to the power 63.1 SHA-1 evaluations, described as the equivalent of 6,500 CPU-years plus 110 GPU-years, and about 100,000 times cheaper than a brute-force birthday search.
5. On 5 January 2020 Gaetan Leurent and Thomas Peyrin announced **SHAmbles**, a chosen-prefix collision at about 2 to the power 63.4, costed at roughly 45,000 US dollars of rented GPU time. Chosen-prefix is the dangerous kind, because the attacker picks both meaningful beginnings.
6. NIST formally deprecated SHA-1 in 2011, disallowed it for digital signatures from 2013, and in 2022 set 31 December 2030 as the full phase-out date.
7. Here is what those numbers mean in the machine used for this chapter. It hashes at about 1,241 MB/s, which is about 1.95×10^7 blocks per second.

Work item	Evaluations	Time on this one machine
SHAttered, $2^{63.1}$	9.9×10^{18}	about 16,000 years
Birthday bound 2^{80}	1.2×10^{24}	about 2×10^9 years
Full preimage 2^{160}	1.5×10^{48}	about 2×10^{33} years

8. What git did. From **Git 2.13, released in May 2017**, git ships the collision-detecting SHA-1 implementation by Marc Stevens of CWI and Dan Shumow of Microsoft. The Git 2.13 release notes say it “has been integrated and made the default”.
9. That code computes SHA-1 normally but also watches for the internal disturbance vectors that any known collision attack must use. If it sees them, git aborts rather than storing the object. The two SHAttered PDFs cannot be committed to a modern git.
10. Separately, git has been growing a SHA-256 object format. The design document dates from 2017 and 2018, experimental support began landing from **Git 2.19 in September 2018**, and `git init --object-format=sha256` arrived in **Git 2.29 in October 2020**.
11. It works. In the sandbox:

```
$ git init --object-format=sha256 sha256demo
$ git hash-object intro.md
22c6af3b0fccae1e36b21923804fd096c8636e54da038f04c424208
d2ecb1650
```
12. That is 64 hexadecimal characters, and it verifies by hand exactly the same way: `printf 'blob 14\0Introduction.\n' | sha256sum` gives the same value.
13. But it is still not the default in 2026, and git’s own documentation says that until the wire protocol gains SHA-256 support, using SHA-256 storage on public-facing servers is strongly discouraged. Repositories in the two formats cannot yet talk to each other.
14. The honest version, and the part people argue about: Linus Torvalds has said publicly that git’s hash was chosen mainly to guard against accidental corruption and to give a stable name, not as a signature scheme. Critics reply that in practice people do rely on commit hashes as identity, in deploy pipelines and in audit trails. Both points are true.

15. Where experts disagree: some argue the SHA-256 migration is overdue and the ecosystem cost is worth paying now. Others argue that with collision detection turned on, a real attack on a git repository is far harder than an attack on a bare hash, so the migration can proceed slowly. There is no settled answer.

■ 38.2.6 WORDS – remember these

1. Hash function — arithmetic that turns any data into a short fixed code — a map from arbitrary-length input to fixed-length digest.
2. Avalanche effect — one small change scrambles the whole answer — a one-bit input change flips about half the output bits.
3. Collision — two different inputs with the same code — two distinct pre-images mapping to one digest.
4. Preimage resistance — you cannot work backwards from the code — finding any input for a given digest should cost about 2^{160} for SHA-1.
5. SHAttered — the 2017 demonstration that SHA-1 collisions are buildable — CWI Amsterdam and Google, 23 February 2017, cost about $2^{63.1}$.
6. sha1dc — git's hardened SHA-1 that spots attacks — the collision-detecting SHA-1 of Marc Stevens and Dan Shumow, default since Git 2.13, May 2017.

38.3 The four object types

■ 38.3.1 PLAIN – in simple words

1. Git stores exactly four kinds of object. Everything in a repository is one of these four.
2. A **blob** is the content of one file. Just the bytes. It does not know its own name, its folder, or when it was made.
3. A **tree** is one directory listing. It maps names to blobs and to other trees, and records each entry's permission mode.
4. A **commit** is a snapshot marker. It names exactly one tree, names zero or more parent commits, records who wrote it and who recorded it with times, and carries a message.
5. A **tag object** is a named, described pointer, normally to a commit, with its own author and message, and optionally a signature.
6. That is the whole vocabulary. Four nouns.
7. Notice what is missing. There is no “file” object holding a name, no “change” object, no “diff” object, and no “branch” object. Those are all built from the four.

■ 38.3.2 PLAIN – a picture in your head

1. Think about a warehouse that stores photographs of a whole office, taken every day.
2. A blob is one printed page in a filing cabinet. It has no label on it. It is just the paper.
3. A tree is an index card for one room. It says “the page called README is card number f6da25f, the cupboard called docs is index card 80b4ad5”.
4. A commit is the front cover of one day's survey. It says “here is the index card for the whole office, taken at 10:00 on 5 January, by this person, for this reason, and yesterday's cover was that one over there”.
5. A tag object is a brass plaque screwed on to one particular day's cover, saying “this one is version 1.0, blessed by this person on this date”.

Where this comparison breaks:

6. In a warehouse, tomorrow's survey needs a whole new set of pages. In git, tomorrow's cover reuses every index card and every page that did not change. Only the changed cards are re-cut.
7. And in a warehouse the covers are dated by the clerk. In git the cover's own identity is computed from its contents, including the date, so you cannot alter the date and keep the identity.

■ 38.3.3 PLAIN - a worked example

1. Here is a real repository. Three commits, two directories, five files by the end. Every hash below came out of the sandbox.
2. A blob. `git cat-file -t` says the type, `-s` says the size in bytes, `-p` pretty-prints the content:

```
$ git cat-file -t 0e2a325
blob
$ git cat-file -s 0e2a325
14
$ git cat-file -p 0e2a325
Introduction.
```

3. Notice: no file name anywhere. This blob does not know it is `intro.md`.
4. A tree. This is the top directory of the first commit:

```
$ git cat-file -t b39d894
tree
$ git cat-file -p b39d894
100644 blob f6da25f44e6006699370496c1d1033320df8802b    README.md
040000 tree 80b4ad5b31db187c032b03fca7a3b9a0cbdc2747    docs
040000 tree ed46dd19f6204c92947780231982716d4016b9bb    src
```

5. Three entries. One blob and two sub-directories. The names live here, in the tree, not in the blobs.
6. A commit. This is the third commit:

```
$ git cat-file -t b53a9f4
commit
$ git cat-file -p b53a9f4
tree 19f6e3d84c4955832c7f9d39e5205c273dd15d91
parent fb17f98cd37f546dfedb2f91e1b7a9762bf45d17
author KedByte Reader <reader@example.com> 1767594600 +0530
committer KedByte Reader <reader@example.com> 1767594600 +0530

Third commit: add src/util.c
```

7. That is the entire commit. One tree line, one parent line, two people lines with timestamps, a blank line, then the message.
8. A tag object, made with `git tag -a v1.0 -m "First release of the demo":`

```
$ git cat-file -t v1.0
tag
$ git cat-file -p v1.0
object b53a9f46d432aa53e687328841c6dd2b89963809
type commit
tag v1.0
tagger KedByte Reader <reader@example.com> 1767598200 +0530

First release of the demo
```

9. The tag object is a separate object with its own hash, `d54ba1826a59225bc14a2b55e832536cb7a8e4ac`, pointing at the commit.

■ 38.3.4 PLAIN – what is really happening inside

1. Every one of the four objects is stored the same way: a header, then the content, hashed and compressed together.
2. The header is the type word, a space, the content length in bytes, then a single zero byte.
3. So the whole rule of the object store is one line: `hash = SHA1(type + " " + size + "\0" + content)`.
4. Let us prove it for all four types with real numbers.
5. Blob. Content is 14 bytes.

```
$ printf 'blob 14\0Introduction.\n' | shasum
0e2a325c7de3369b164d48fcb823bca9c2cec4e
```

6. Tree. Content is 34 bytes of binary, so we pipe git's own raw bytes back in:

```
$ git cat-file tree ed46dd19 | wc -c
34
$ { printf 'tree 34\0'; git cat-file tree ed46dd19; } | shasum
ed46dd19f6204c92947780231982716d4016b9bb
```

7. Commit. Content is 208 bytes:

```
$ git cat-file commit d9cbb74 | wc -c
208
$ { printf 'commit 208\0'; git cat-file commit d9cbb74; } | shasum
d9cbb74f1fb9bce240d20db0c8e545caf68c802b
```

8. Tag. Content is 156 bytes:

```
$ { printf 'tag 156\0'; git cat-file tag v1.0; } | shasum
d54ba1826a59225bc14a2b55e832536cb7a8e4ac
```

9. Four for four. There is no secret step. You can reproduce every hash in a git repository with `printf` and `shasum`.
10. One warning about the tree. `git cat-file -p` shows you a friendly version. The bytes on disk are not that. Here is the truth:

```
00000000 31 30 30 36 34 34 20 52 45 41 44 4d 45 2e 6d 64
00000010 00 f6 da 25 f4 4e 60 06 69 93 70 49 6c 1d 10 33
00000020 32 0d f8 80 2b 34 30 30 30 30 20 64 6f 63 73 00
00000030 80 b4 ad 5b 31 db 18 7c 03 2b 03 fc a7 a3 b9 a0
00000040 cb dc 27 47 34 30 30 30 30 20 73 72 63 00 ed 46
00000050 dd 19 f6 20 4c 92 94 77 80 23 19 82 71 6d 40 16
00000060 b9 bb
```

11. Each entry is: the mode in ASCII, a space, the file name in ASCII, a zero byte, then the 20 raw bytes of the hash. Not 40 hex characters. 20 binary bytes.
12. Also notice the directory mode is stored as `40000`, five characters, even though `git ls-tree` prints `040000`. The printed leading zero is cosmetic.

■ 38.3.5 TECHNICAL – the engineer's version

1. Object format, canonical for both SHA-1 and SHA-256 repositories: `<type> SP <size in bytes, decimal ASCII, no leading zeros> NUL <content>`.
2. Tree entry format, repeated and concatenated with no separator: `<mode ASCII> SP <name> NUL <20-byte raw object id>`.

3. Tree entries are sorted by name, with directory names compared as if they ended in a slash. This ordering is part of the format, not a convention: two git implementations must agree or the hashes differ.
4. Only five modes are legal in a tree. All five were produced in the sandbox:

```
040000 tree 0479003445f4e5a5ff25360c607ca79ffe4e4ea1 d
120000 blob dab8c79946b1756dcd7db770a986ad40d00c07f4 link.txt
100644 blob b9bca019c83a65e6d717d0b6da86215f45dde1b3 plain.txt
100755 blob 4163036efa65bd4a469e752267498f01ea36a55c run.sh
160000 commit 0f0c4412ec5e57f084c7a39a254a1f9d67f3e965 sub
```

Mode	Meaning
100644	regular file
100755	executable regular file
120000	symbolic link
040000	directory, a sub-tree
160000	gitlink, a submodule commit

5. Git records only the executable bit. It does not record read or write permission, owner, group, or modification time. Those are deliberately outside the model.
6. A symbolic link is stored as a blob whose content is the target path. The blob above holds exactly the nine bytes `plain.txt`.
7. Commit object grammar, in order: one tree line, then zero or more parent lines, then author, then committer, then optional headers such as `gpgsig` and `encoding`, then a blank line, then the message.
8. Timestamps are two fields: seconds since the Unix epoch of 1 January 1970 UTC, then the author's local UTC offset as `+HHMM`. The offset is stored so the original wall-clock time can be reproduced. It does not affect ordering.
9. Two universal object ids you will meet in real work, and they are the same in every SHA-1 repository on earth:

```
$ git hash-object -t tree /dev/null
4b825dc642cb6eb9a060e54bf8d69288fbee4904
$ git hash-object -t blob /dev/null
e69de29bb2d1d6434b8b29ae775ad8c2e48c5391
```

10. The first is the empty tree, useful for diffing a first commit against nothing. The second is the empty file.
11. You can construct all of this by hand. The plumbing path from bytes to a checked-out commit, run in the sandbox:

```
$ B=$(printf 'Hello from plumbing.\n' | git hash-object -w --stdin)
$ printf '100644 blob %s\thello.txt\n' "$B" | git mktree
ae0afea72a045c4653880d3b19ffd7a4979d8d0d
$ git commit-tree ae0afea -m "Made entirely by plumbing"
f0803fab3f189b2ed4f674bf2c63655cc7d7cfde
$ git update-ref refs/heads/main f0803fa
$ git log --oneline
f0803fa Made entirely by plumbing
```

12. No `git add`, no `git commit`. The high-level commands are convenience over exactly these four steps.

■ 38.3.6 WORDS – remember these

1. Blob — stored file content with no name — an object of type blob, raw bytes, addressed by SHA of blob <size>\0<bytes>.
2. Tree — one directory listing — an object mapping sorted names to modes and object ids, using 20 raw bytes per id.
3. Commit — a snapshot marker with a message and a parent — an object naming one tree, zero or more parents, author, committer and message.
4. Annotated tag — a named marker that is itself a stored object — an object of type tag with tagger, message and optional signature.
5. Mode — the small number in front of each tree entry — the six-digit file mode; only 100644, 100755, 120000, 040000 and 160000 are valid.
6. Gitlink — a pointer to a commit in another repository — a tree entry with mode 160000 recording a submodule's commit id.

38.4 How the four types compose

■ 38.4.1 PLAIN – in simple words

1. The four object types stack into one picture.
2. A commit points down at one tree. That tree points at blobs and at more trees. Those point at more blobs.
3. The whole content of the project at one moment hangs off that single commit hash.
4. A commit also points sideways, at its parent commit, which has its own tree, which shares most of the same blobs and sub-trees.
5. When you change one file, git does not copy the project. It creates one new blob for that file, one new tree for the directory containing it, one new tree for each directory above that, and one new commit.
6. Everything else is pointed at again, unchanged.
7. So the cost of a commit is proportional to the depth of the change, not to the size of the project.

■ 38.4.2 PLAIN – a picture in your head

1. Imagine a company organization chart printed on a wall, with a card for each department and a card for each person.
2. Somebody changes their phone number. You do not reprint the wall.
3. You print one new card for that person, one new card for their team naming the new person card, one new card for their division naming the new team card, and one new card for the whole company.
4. Every other card on the wall is still valid and is still pointed at by the new cards.
5. Now you have two complete company charts on the wall, yesterday's and today's, and they share almost all their cards.

Where this comparison breaks:

6. Cards on a wall are pointed at by position. Git objects are pointed at by hash, so a “new card” for identical content is impossible. If two people ended up with the identical card, there would be exactly one card.
7. And a wall chart has to be walked from the top. Git can jump directly to any card, at any depth, if it knows the hash.

■ 38.4.3 PLAIN – a worked example

- Here is the complete object graph of the real three-commit repository, with every object and every arrow. Fifteen objects: 3 commits, 7 trees, 5 blobs.

COMMITTS (each points left to its parent)

```

d9cbb74 <----- fb17f98 <----- b53a9f4
  C1              C2              C3
  |              |              |
  | tree         | tree         | tree
  v              v              v

```

ROOT TREES

```

b39d894      5b9f378      19f6e3d
| | |      | | |      | | |
| | +--src-->| | +--src-->| | +--src-->
| | +--docs-+| | +--docs-+| | +--docs-+|
+--README-+| +--README-+| +--README-+|
      ||      ||      ||
      vv      vv      vv v

```

- Rather than draw crossing lines, here is the same information written out. Each root tree has exactly three entries:

```

b39d894 (root tree of C1)
  README.md -> blob f6da25f
  docs      -> tree 80b4ad5
  src       -> tree ed46dd1

5b9f378 (root tree of C2)
  README.md -> blob f6da25f      SAME as C1
  docs      -> tree dbec85e      NEW
  src       -> tree ed46dd1      SAME as C1

19f6e3d (root tree of C3)
  README.md -> blob f6da25f      SAME as C1 and C2
  docs      -> tree dbec85e      SAME as C2
  src       -> tree 069dcc5      NEW

```

- And the sub-trees, with their blobs:

```

80b4ad5 docs at C1      dbec85e docs at C2 and C3
  intro.md -> 0e2a325    intro.md -> bce6753

ed46dd1 src at C1 and C2 069dcc5 src at C3
  main.c -> 78f2de1      main.c   -> 78f2de1
                        util.c   -> df76ea6

```

- The five blobs, with their real sizes:

Blob	Bytes	It is the content of
f6da25f	25	README.md, all commits
0e2a325	14	docs/intro.md at C1
bce6753	38	docs/intro.md at C2, C3
78f2de1	29	src/main.c, all commits
df76ea6	22	src/util.c at C3

Blob	Bytes	It is the content of

5. Now the important part. Commit 2 changed exactly one file, docs/intro.md. Here is what that cost.

```

EDIT ONE FILE IN ONE DIRECTORY: C1 -> C2

NEW objects (4)                REUSED objects (4)
-----
blob bce6753 intro.md          blob f6da25f README.md
tree dbec85e docs/             tree ed46dd1 src/
tree 5b9f378 root              blob 78f2de1 src/main.c
commit fb17f98                 blob 0e2a325 old intro.md
                                (kept, still in C1)

```

- One blob for the new content. One tree for the directory it is in. One tree for the root above it. One commit. Four objects.
- The src directory was not touched, so tree ed46dd1 is pointed at again by the new root tree. Not copied. Pointed at.
- That is the rule: new objects equal one blob, plus one tree per directory level from the change up to the root, plus one commit.
- Adding src/util.c in commit 3 cost the same shape: new blob df76ea6, new src tree 069dcc5, new root tree 19f6e3d, new commit b53a9f4.

■ 38.4.4 PLAIN - what is really happening inside

- When you run `git commit`, git works from a staging area called the index, which holds the intended next snapshot as a flat list of paths and blob ids.
- Git writes the deepest directories first. For each directory it builds the tree bytes, hashes them, and writes the tree object if it is not already there.
- Because it hashes before writing, an unchanged directory produces exactly the same tree bytes as last time, so exactly the same hash, so no write happens at all.
- Then it builds the parent directory's tree, which now contains the just-computed child hashes, and so on up to the root.
- Finally it builds the commit object: the root tree hash, the current branch tip as parent, your identity and the time, and your message.
- It hashes that, writes it, and moves the branch file to the new commit hash.
- Nothing was diffed. Nothing was compared with the previous commit. The reuse is automatic because equal content produces equal names.
- And here is the proof that git stores whole content, not changes. The second version of docs/intro.md is stored complete:

```

$ git cat-file -s bce6753
38
$ git cat-file -p bce6753
Introduction.
Now with a second line.

```

- Thirty-eight bytes: the full new file, both lines. Not "add one line at the end".
- The diff you see in `git show` is worked out at the moment you ask, by comparing two trees:

```

$ git diff-tree -r d9cbb74 fb17f98
:100644 100644 0e2a325... bce6753... M docs/intro.md

```

- Git compared the two trees, saw one entry whose hash differed, and only then computed the line-by-line difference for display.

■ 38.4.5 TECHNICAL – the engineer’s version

- The object graph is a Merkle DAG. Nodes are objects, edges are embedded object ids, and it is acyclic because an object’s id depends on the ids it contains, so a cycle would require a hash to contain itself.
- Write cost of a commit is $O(d + 1)$ new objects, where d is the number of directory levels from the deepest change to the root, plus one commit and one blob per changed file.
- That is why deep directory hierarchies cost slightly more per commit than flat ones, and why a repository with one enormous directory costs more per commit than you might expect: the whole tree object for that directory is rewritten whenever any entry in it changes.
- Real figures from the sandbox repository at the three-commit point:

Measure	Value
Distinct objects	15
Commits / trees / blobs	3 / 7 / 5
Files in final snapshot	4
Tree objects if no reuse	9 instead of 7

- Only two tree objects were saved in this tiny example. In a repository with thousands of directories and a hundred thousand commits, the saving is the difference between a workable repository and an impossible one.
- Verify the reuse yourself with `git rev-parse` on paths:

```
$ git rev-parse d9cbb74^{tree}:src
ed46dd19f6204c92947780231982716d4016b9bb
$ git rev-parse fb17f98^{tree}:src
ed46dd19f6204c92947780231982716d4016b9bb
```
- Identical, from two different commits. One stored object.
- Implementation detail, not part of the model: git also keeps a cache-tree inside `.git/index` so that unchanged directories do not even need their tree bytes rebuilt during commit. That is a speed optimization; the resulting hashes are identical either way.

■ 38.4.6 WORDS – remember these

- Snapshot — the complete state of the project at one commit — the transitive closure of objects reachable from a commit’s root tree.
- Structural sharing — new versions reusing old parts — persistent data structure behaviour, where unchanged sub-trees are referenced not copied.
- Index — git’s staging area — `.git/index`, a binary file listing paths, modes, blob ids and stat data for the next commit.
- Merkle DAG — a graph where every node names its children by hash — a directed acyclic graph with hash-derived edges, giving whole-graph integrity.
- diff-tree — the command that compares two snapshots — plumbing that walks two trees and reports entries whose object ids differ.

38.5 Why a commit points at its parent

■ 38.5.1 PLAIN – in simple words

1. Every commit except the very first one records the hash of the commit that came before it.
2. That single line, parent <hash>, is what turns a pile of snapshots into a history.
3. Follow the parent links backwards and you reach the beginning. That is what `git log` does.
4. It is not a line, though. It is a **graph**. A commit can have two parents, which is what a merge is. And two different commits can share one parent, which is what a branch is.
5. It is **acyclic**, meaning you can never walk forwards and end up where you started. That is guaranteed by the hashes, not by a rule someone enforces.
6. Because a commit's hash covers its parent's hash, and that parent's hash covers its own parent, one hash at the tip covers the entire history behind it.
7. Change anything anywhere in the past and every hash from that point forward changes. History is therefore tamper-evident.
8. Tamper-evident is not the same as tamper-proof. Anyone can rewrite history and hand you the new version. They just cannot do it invisibly if you already know the old hash.

■ 38.5.2 PLAIN – a picture in your head

1. Think of a family of numbered wax seals.
2. Each seal is made by melting together the day's document and a copy of yesterday's seal.
3. So today's seal depends on yesterday's, which depended on the day before, all the way to the first day.
4. If somebody quietly edits a document from three years ago, they have to make a new seal for that day. That changes the next day's seal, and every seal after it.
5. You hold only the most recent seal in your hand. That one seal proves the whole chain.

Where this comparison breaks:

6. A wax seal can be forged by someone with the same stamp. A hash cannot be forged without solving arithmetic nobody can currently solve.
7. But the comparison also flatters git. Your seal only proves things if you wrote down what the seal looked like. If you never recorded it, someone can hand you a completely different chain of seals and you cannot tell.
8. And unlike a family seal, git history can legitimately fork. Two people can both build on yesterday's seal and both be right.

■ 38.5.3 PLAIN – a worked example

1. Here is a real history from the sandbox with a real merge, drawn by git itself:

```
$ git log --graph --oneline --all
* 7fc6cf8 Merge feature into main
|\
| * 7c7506f Fourth commit: add docs/feature.md on feature
* | 25478c1 Fifth commit: extend README on main
|/
* b53a9f4 Third commit: add src/util.c
* fb17f98 Second commit: edit docs/intro.md
* d9cbb74 First commit: readme, source and docs
```

2. That is a diamond, not a line. Two commits both have b53a9f4 as parent, and one commit has both of them as parents.

3. Look inside the merge commit. It has two parent lines:

```
$ git cat-file -p 7fc6cf8
tree b704d3e37ec1cb98ac5712b56206dbe28b5aac6e
parent 25478c16e00d681e80a0db23a6c7bca204e07404
parent 7c7506f6a3b659163ac6f5d9f155a1a9b89f298e
author KedByte Reader <reader@example.com> 1767681000 +0530
committer KedByte Reader <reader@example.com> 1767681000 +0530

Merge feature into main
```

4. The order of the parent lines matters and is not arbitrary. The first parent is the branch you were on. The second is the branch you merged in.
5. That is what the ^ numbers select:

```
$ git rev-parse HEAD^1
25478c16e00d681e80a0db23a6c7bca204e07404
$ git rev-parse HEAD^2
7c7506f6a3b659163ac6f5d9f155a1a9b89f298e
```

6. And the very first commit has no parent line at all. Compare:

```
$ git cat-file -p d9cbb74
tree b39d894c54aa6e9c3c2545eef059431d7b208ebf
author KedByte Reader <reader@example.com> 1767587400 +0530
committer KedByte Reader <reader@example.com> 1767587400 +0530

First commit: readme, source and docs
```

7. No parent line. That is a **root commit**.

■ 38.5.4 PLAIN – what is really happening inside

1. The word “ancestor” has an exact meaning here. Commit A is an ancestor of commit B if you can get from B to A by following parent links, in any number of steps.
2. “Descendant” is the same relation read the other way.
3. Merging looks for the **merge base**, the closest commit that is an ancestor of both sides. In the example above that is b53a9f4.
4. Immutability is not a rule that git enforces with a lock. It is a consequence of naming.
5. If you want to change a commit’s message, git cannot edit the object, because the object’s name is derived from its bytes including the message. Changing the message produces a different object with a different name.
6. So `git commit --amend` does not amend anything. It builds a brand new commit object and moves the branch file to point at it. The old object is still on disk.
7. The same is true of rebase, of `git filter-repo`, and of every other “history rewriting” tool. They all create new objects.
8. The sealing works like this. Suppose an attacker wants to change one character in the first commit’s README.
9. That changes the README blob’s hash. That changes the root tree’s hash. That changes commit 1’s hash. Commit 2 contains commit 1’s hash, so commit 2’s hash changes. And so on to the tip.
10. If you wrote down the tip hash yesterday and it still matches today, then every byte of every file in every commit behind it is unchanged.

■ 38.5.5 TECHNICAL – the engineer’s version

1. Git history is a directed acyclic graph, a DAG, with commits as vertices and parent references as edges. Merge commits have out-degree 2 or more.
2. Octopus merges with three or more parents are legal. The default merge strategy in modern git, ort, refuses to resolve conflicts in an octopus merge, so they are rare in practice.
3. Acyclicity is structural. A commit’s id is a hash over content that includes its parents’ ids, so creating a cycle would require finding a hash preimage, which is why nobody argues about whether cycles are possible.
4. `git merge-base A B` computes the lowest common ancestor. With criss-cross histories there can be several, and the ort strategy handles that by recursively merging the candidate bases.
5. Topological order is a partial order, not a total one. `git log` defaults to showing commits in reverse commit-date order, which can mislead when clocks disagree. Use `git log --topo-order` when the shape matters.
6. Signed commits. A commit signature is stored as a `gpgsig` header inside the commit object itself, so the signature is covered by the commit hash. Here is a real one, created and verified in the sandbox with an SSH key:

```
$ git cat-file -p HEAD
tree 4588a5c622c7b494a501343b782d2d928c5e447f
author KedByte Reader <reader@example.com> 1767846600 +0530
committer KedByte Reader <reader@example.com> 1767846600 +0530
gpgsig -----BEGIN SSH SIGNATURE-----
U1NIU0lHAAAAAQAADMAAAALc3NoLWVkJU1MTkAAAAgrLzsFF...
...
-----END SSH SIGNATURE-----

A signed commit
```

7. The base64 lines are trimmed here to fit the page. The unsigned commit object was 208 bytes; the signed one is 492 bytes.
8. Verification, again real output:

```
$ git verify-commit HEAD
Good "git" signature for reader@example.com with ED25519 key
SHA256:32dP45eSMmVSt/G/CGvcxL/P+M03Nwj9xeTh/GSA2wc
```

9. What a signature adds, precisely: it binds a key to that exact commit hash, and therefore to the whole history behind it. It answers “who asserted this tip”, which the hash alone cannot.
10. What it does not add: it does not stop rewriting. An attacker with commit access rewrites history and signs the new version with their own key. Verification then fails only if you check the key against a list you trust.
11. This was visible in the sandbox. Before an allowed-signers file was configured, git reported the signature as cryptographically good but with “No principal matched”. Good maths, unknown signer. Those are different questions and git keeps them separate.

Question	Answered by
Are the bytes unchanged?	the object hash
Is the history unchanged?	the tip commit hash
Who asserted this tip?	a valid signature
Should I trust that key?	your allowed-signers list

12. The honest version: git's tamper-evidence protects you against silent modification of a repository you already have a hash for. It does not tell you whether the history you were handed in the first place is the real one.

■ 38.5.6 WORDS - remember these

1. Parent — the commit that came before — an object id recorded in a parent header inside the commit object.
2. Root commit — a commit with no parent — a commit object with zero parent headers; a repository may have several.
3. Merge commit — a commit joining two lines of work — a commit object with two or more parent headers, first parent being the branch merged into.
4. Ancestor — reachable by walking parents backwards — the transitive closure of the parent relation.
5. Merge base — the closest shared ancestor of two commits — the lowest common ancestor in the commit DAG, computed by `git merge-base`.
6. Tamper-evident — changes cannot be hidden — any modification alters the object id and propagates to every descendant hash.

38.6 What a branch really is

■ 38.6.1 PLAIN - in simple words

1. A branch is a file. That is the whole answer.
2. The file lives at `.git/refs/heads/` followed by the branch name.
3. Inside that file are 40 hexadecimal characters and a newline. Forty-one bytes.
4. Those 40 characters are the hash of one commit: the tip of the branch.
5. A branch does not contain commits. It points at one commit. The commits it “contains” are simply the ones you reach by walking parents backwards from there.
6. Creating a branch writes one 41-byte file. Nothing is copied. No files are duplicated. That is why branching is nearly free.
7. Deleting a branch deletes one 41-byte file. The commits are untouched.
8. Committing means writing a new commit object and then overwriting those 41 bytes with the new hash.

■ 38.6.2 PLAIN - a picture in your head

1. Think of a long shelf of books, in order, each book naming the one before it.
2. A branch is not a copy of the shelf. It is a sticky note on the spine of one book saying “main”.
3. Adding a branch means writing one more sticky note. It takes a second and costs one note.
4. Moving a branch forward means peeling the note off one book and putting it on the next.
5. Removing a branch means throwing away a sticky note. Every book is still on the shelf.

Where this comparison breaks:

6. A sticky note can fall off and be lost. Git writes the move into a log, the reflog, so you can put it back. Section 38.9 covers that.
7. And a shelf is one physical thing. In git, two people can have sticky notes with the same name on completely different books, and neither is wrong until they try to agree.

■ 38.6.3 PLAIN – a worked example

1. Real output from a fresh sandbox repository with two commits.

```
$ ls -l .git/refs/heads/
-rw-r--r-- 1 root root 41 Aug 13 03:18 main
$ cat .git/refs/heads/main
bc7fc422aec1054a108922e49253ce8271b1e957
```

2. Forty-one bytes. Forty hexadecimal characters and a newline, confirmed by dumping the raw bytes:

```
| 0000040 7 1 b 1 e 9 5 7 \n
```

3. Now create two more branches, one at the tip and one at the previous commit:

```
$ git branch topic
$ git branch spike HEAD~1
$ ls -l .git/refs/heads/
-rw-r--r-- 1 root root 41 main
-rw-r--r-- 1 root root 41 spike
-rw-r--r-- 1 root root 41 topic
```

4. Three files, 41 bytes each, 123 bytes in total. Their contents:

```
main bc7fc422aec1054a108922e49253ce8271b1e957
topic bc7fc422aec1054a108922e49253ce8271b1e957
spike 1dfe2f9b9521c9a46513a095c135831a8b54ef01
```

5. main and topic hold the same 40 characters. They are two names for one commit, and the repository is not one byte larger for it.
6. Deleting a branch does not delete the commit:

```
$ git branch -D spike
Deleted branch spike (was 1dfe2f9).
$ git cat-file -t 1dfe2f9
commit
```

7. The commit is still there, still readable, still has its tree and its blobs. Only the pointer went.
8. You can move a branch by hand, because it really is just a file:

```
$ git update-ref refs/heads/topic 1dfe2f9b9521c9a4...
$ git branch -v
* main 0f0c441 three
  topic 1dfe2f9 one
```

■ 38.6.4 PLAIN – what is really happening inside

1. Sometimes you look for .git/refs/heads/main and it is not there. The branch still exists. It has simply been packed.
2. Git can move all its ref files into one file called .git/packed-refs, to avoid thousands of tiny files.
3. Watch it happen for real:

```
$ git pack-refs --all
$ ls .git/refs/heads/
(empty)
$ cat .git/packed-refs
# pack-refs with: peeled fully-peeled sorted
bc7fc422aec1054a108922e49253ce8271b1e957 refs/heads/main
```

```
1dfe2f9b9521c9a46513a095c135831a8b54ef01 refs/heads/spike
bc7fc422aec1054a108922e49253ce8271b1e957 refs/heads/topic
```

4. The directory is empty and everything still works, because git looks in both places.
5. The rule is: a loose file wins over the packed file. Commit once more and the loose file comes back for that branch only:

```
$ git commit -m "three"
$ cat .git/refs/heads/main
0f0c4412ec5e57f084c7a39a254a1f9d67f3e965
$ grep main .git/packed-refs
bc7fc422aec1054a108922e49253ce8271b1e957 refs/heads/main
```

6. Two different values for refs/heads/main exist on disk at once, and that is fine. The loose file is the current one. The packed entry is stale and will be tidied later.
7. This is why you should never read ref files yourself in a script. Ask git: `git rev-parse main`, or `git show-ref`, or `git for-each-ref`.
8. Contrast with a system where a branch is a copy. If branching meant copying the working tree, then in the sandbox's 200-commit repository each branch would cost 109,408 bytes of file content. A thousand branches would be about 104 MiB.
9. In git, a thousand branches cost 41,000 bytes of actual content.

■ 38.6.5 TECHNICAL – the engineer's version

1. A ref is a name in a hierarchical namespace, refs/heads/* for local branches, that resolves to an object id.
2. Storage back-ends, as of Git 2.43: loose files under .git/refs, plus .git/packed-refs. A newer refable back-end exists as an option in recent releases and is not the default.
3. Measured in the sandbox on a 200-commit repository:

Operation	Measured cost
Create 1,000 branches	2.28 s, 41,000 bytes
Disk blocks for those refs	4.0 MB (4 KiB per file)
After <code>git pack-refs --all</code>	one file of 56,996 bytes
Disk blocks after packing	28 KB

4. Note the gap between 41,000 bytes of content and 4.0 MB of disk. Each 41-byte file still occupies a whole filesystem block. That is the real reason packed-refs exists, and why repositories with tens of thousands of refs feel slow before it is used.
5. Ref updates are made atomic by writing a temporary file and renaming it over the target, and by taking a .lock file. This is why two concurrent commits in the same repository cannot half-write a branch.
6. Historical contrast, and it is worth knowing why git felt revolutionary in 2005. In CVS, released in 1990, a branch was recorded inside every single file's history, so branching a large tree touched every file. In Subversion, released in 2000, a branch is a cheap server-side copy, but it appears as a real directory path and switching a working copy is not free.
7. Git's design goal, stated by Linus Torvalds when he began the project on 3 April 2005 after the BitKeeper licence withdrawal, was that branching and merging should be cheap enough to do casually. Writing 41 bytes achieves that.

- Convention, not standard: the default branch name. Git shipped `master` as the default from 2005. GitHub changed the default for new repositories to `main` in October 2020, and git itself added `init.defaultBranch` so the choice is configurable. Neither name means anything to the software.

■ 38.6.6 WORDS - remember these

- Ref — a name that points at a commit — an entry in the `refs/` namespace resolving to an object id.
- Branch — a moving pointer to the tip of a line of work — a ref under `refs/heads/` that is advanced automatically when you commit.
- packed-refs — one file holding many refs — `.git/packed-refs`, a sorted text file consulted when no loose ref file exists.
- Loose ref — a ref stored as its own small file — a 41-byte file under `.git/refs/`, which takes precedence over the packed entry.
- update-ref — the command that sets a ref by hand — plumbing that writes a ref value with locking and reflog recording.

38.7 HEAD

■ 38.7.1 PLAIN - in simple words

- HEAD is another file, at `.git/HEAD`, and it answers one question: where am I right now.
- Normally it does not contain a commit hash. It contains the name of a branch.
- Its whole content is the text `ref: refs/heads/main` and a newline. Twenty-one bytes.
- That is called **attached** HEAD. You are “on” a branch. When you commit, git writes the new commit and then moves that branch forward.
- Sometimes HEAD contains a commit hash directly instead of a branch name. That is **detached** HEAD.
- Detached means you are looking at a commit without being on any branch. You can look, build, test, even commit.
- It is not an error. It is a normal state. Git even prints a helpful notice when you enter it.
- The danger is only this: if you commit while detached and then walk away, nothing points at your new commit, so it is easy to lose track of it.

■ 38.7.2 PLAIN - a picture in your head

- Think of the shelf of books again, with sticky notes for branch names.
- HEAD is your finger. Normally your finger rests on a sticky note, not on a book. When the note moves, your finger goes with it.
- Detached HEAD is when you take your finger off the notes and put it directly on a book.
- You can still read that book, and you can still write new books after it. But no sticky note follows you.
- If you then move your finger back to a note, the books you wrote are still on the shelf, but with nothing labelling them, they are easy to overlook.

Where this comparison breaks:

- On a real shelf you would still see the new books. In git nothing is visible in `git branch` or `git log` unless something points at it.
- But git is kinder than the shelf: it writes down where your finger has been. That log is the reflog, and it is how you find those books again.

■ 38.7.3 PLAIN – a worked example

1. Attached state, real output:

```
$ cat .git/HEAD
ref: refs/heads/main
$ git symbolic-ref HEAD
refs/heads/main
$ git status -sb
## main
```

2. Now detach on purpose. Git prints a long, genuinely useful notice:

```
$ git checkout HEAD~2
Note: switching to 'HEAD~2'.

You are in 'detached HEAD' state. You can look around, make
experimental changes and commit them, and you can discard any
commits you make in this state without impacting any branches
by switching back to a branch.

If you want to create a new branch to retain commits you create,
you may do so (now or later) by using -c with the switch command.
Example:

    git switch -c <new-branch-name>

Or undo this operation with:

    git switch -

HEAD is now at b53a9f4 Third commit: add src/util.c
```

3. Look at the file now. No branch name. A raw hash:

```
$ cat .git/HEAD
b53a9f46d432aa53e687328841c6dd2b89963809
$ git symbolic-ref HEAD
fatal: ref HEAD is not a symbolic ref
$ git status -sb
## HEAD (no branch)
```

4. Commit something while detached and HEAD simply advances by itself:

```
$ git commit -m "Work done while detached"
$ git rev-parse HEAD
3a0a3d62188c8a51d4d914b5efd000ea8483695b
$ cat .git/HEAD
3a0a3d62188c8a51d4d914b5efd000ea8483695b
```

5. No branch moved, because no branch was involved.

6. Now leave. Git warns you, by name and by hash:

```
$ git checkout main
Warning: you are leaving 1 commit behind, not connected to
any of your branches:

    3a0a3d6 Work done while detached

If you want to keep it by creating a new branch, this may be a
good time to do so with:
```

```
git branch <new-branch-name> 3a0a3d6
```

```
Switched to branch 'main'
```

7. That warning contains everything you need to recover. Copy the hash and run `git branch keep-this 3a0a3d6`.

■ 38.7.4 PLAIN – what is really happening inside

1. HEAD is a **symbolic reference**: a ref whose value is the name of another ref rather than an object id.
2. When git needs “the current commit”, it reads HEAD. If the content starts with `ref :`, it follows that name and reads the branch file. Otherwise it uses the hash directly.
3. That one indirection is why committing on a branch moves the branch. Git updates whatever HEAD points to.
4. How you end up detached, in practice:
 1. `git checkout <sha>` or `git checkout <tag>` or `git checkout origin/main`.
 2. `git rebase` while it is replaying commits.
 3. A continuous integration job doing `git checkout $COMMIT_SHA`, which is why almost every CI build runs detached.
 4. `git bisect`, which walks you across commits.
5. How to recover, in order of preference:
 1. If you have not committed: `git switch -` or `git checkout main`. Nothing is at risk.
 2. If you have committed and want to keep it: `git branch <name>` right there, or `git switch -c <name>`.
 3. If you already left and lost the hash: use the reflog, section 38.9.
6. The commits you made while detached are ordinary objects. They are not marked, not special, not fragile. They are simply unreferenced, and unreferenced objects are eventually swept up by garbage collection.

■ 38.7.5 TECHNICAL – the engineer’s version

1. `.git/HEAD` is 21 bytes in the attached state and 41 bytes in the detached state. Both are plain text.
2. The plumbing commands are `git symbolic-ref HEAD` to read or write the symbolic form, and `git rev-parse HEAD` to resolve either form to an object id.
3. `git rev-parse --abbrev-ref HEAD` prints the branch name when attached and the literal string HEAD when detached. Scripts use this to decide.
4. Other pseudo-refs live in `.git/` alongside HEAD and appear during operations. All of these were observed in the sandbox:

Pseudo-ref	Present during / after
ORIG_HEAD	reset, merge, rebase
FETCH_HEAD	after <code>git fetch</code>
MERGE_HEAD	an unfinished merge
CHERRY_PICK_HEAD	an unfinished cherry-pick
AUTO_MERGE	ort strategy’s merged tree

5. `advice.detachedHead` controls the long notice. Setting it to false silences it, which is standard practice in CI images where every checkout is detached by design.

6. A worktree created with `git worktree add` gets its own HEAD, stored under `.git/worktrees/<name>/HEAD`. That is why two worktrees of one repository can sit on different commits while sharing one object store.
7. The honest version: people describe detached HEAD as dangerous. It is not. It is exactly as safe as any commit that no branch points at. The risk is purely about visibility, and the reflog removes most of that risk.

■ 38.7.6 WORDS – remember these

1. HEAD — the file saying where you are — a pseudo-ref at `.git/HEAD`, usually symbolic.
2. Symbolic ref — a ref pointing at another ref by name — content of the form `ref: refs/heads/<name>`.
3. Attached HEAD — you are on a branch — HEAD is symbolic and commits advance the named branch.
4. Detached HEAD — you are on a commit with no branch — HEAD holds an object id directly; new commits are unreferenced.
5. Pseudo-ref — a special one-off ref in the git directory — names such as `ORIG_HEAD` and `MERGE_HEAD`, written by particular operations.

38.8 The rest of the refs

■ 38.8.1 PLAIN – in simple words

1. Branches are only one kind of ref. All refs live in the same namespace and all of them work the same way: a name that resolves to an object id.
2. `refs/heads/` holds your local branches.
3. `refs/tags/` holds tags. There are two kinds and they differ on disk.
4. A **lightweight tag** is just a ref file pointing straight at a commit. No extra object exists.
5. An **annotated tag** points at a tag object, and that tag object points at the commit. It carries a tagger, a date, a message and, optionally, a signature.
6. `refs/remotes/` holds remote-tracking refs, such as `origin/main`. These are your local cached memory of what a remote looked like the last time you spoke to it.
7. `refs/notes/` holds notes, a way of attaching text to a commit without changing the commit.
8. `refs/stash` holds stashed work. There are a few other special names too.

■ 38.8.2 PLAIN – a picture in your head

1. Think of the shelf of books once more, and the sticky notes.
2. A branch note is one you move forward every day.
3. A lightweight tag is a note you stick on and never move.
4. An annotated tag is not a note at all. It is a small printed card in a sleeve, with a date, a signature and a sentence explaining why this book matters, and the card names the book.
5. A remote-tracking note is a note in a different colour saying “when I last visited the other library, their note called `main` was on this book”.
6. It does not move when their note moves. It moves when you next visit.

Where this comparison breaks:

7. On a shelf you could check the other library instantly by looking across the room. In git, checking costs a network round trip, which is exactly why the cached note exists and exactly why it goes stale.

■ 38.8.3 PLAIN – a worked example

1. The complete ref tree of the sandbox repository, exactly as git reports it:

```
$ git for-each-ref --format='%(objectname:short) %(objecttype) %(refname)'
7c7506f commit refs/heads/feature
70a5d62 commit refs/heads/fix
39bf0c8 commit refs/heads/main
cc1849e commit refs/notes/commits
b53a9f4 commit refs/remotes/origin/main
b53a9f4 commit refs/tags/v1-light
d54ba18 tag refs/tags/v1.0
```

2. Look at the last two rows. Both are tags, both point at the same release, but the object types differ.
3. refs/tags/v1-light has type commit. The ref points at the commit directly. That is a lightweight tag.
4. refs/tags/v1.0 has type tag. The ref points at a tag object, which in turn points at the commit. That is an annotated tag.
5. On disk, both are 41-byte files with 40 hex characters. The difference is what those characters name:

```
.git/refs/tags/v1-light -> b53a9f46... (a commit)
.git/refs/tags/v1.0 -> d54ba182... (a tag object)
```

6. And the tag object itself, which the lightweight tag simply does not have:

```
$ git cat-file -p v1.0
object b53a9f46d432aa53e687328841c6dd2b89963809
type commit
tag v1.0
tagger KedByte Reader <reader@example.com> 1767598200 +0530

First release of the demo
```

■ 38.8.4 PLAIN – what is really happening inside

1. Remote-tracking refs are updated by exactly two things: git fetch and git push. Nothing else touches them.
2. So origin/main is not a live reading of the server. It is a note of what the server said last time. This matters enormously and section 38.12 returns to it.
3. git ls-remote is the command that asks the server right now, over the network, without changing anything locally:

```
$ git ls-remote origin
b53a9f46d432aa53e687328841c6dd2b89963809 HEAD
b53a9f46d432aa53e687328841c6dd2b89963809 refs/heads/main
b53a9f46d432aa53e687328841c6dd2b89963809 refs/tags/v1-light
d54ba1826a59225bc14a2b55e832536cb7a8e4ac refs/tags/v1.0
b53a9f46d432aa53e687328841c6dd2b89963809 refs/tags/v1.0^{}
```

4. Notice the last line. The suffix ^{} means “the object this tag finally resolves to after following it through”. Servers advertise both, so clients need not fetch the tag object just to learn what it points at.
5. The packed-refs file records the same fact with a caret line:

```
d54ba1826a59225bc14a2b55e832536cb7a8e4ac refs/tags/v1.0
^b53a9f46d432aa53e687328841c6dd2b89963809
```

6. A note is stored as a whole commit and tree of its own, under `refs/notes/commits`. The tree maps a commit's hash, used as a file name, to a blob holding the note text.
7. That is why notes can be added and changed without altering the commit they describe. The commit does not know about them.
8. A stash entry is a merge commit with two or three parents: the commit you were on, a commit holding the index state, and if needed one holding untracked files.

```
$ git cat-file -p refs/stash
tree a5419a1446acbb442a6da16df29e43c605ebd018
parent 39bf0c8354d383aaf21ff05eaff4304acc24f346
parent 96a1b317649d3354ec613c5f61bcc7ba7eba40c1
```

9. So a stash is not a special storage area. It is ordinary commits with a ref pointing at them.

■ 38.8.5 TECHNICAL – the engineer's version

1. The ref namespace, with the parts you will actually meet:

Namespace	Holds
<code>refs/heads/*</code>	local branches
<code>refs/tags/*</code>	tags, both kinds
<code>refs/remotes/<r>/*</code>	remote-tracking refs
<code>refs/notes/*</code>	note trees

2. Beyond those: `refs/stash`, `refs/bisect/*` during a bisect, `refs/replace/*` for object replacement, and on GitHub the server-side `refs/pull/<n>/head` and `refs/pull/<n>/merge`, which are a hosting convention rather than part of git.
3. Lightweight versus annotated is a real operational difference, not a style choice:

Aspect	Lightweight	Annotated
Extra object	none	one tag object
Has message	no	yes
Has tagger and date	no	yes
Can be signed	no	yes
describe prefers it	no	yes

4. `git describe` ignores lightweight tags unless you pass `--tags`. Release engineering therefore uses annotated tags almost universally.
5. The default `fetch refspec`, written into `.git/config` by `git clone`, is `+refs/heads/*:refs/remotes/origin/*`. The leading plus means non-fast-forward updates are allowed for these refs, which is why a force-push upstream quietly rewrites your `origin/*` refs.
6. `git for-each-ref` is the scriptable interface. `git show-ref` is the older one. Both read loose and packed refs correctly, which hand-written scripts that cat ref files do not.

■ 38.8.6 WORDS – remember these

1. Lightweight tag — a fixed pointer to a commit — a ref under `refs/tags/` whose value is a commit id.
2. Annotated tag — a tag with a message and author — a ref pointing at a tag object carrying tagger, date, message and optional signature.

3. Remote-tracking ref — your cached memory of a remote branch — a ref under `refs/remotes/`, updated only by fetch and push.
4. Refspec — the rule mapping their refs to yours — for example `+refs/heads/*:refs/remotes/origin/*`.
5. Peeled ref — the object a tag finally points to — shown as `<tag>^{}` and recorded with a caret line in `packed-refs`.
6. Note — text attached to a commit after the fact — a blob in a tree under `refs/notes/`, keyed by the commit's object id.

38.9 The reflog

■ 38.9.1 PLAIN – in simple words

1. Every time a ref changes value, git writes a line in a log saying where it was and where it went.
2. That log is the **reflog**. There is one for HEAD and one for each branch.
3. It records the old hash, the new hash, who did it, when, and which command caused it.
4. This log is the reason “I destroyed my work with git” is almost always false.
5. A hard reset, a bad rebase, a deleted branch, an amended commit: in every case the old commit object is still on disk and the reflog still knows its hash.
6. The reflog is local and private. It is never pushed, never fetched, and never shared. Cloning a repository does not bring its reflog.
7. Entries do not last forever. By default reachable entries survive 90 days and unreachable ones 30 days.

■ 38.9.2 PLAIN – a picture in your head

1. Think of a security camera pointed at the sticky notes on the shelf.
2. It does not record the books. It records every time a note moved, and to where.
3. If you come back and find a note in the wrong place, you rewind the tape, read off which book it used to be on, and put it back.
4. The books never went anywhere. Only the note moved. That is the whole trick.

Where this comparison breaks:

5. A camera records what everyone did. The reflog records only what happened in your copy, on your machine. Your colleague's reflog is a different tape.
6. And the tape is wiped on a schedule. After about 30 days, a commit that nothing points at can genuinely be collected and deleted.

■ 38.9.3 PLAIN – a worked example

1. Here is a real disaster and a real recovery, done in the sandbox. The starting point is a repository whose main is at a merge commit.

```
$ git log --oneline -3
7fc6cf8 Merge feature into main
25478c1 Fifth commit: extend README on main
7c7506f Fourth commit: add docs/feature.md on feature
```

2. Now the mistake. A hard reset two commits back, which throws away the merge and everything after it:

```
$ git reset --hard HEAD~2
HEAD is now at b53a9f4 Third commit: add src/util.c
```

```
$ git log --oneline -3
b53a9f4 Third commit: add src/util.c
fb17f98 Second commit: edit docs/intro.md
d9cbb74 First commit: readme, source and docs
$ ls
README.md docs src
```

3. The merge is gone from the log. Files that only existed after it are gone from the working directory. This is the moment people panic.
4. It is not gone. The commit object is still there and still readable:

```
$ git cat-file -t 7fc6cf8
commit
$ git cat-file -p 7fc6cf8 | head -3
tree b704d3e37ec1cb98ac5712b56206dbe28b5aac6e
parent 25478c16e00d681e80a0db23a6c7bca204e07404
parent 7c7506f6a3b659163ac6f5d9f155a1a9b89f298e
```

5. And even without knowing that hash, the reflog tells you it:

```
$ git reflog
b53a9f4 HEAD@{0}: reset: moving to HEAD~2
7fc6cf8 HEAD@{1}: checkout: moving from 3a0a3d6... to main
3a0a3d6 HEAD@{2}: commit: Work done while detached
```

6. HEAD@{1} is where HEAD was one move ago: 7fc6cf8. That is the merge.
7. The branch has its own reflog, which is usually the cleaner one to read:

```
$ git reflog show main
7fc6cf8 main@{0}: merge feature: Merge made by the 'ort' strategy
25478c1 main@{1}: commit: Fifth commit: extend README on main
b53a9f4 main@{2}: commit: Third commit: add src/util.c
```

8. The recovery is one command:

```
$ git rev-parse main@{1}
7fc6cf85594a850b727418867d4054af04412e88
$ git reset --hard main@{1}
HEAD is now at 7fc6cf8 Merge feature into main
$ git log --oneline -3
7fc6cf8 Merge feature into main
25478c1 Fifth commit: extend README on main
7c7506f Fourth commit: add docs/feature.md on feature
```

9. Everything is back. Total elapsed effort: one lookup and one command.

■ 38.9.4 PLAIN – what is really happening inside

1. The reflog is a plain text file per ref. HEAD's log is `.git/logs/HEAD`. A branch's log is `.git/logs/refs/heads/<name>`.
2. Each line has five fields, tab-separated at the end: old object id, new object id, the person, the timestamp with offset, then the reason.
3. Here is one real line, wrapped across two lines to fit this page:

```
fb17f98cd37f546dfedb2f91e1b7a9762bf45d17 b53a9f46d432aa53e6873
28841c6dd2b89963809 KedByte Reader <reader@example.com>
1767594600 +0530 commit: Third commit: add src/util.c
```

- The very first line of a branch's log has all zeros as the old id, because the branch did not exist before:

```
0000000000000000000000000000000000000000000000000000000000000000 d9cbb74f1fb9bce240d20d
b0c8e545caf68c802b ... commit (initial): First commit ...
```

- The `@{n}` syntax counts entries in that file. `main@{0}` is the current value, `main@{1}` is the value before the most recent change, and so on.
- There is also a time form. `main@{2026-01-06}` asks what main pointed at on that date. If the log does not go back that far, git says so:

```
warning: log for 'main' only goes back to Thu, 13 Aug 2026 03:12:55
```
- Notice `@{n}` and `~n` are completely different questions. `HEAD~1` means “the parent commit in the history”. `HEAD@{1}` means “wherever HEAD was pointing one move ago”. They frequently give different answers.
- Reflogs are only kept if `core.logAllRefUpdates` is on, which it is by default for non-bare repositories. Bare repositories, the kind that sit on a server, do not keep reflogs by default. That is worth remembering before you rely on one.

■ 38.9.5 TECHNICAL - the engineer's version

- Expiry defaults, from git's own documentation:

Setting	Default
<code>gc.reflogExpire</code>	90 days
<code>gc.reflogExpireUnreachable</code>	30 days
<code>gc.pruneExpire</code>	2 weeks ago
<code>gc.auto</code>	6700 loose objects
<code>gc.autoPackLimit</code>	50 packs

- “Unreachable” here means the reflog entry names a commit that is no longer reachable from any ref. Those are the entries you most need after a mistake, and they are the ones that expire soonest.
- Reflog entries keep their objects alive. `git gc` treats reflog-referenced objects as reachable, which is why a commit lost by reset is not collected the same afternoon.
- Proof from the sandbox. Immediately after abandoning a detached commit, `git fsck --unreachable` reported nothing, because the reflog still held it. Adding `--no-reflogs` revealed the truth:

```
$ git fsck --unreachable --no-reflogs
unreachable tree bcb2c24a564e8ff3d64369f03559123b68b04b03
unreachable blob 9a5abed11a92dda94398c590ec782181a789f4c5
unreachable commit 3a0a3d62188c8a51d4d914b5efd000ea8483695b
```

- The recovery toolkit, in the order you should reach for it:
 - `git reflog` or `git reflog show <branch>` — find the old hash.
 - `git reset --hard <sha>` — move the branch back, discarding current work.
 - `git branch rescue <sha>` — safer: give the lost commit a name without touching your current branch.
 - `git fsck --lost-found` — last resort, when the reflog was pruned or the repository is bare. Writes dangling objects into `.git/lost-found/`.

6. `git log -g` prints the reflog as commits, with full messages, which is often easier to read than `git reflog` when you need to identify work by content.
7. Danger commands and what saves you from each:

Command	Reflog entry that saves you
<code>git reset --hard X</code>	<code>HEAD@{1}</code> and <code><branch>@{1}</code>
<code>git rebase</code>	<code><branch>@{1}</code> , before the rebase
<code>git commit --amend</code>	<code>HEAD@{1}</code> holds the pre-amend commit
<code>git branch -D X</code>	the deletion message prints the hash
<code>git checkout detach</code>	the “leaving N commits behind” warning

8. What the reflog does not save: uncommitted changes in the working tree. `git reset --hard`, `git checkout -- <file>` and `git clean -fd` destroy work that was never turned into an object, and no log exists for it. Anything you staged with `git add` survives, as a dangling blob findable with `git fsck --lost-found`.

■ 38.9.6 WORDS – remember these

1. Reflog — a local log of where each ref has been — per-ref append-only log in `.git/logs/`, recording old id, new id, actor, time and reason.
2. `@{n}` — the value a ref had `n` moves ago — reflog index selector, distinct from the `~n` ancestry selector.
3. Unreachable object — an object no ref points at — a candidate for pruning once its reflog entry expires.
4. Dangling object — an unreachable object with nothing pointing at it at all — reported by `git fsck` and recoverable with `--lost-found`.
5. Prune — permanently delete unreachable objects — `git prune`, or the pruning step inside `git gc`, honouring `gc.pruneExpire`.

38.10 The commands that reveal the machinery

■ 38.10.1 PLAIN – in simple words

1. Git has two layers of commands, and it is worth knowing which is which.
2. **Porcelain** commands are the ones you use daily: `add`, `commit`, `log`, `merge`, `status`, `push`. They are built for people. Their output is meant to read nicely and is allowed to change between versions.
3. **Plumbing** commands are the low-level ones underneath: `cat-file`, `hash-object`, `ls-tree`, `rev-parse`, `rev-list`, `update-ref`. They are built for scripts. Their output format is stable on purpose.
4. The names are git’s own, from its documentation, and they come from the idea that you see the porcelain of a bathroom while the plumbing does the work.
5. Rule for scripts: never parse porcelain output. Use plumbing, or use the porcelain commands’ `--porcelain` flags, which are stable despite the confusing name.
6. This section is a tour of the plumbing, with real output for each command.

■ 38.10.2 PLAIN – a picture in your head

1. A car has a dashboard and it has an engine.
2. The dashboard tells you the speed in a form you can act on. The designer may redesign it next year and nobody minds.
3. The engine has bolts of exact sizes that have not changed in a decade, because tools depend on them.

4. Porcelain is the dashboard. Plumbing is the bolts.
5. You drive with the dashboard. You diagnose with the bolts.

Where this comparison breaks:

6. In a car you rarely need the engine. In git the plumbing is genuinely useful during ordinary work, especially when something has gone wrong and you need an answer that is exactly true rather than nicely presented.

■ 38.10.3 PLAIN – a worked example

1. `git cat-file` with its three most useful flags. `-t` gives the type, `-s` the size in bytes, `-p` the content:

```
$ git cat-file -t b53a9f4
commit
$ git cat-file -s b53a9f4
247
$ git cat-file -t b53a9f4^{tree}
tree
```

2. `git rev-parse` turns any way of naming a commit into the one true hash:

```
$ git rev-parse HEAD
39bf0c8354d383aaf21ff05eaff4304acc24f346
$ git rev-parse --short HEAD
39bf0c8
$ git rev-parse --short=12 HEAD
39bf0c8354d3
$ git rev-parse --abbrev-ref HEAD
main
$ git rev-parse --git-dir
.git
$ git rev-parse --show-toplevel
/tmp/kb38/demo
```

3. It also resolves paths inside a commit, which is how you get a blob's hash without looking at a tree:

```
$ git rev-parse HEAD:docs/intro.md
bce6753328d0de8aaa42692aba92b99182ded5ce
```

4. `git hash-object` computes a name without storing anything, and with `-w` stores it:

```
$ printf 'Introduction.\n' | git hash-object --stdin
0e2a325c7de3369b164d48fcb823bca9c2cec4e
```

5. `git ls-tree` reads a tree. Plain, recursive, and with sizes:

```
$ git ls-tree HEAD
100644 blob 6af3a5ad4b99c155602b8f78298d89fc15b61209    README.md
040000 tree 8c33b40fe5eb264b8d43c66f01dc437cc4c90aa5    docs
040000 tree 069dcc578e4a416937da34a3dcc4d209c1048c63    src

$ git ls-tree -r HEAD
100644 blob 6af3a5ad... README.md
100644 blob 76c95066... docs/feature.md
100644 blob bce67533... docs/intro.md
100644 blob 61a98438... docs/mainnote.md
100644 blob 78f2de10... src/main.c
100644 blob df76ea63... src/util.c
```

6. `git count-objects -v` tells you the shape of the object store:

```
$ git count-objects -vH
count: 15
size: 60.00 KiB
in-pack: 31
packs: 1
size-pack: 4.60 KiB
```

7. `git rev-list` lists commit hashes, and counts them:

```
$ git rev-list --count HEAD
7
$ git rev-list --count --all
9
```

■ 38.10.4 PLAIN – what is really happening inside

1. The revision syntax deserves its own explanation because two of its forms look alike and mean different things.
2. `X~n` means “go back *n* steps, always taking the first parent”. `HEAD~2` is the grandparent.
3. `X^n` means “the *n*-th parent of this one commit”. `HEAD^2` is the second parent, which only exists on a merge commit.
4. On the real merge commit in the sandbox:

```
$ git rev-parse HEAD      # the merge
7fc6cf85594a850b727418867d4054af04412e88
$ git rev-parse HEAD^1    # first parent, the branch merged into
25478c16e00d681e80a0db23a6c7bca204e07404
$ git rev-parse HEAD^2    # second parent, the branch merged in
7c7506f6a3b659163ac6f5d9f155a1a9b89f298e
$ git rev-parse HEAD~1    # same as ^1
25478c16e00d681e80a0db23a6c7bca204e07404
$ git rev-parse HEAD~2    # two first-parent steps back
b53a9f46d432aa53e687328841c6dd2b89963809
```

5. `HEAD~1` and `HEAD^1` gave the same answer. `HEAD~2` and `HEAD^2` gave completely different answers. That is the trap.
6. And `branch@{1}` is a third thing again: not ancestry at all, but the reflog. In the sandbox `main@{1}` was `7fc6cf8` while `main~1` was a different commit entirely.
7. `git show` is porcelain that stitches several plumbing operations together. Given a commit it prints the metadata plus a computed diff. Given a blob it prints content. Given a tree it prints a listing.
8. `git log --graph --oneline --all` is the single most useful shape-revealing command. `--all` is the important part: without it you only see history reachable from `HEAD`.

■ 38.10.5 TECHNICAL – the engineer’s version

1. Command classification, with the stability promise:

Command	Layer	Output stability
<code>git status</code>	porcelain	may change
<code>git status --porcelain=v2</code>	porcelain	stable, versioned
<code>git cat-file</code>	plumbing	stable
<code>git rev-parse</code>	plumbing	stable
<code>git for-each-ref</code>	plumbing	stable, formattable

2. `git cat-file --batch-check` is the high-throughput form. It reads object names on standard input and writes name, type and size, avoiding one process per object:

```
$ git cat-file --batch-all-objects --batch-check
0e2a325c7de3369b164d48fcb823bca9c2cec4e blob 14
6af3a5ad4b99c155602b8f78298d89fc15b61209 blob 52
78f2de106c92b0d60772bd5aa6c1e6da7bf71005 blob 29
```

3. `git verify-pack -v` lists a packfile's contents. Columns are: object id, type, size, size in the packfile, offset in the packfile, and for deltified objects the chain depth and the base object id:

```
5087b1a6efba7b591bda30d3badbd5056b4fab4b blob 111810 15280 30437
23841aba9acef22ead7d8505ba90653bc3544934 blob 78 93 45717 1 5087
6578910fb9573331428c33593424cb14b02cb49a blob 38 52 45810 2 2384
```

4. Read that carefully. The first blob's real size is 111,810 bytes and it occupies 15,280 bytes in the pack. The second's "size" column reads 78, but that is the size of the delta, not of the object. Depth 1 means one hop to its base.
5. `git rev-list` is the engine under `git log`. It walks the DAG and emits object ids. `--objects` also emits the trees and blobs reachable from each commit, which is exactly what `git pack-objects` consumes during a push.
6. `git fsck` verifies the whole store: every object's hash against its content, every referenced object present, every ref resolvable. It is the command that turns content addressing into a usable integrity check.
7. Useful one-liners worth memorizing:

```
git cat-file -p HEAD^{tree}          # top directory of HEAD
git rev-list --count main ^origin/main # commits not pushed yet
git for-each-ref --sort=-committerdate refs/heads/
git log --graph --oneline --all --decorate
git rev-parse --verify --quiet <sha> # test existence, no output
```

■ 38.10.6 WORDS – remember these

1. Porcelain — the commands people use — the human-facing layer whose output format carries no stability promise.
2. Plumbing — the commands scripts use — the low-level layer with stable, machine-readable output.
3. `rev-parse` — turn a name into a hash — the revision-parsing plumbing that resolves every form of object naming.
4. `~` and `^` — steps back, versus which parent — `~n` is `n` first-parent steps, `^n` selects the `n`-th parent of one commit.
5. `--batch-check` — ask about many objects at once — `git cat-file` batch mode giving id, type and size without one process per object.

38.11 How git stores things efficiently

■ 38.11.1 PLAIN – in simple words

1. Everything so far has described whole snapshots. That sounds wasteful, and on its own it is.
2. Git solves this in two stages.
3. Stage one, **loose objects**. Each object gets its own file, squeezed with zlib compression. Simple, fast to write, wasteful of disk blocks.

4. Stage two, **packfiles**. Git gathers thousands of objects into one big file and, inside that file, stores similar objects as differences from one another.
5. This is the important sentence of the whole section: those differences are a storage trick only. Git's idea of history is still whole snapshots. The deltas exist below that, and you never see them.
6. Git does the packing when you push, when you clone, and when housekeeping runs.
7. `git gc` is the command that does the housekeeping: pack loose objects, pack refs, trim reflogs, and delete objects nothing points at any more.

■ 38.11.2 PLAIN – a picture in your head

1. Imagine keeping every draft of a long report in a filing cabinet, one folder per draft.
2. At first you photocopy the whole report each time. Two hundred drafts, two hundred thick folders. That is loose objects.
3. Then a clerk goes through the cabinet. She keeps one full copy of the report, and replaces the other 199 folders with slips of paper saying “same as the previous draft, but line 812 now reads this”.
4. The cabinet drawer that was full is now nearly empty.
5. Crucially, when you ask for draft 137, she reconstructs it and hands you a complete report. You never see the slips.

Where this comparison breaks:

6. A clerk works from the previous draft. Git compares each object against a window of candidates and picks whichever gives the smallest difference, which is often not the chronological predecessor.
7. And the clerk's slips would be useless if the full copy were lost. Git guarantees every chain terminates at a complete object inside the same packfile.

■ 38.11.3 PLAIN – a worked example

1. Here is a real repository built for this section: one text file of about 110 KB, edited and committed 200 times, one line changed each time.
2. Before any packing:

```
$ git count-objects -vH
count: 600
size: 6.25 MiB
in-pack: 0
packs: 0
$ du -sh .git/objects
7.2M    .git/objects
```

3. Six hundred loose objects: 200 blobs, 200 trees, 200 commits.
4. The total content, uncompressed, is much larger than what is on disk already:

```
$ git cat-file --batch-all-objects --batch-check='%(objectsize)'
(summed)
22463780 bytes = 21.42 MiB
```

5. So zlib alone took 21.42 MiB of content down to about 4.6 MiB of file bytes, occupying 7.2 MB of disk blocks.
6. Now run housekeeping:

```
$ git gc
$ git count-objects -vH
```

```
count: 0
size: 0 bytes
in-pack: 600
packs: 1
size-pack: 100.87 KiB
$ du -sh .git/objects
140K    .git/objects
```

- Read those numbers again. 21.42 MiB of content is now in one packfile of 85,423 bytes, with a 17,872-byte index beside it.

Stage	Bytes	Disk
Raw object content	22,463,780	n/a
Loose, zlib only	4,601,531	7.2 MB
Packed with deltas	85,423	140 KB

- That is a reduction of about 263 to 1 against the raw content, and about 54 to 1 against the already-compressed loose form.
- Where did it come from? Look inside the pack:

```
5087b1a6... blob 111810 15280 30437
23841aba... blob 78 93 45717 1 5087b1a6...
6578910f... blob 38 52 45810 2 23841aba...
2048ca7c... blob 44 58 45862 3 6578910f...
```

- The first blob is stored whole: 111,810 bytes, compressed to 15,280. Every following version is stored as a delta of 38 to 78 bytes.
- Of the 200 blobs, 198 are stored as deltas and only 2 are stored whole.

■ 38.11.4 PLAIN - what is really happening inside

- A packfile begins with the four ASCII bytes PACK, then a 4-byte version number, then a 4-byte object count. Here is the real header of the pack above:

```
| 00000000 50 41 43 4b 00 00 00 02 00 00 02 58 93 0e 78 9c
```

- 50 41 43 4b is PACK. 00 00 00 02 is version 2. 00 00 02 58 is 600 in hexadecimal, exactly the object count git reported.
- The last 20 bytes of the file are a SHA-1 checksum over everything before them, and that checksum is what the file is named after. The pack above is pack-700da35f...b936f4f9ea0477, and the file's final bytes are b9 36 f4 f9 ea 04 77.
- Beside it sits a .idx file starting with the magic bytes ff 74 4f 63 and version 2. It is a sorted table letting git find any object's offset in the pack without scanning it.
- Delta selection works like this. Git sorts objects by type, then by a path hint, then by size descending. It then slides a window over that order and, for each object, tries to express it as a difference against the others in the window.
- Two limits control the result. The window size, default 10, is how many candidates are considered. The depth, default 50, is how many hops a chain may have.
- The sandbox pack hit that limit exactly:

```
chain length = 48: 14 objects
chain length = 49: 24 objects
chain length = 50: 27 objects
```

8. Nothing has depth 51, because 50 is the ceiling. Deeper chains would compress better but cost more to read, because reading one object means applying every delta along the chain.
9. Note the direction. Git usually stores newer objects as deltas against older ones or the reverse, depending on size; the ordering heuristic prefers larger objects as bases. There is no rule that the base is the previous version in time.
10. `git gc` runs several jobs: repack loose objects into a pack, pack the refs into packed-refs, expire old reflog entries, prune unreachable objects older than the prune window, and update helper indexes such as the commit-graph.

■ 38.11.5 TECHNICAL – the engineer’s version

1. Packfile format version 2 has been the on-disk format since 2005 and is stable. It is also the wire format: what travels during clone, fetch and push is a packfile.
2. Two delta encodings exist inside a pack. `OBJ_OFS_DELTA` refers to its base by a relative offset within the same pack, and `OBJ_REF_DELTA` refers to it by full object id. Offsets are smaller, so modern git prefers them locally and uses reference deltas for thin packs on the wire.
3. A **thin pack** omits bases the receiver is known to have. The receiving side completes it with `git index-pack --fix-thin`. This is why a push of one small change is measured in kilobytes even in a large repository.
4. Measured configuration and results from the sandbox:

Item	Value
<code>pack.window default</code>	10 candidates
<code>pack.depth default</code>	50
Deltified blobs observed	198 of 200
Longest chain observed	50
Pack file / index size	85,423 B / 17,872 B

5. Delta compression is completely orthogonal to git’s data model. Every object in a pack still has the same object id it had when loose, still hashes to the same value once reconstructed, and `git cat-file -p` gives identical output. You cannot tell from the model whether an object is deltified.
6. Consequences that do show through, and they matter in real work:
 1. Binary files that do not delta well, such as compressed images, video and compiled artefacts, cost their full size in every version forever.
 2. `core.bigFileThreshold`, default 512 MiB, makes git skip delta attempts and store such files whole.
 3. Repacking a very large repository is memory hungry. `pack.windowMemory` and `pack.threads` exist to control that.
7. `git gc --aggressive` re-computes deltas with a much larger window, by default 250. It can take hours on a large repository and typically yields a modest further reduction. It is rarely the right answer.
8. Modern maintenance uses `git maintenance run` with incremental repacking rather than periodic full `git gc`. That is a change of practice within the last several years, not a change to the format.
9. Historical note: packfiles were not in the first version of git. Linus Torvalds began the project on 3 April 2005 and committed the first version on 7 April 2005, with the message Initial revision of "git", the information manager from hell. Loose objects came first, and packing was added later in 2005 when the loose-object-only design proved too slow for the Linux kernel history. Junio Hamano took over as maintainer in July 2005 and released version 1.0 on 21 December 2005.

■ 38.11.6 WORDS – remember these

1. Loose object — one object in one file — zlib-compressed file under `.git/objects/xx/`.
2. Packfile — many objects in one file — the `.pack` format, version 2, with a `.idx` lookup table beside it.
3. Delta — an object stored as a difference from another — `OBJ_OFS_DELTA` or `OBJ_REF_DELTA` inside a pack, purely a storage encoding.
4. Delta chain depth — how many hops to reach a whole object — controlled by `pack.depth`, default 50.
5. Thin pack — a pack that assumes you already have the bases — used on the wire, completed by `git index-pack --fix-thin`.
6. Garbage collection — tidying the object store — `git gc`, which repacks, packs refs, expires reflogs and prunes unreachable objects.

38.12 Reading the reader's own situation

■ 38.12.1 PLAIN – in simple words

1. During the network outage described in this book, the reader's machine reported `origin/main` as `0a95cc8`.
2. Three separate facts are hidden in that one short line, and telling them apart is the whole skill.
3. First, `0a95cc8` is an abbreviated object id. It is the first 7 of the 40 hexadecimal characters of a commit's hash.
4. Second, `origin/main` is a remote-tracking ref. It is a small local file holding that hash.
5. Third, and this is the part people get wrong, that file was written the last time the reader successfully talked to GitHub. It was not read from GitHub at the moment it was displayed.
6. During an outage, nothing on your machine can tell you what the server currently holds. Your machine can only tell you what it remembers.
7. The reader also rebased a local branch onto a moved `main`, and the branch's hash changed afterwards. Given everything in this chapter, that was unavoidable.

■ 38.12.2 PLAIN – a picture in your head

1. Imagine you write a friend's address in your notebook after visiting them.
2. Months later somebody asks where your friend lives. You read out the notebook.
3. You are not reporting where they live. You are reporting where they lived when you last checked.
4. If the phone lines are down, you cannot check. The notebook is all you have, and it is still the same notebook whether they moved yesterday or not.
5. `origin/main` is that notebook page. `git ls-remote` is the phone call.

Where this comparison breaks:

6. A person might tell you they moved. A git server never volunteers anything. It answers only when asked, and only over the network.
7. And your notebook page can be updated by two events, not one: a fetch, and also a successful push, because after a push you know what you just put there.

■ 38.12.3 PLAIN – a worked example

1. Start with the string itself. Seven characters, `0a95cc8`. What can you learn?

```
$ git cat-file -t 0a95cc8  
commit
```

```
$ git cat-file -s 0a95cc8
$ git cat-file -p 0a95cc8
```

- Those three commands tell you the type, the size and the full contents: the tree, the parent, the author, the committer and the message.
- If the object is not present locally, git says so plainly. Run against the sandbox repository, which has never seen that commit:

```
$ git cat-file -t 0a95cc8
fatal: Not a valid object name 0a95cc8
$ git rev-parse 0a95cc8
fatal: ambiguous argument '0a95cc8': unknown revision or path
not in the working tree.
```

- That message is worth reading carefully. Git cannot tell the difference between “no such commit” and “a commit I have not fetched”. Both look identical from here.
- To expand the abbreviation into the full 40 characters:

```
$ git rev-parse 0a95cc8
$ git rev-parse --short=12 origin/main
```

- To see what the remote-tracking ref currently says, and where that value physically lives:

```
$ git rev-parse origin/main
b53a9f46d432aa53e687328841c6dd2b89963809
$ cat .git/refs/remotes/origin/main
b53a9f46d432aa53e687328841c6dd2b89963809
```

- And to ask the server, right now, over the network:

```
$ git ls-remote origin refs/heads/main
b53a9f46d432aa53e687328841c6dd2b89963809    refs/heads/main
```

- Compare those two values. If they differ, your cached ref is stale. If `git ls-remote` fails, you have learned about the network and nothing at all about the server’s contents.

■ 38.12.4 PLAIN – what is really happening inside

- Why a rebase changes the hash. Recall the rule from section 38.3: a commit’s name is the hash of its bytes, and its bytes include the tree, the parent, both people, both timestamps and the message.
- A rebase does not move a commit. It cannot. It builds a new commit with the same message and the same changes but a different parent.
- Here is exactly that, done in the sandbox. A branch `fix` was created off `main`, then `main` moved on, then `fix` was rebased.
- Before the rebase:

```
tree 8376d5522743401a5e02cb99e72435cb6930e5a6
parent 7fc6cf85594a850b727418867d4054af04412e88
author KedByte Reader <reader@example.com> 1767760200 +0530
committer KedByte Reader <reader@example.com> 1767760200 +0530

Fix: add docs/fix.md
```

Its hash was `26c500778e51ea3a240b916e1ca97c33f2c37f55`.

- After the rebase:

```
tree 353596612537fa8a5e94b31dfa28bd33108ad139
parent 39bf0c8354d383aaf21ff05eaff4304acc24f346
author KedByte Reader <reader@example.com> 1767760200 +0530
committer KedByte Reader <reader@example.com> 1767767400 +0530

Fix: add docs/fix.md
```

Its hash is now 70a5d6220cc7944c8b3824701b4952027bc539af.

6. Compare the two blocks line by line. The message is identical. The author line is identical, including the original author timestamp.
7. Three things changed: the parent, because it is now on top of main; the tree, because the snapshot now also contains main's newer file; and the committer timestamp, because the commit was recorded again just now.
8. Any one of those three would have been enough to change the hash. All three changed.
9. The old commit still exists. Nothing was destroyed:

```
$ git reflog fix
70a5d62 fix@{0}: rebase (finish): refs/heads/fix onto 39bf0c8
26c5007 fix@{1}: commit: Fix: add docs/fix.md
7fc6cf8 fix@{2}: branch: Created from main
$ git cat-file -t 26c5007
commit
```

10. So "the SHA changed after a rebase" is not really true. A different commit now exists, and the branch file was rewritten to point at it. Both commits are on disk.

■ 38.12.5 TECHNICAL - the engineer's version

1. Abbreviation length. Git's default is `core.abbrev=auto`, which picks a length long enough that a collision among the objects present is unlikely, with a floor of 7 characters. Small repositories therefore show 7.
2. A 7-character prefix is 28 bits, about 268 million values. By the birthday bound, ambiguity becomes likely once a repository holds a few tens of thousands of objects, which is why large repositories abbreviate to 10, 12 or more.
3. An abbreviation is only unique within one repository at one moment. Adding objects can make a previously unique prefix ambiguous. Never store an abbreviated hash as a durable identifier; store all 40 characters.
4. What actually updates `refs/remotes/origin/*`:

Event	Updates origin/main?
git fetch	yes
git pull	yes, it fetches first
Successful git push	yes
git ls-remote	no, reads only
Someone else pushing	no
Time passing	no

5. The session evidence, applied. During the outage the reader had cached `origin/main` as `0a95cc8`. That was a true statement about the past and carried no information about the present.
6. Two pushes in that session failed with `send-pack: unexpected disconnect while reading sideband packet`. The write may or may not have landed; a disconnect while reading the response

tells you nothing about the request. The correct next step is not to guess but to re-query with `git ls-remote origin refs/heads/<branch>` and compare hashes.

7. This is why verifying by hash beats verifying by name. A branch name is a pointer that anyone can move. A commit hash is the content itself. In the same session, continuous integration was checked by run identifier against the exact head SHA rather than by trusting a coloured tick next to a branch name, and that is the stronger check for exactly this reason.
8. Practical checklist for “is my local view of the remote correct”:

```
git rev-parse origin/main          # what I remember
git ls-remote origin refs/heads/main # what is true now
git fetch origin && git rev-parse origin/main
git log --oneline origin/main..main # mine, not theirs
git log --oneline main..origin/main # theirs, not mine
```

9. And after a rebase, the correct push is `git push --force-with-lease`, not `--force`. The lease form refuses if the remote moved since your last fetch, which converts a silent overwrite of someone else’s work into an error you can read.

■ 38.12.6 WORDS – remember these

1. Abbreviated object id — the first few characters of a hash — a unique prefix within one repository, length chosen by `core.abbrev`.
2. Remote-tracking ref — your cached copy of a remote branch pointer — a ref under `refs/remotes/`, updated only by fetch and push.
3. `ls-remote` — ask the server what it holds right now — a network query that lists the remote’s refs without changing anything locally.
4. Rebase — replay commits onto a new base — creates new commit objects with new parents, therefore new object ids.
5. `--force-with-lease` — force push, but only if nothing moved — a compare-and- swap on the remote ref against your last known value.

38.13 Why this design is good, and what it costs

■ 38.13.1 PLAIN – in simple words

1. The benefits all fall out of one decision: name things by their content.
2. **Deduplication across all of history.** The same file content, in any commit, on any branch, from any author, is stored once.
3. **Integrity for free.** Every read can be checked against the name. Damage and tampering are both detectable without any extra machinery.
4. **Cheap branching.** A branch is 41 bytes, so having twenty of them costs less than one photograph.
5. **Distributed operation with no coordination.** Two people can create commits at the same time, offline, with no server involved, and the results will never clash, because names are computed from content and not assigned by an authority.
6. That last point is why the reader could keep committing all through a network outage. Nothing in `git commit` needs a server.
7. The costs are real too.
8. Large binary files are handled badly. Rewriting history is confusing. And the whole model takes genuine effort to learn, which is why this chapter exists.

■ 38.13.2 PLAIN – a picture in your head

1. Think of two libraries in two cities that never phone each other.
2. Each catalogues books by a code derived from the book's exact text.
3. When they finally exchange catalogues, matching codes mean identical books, with no argument and no committee.
4. Different codes mean different books, even if the titles match.
5. Neither library needed permission from the other to catalogue anything.

Where this comparison breaks:

6. Real libraries have to decide which copy is the official one. Git also has to decide, and it does not decide by content. A human decides, by choosing what main points at on the server.
7. Content addressing removes the need to coordinate naming. It does not remove the need to agree on what is authoritative.

■ 38.13.3 PLAIN – a worked example

1. Deduplication, measured. In the sandbox, four files with three identical contents produced two blobs, not four.
2. Integrity, measured. A single bit was flipped in one loose object file:

```
$ git fsck
error: inflate: data stream error (incorrect data check)
error: unable to unpack header of .git/objects/6f/e3e873...
error: 6fe3e873...: object corrupt or missing
missing blob 6fe3e87371433ed417646e3cb2354cfb9cff08d3
```

3. That one was caught by zlib's own checksum. So a more careful attack was tried: a perfectly well-formed object, holding different content, written under the old name.

```
$ git cat-file -p 6fe3e87
The EVIL three words.

$ git fsck
error: 8d71e45d309cb1328988a64591163f5c4f8f43f1: hash-path
mismatch, found at: .git/objects/6f/e3e873...
missing blob 6fe3e87371433ed417646e3cb2354cfb9cff08d3
```

4. Read that carefully, because it contains both the strength and an important limitation.
5. The strength: `git fsck` computed the content's true name, `8d71e45...`, found it stored under `6fe3e87...`, and reported the mismatch. The tamper is caught with certainty.
6. The limitation, and it is honest: `git cat-file -p` handed back the evil content without complaint. Git does not re-verify every loose object on every ordinary read. Verification happens on transfer, when configured, and when you ask with `fsck`.
7. Cheap branching, measured: 1,000 branches created in 2.28 seconds, using 41,000 bytes of content.
8. Distributed operation: two commits created independently, offline, will have different hashes unless they are byte-for-byte identical, in which case they are the same commit and it does not matter.

■ 38.13.4 PLAIN – what is really happening inside

1. Now the costs, honestly.
2. **Large binary files.** Git stores whole content per version. A 50 MB video edited ten times is ten blobs. Compressed formats do not delta, so the packfile saves almost nothing.

3. Worse, a clone fetches all of history by default. The 500 MB stays in every clone forever, even after the file is deleted, because the old commits still reference it.
4. The workarounds are all partial: `git lfs`, which stores a pointer file in git and the bytes elsewhere; shallow clones with `--depth`; partial clones with `--filter=blob:none`; and rewriting history with `git filter-repo`, which changes every hash from the rewrite point onwards.
5. **History rewriting is confusing** precisely because it is not rewriting. It is creating parallel objects and moving pointers. The old objects linger, other people still have the old hashes, and any branch built on the old ones must itself be rebuilt.
6. **The model takes effort.** Most tools let you learn the commands without the data model. Git punishes that. Almost every confusing git error makes immediate sense once you know that commits are immutable snapshots and branches are movable pointers, and almost none of them make sense otherwise.
7. There are smaller costs too. Git tracks content, not files, so it has no record of a rename; it infers renames when displaying a diff, and the inference can be wrong. It records only the executable bit, so full permissions and file ownership need a separate tool. And empty directories cannot be represented at all, because a tree with no entries in it is simply not referenced.

■ 38.13.5 TECHNICAL – the engineer’s version

1. Benefits and their mechanisms, stated precisely:

Benefit	Mechanism
Global deduplication	key = hash of content
Integrity verification	re-hash and compare
O(1) branch creation	write one 41-byte ref
Offline commit	ids need no authority

2. The distributed property is worth stating exactly. Git needs no central allocator of identifiers because the identifier space is a hash of content, and independent parties producing identical content produce identical ids by construction. This is the same property that lets content-addressed systems such as IPFS and container image registries work.
3. Costs, with the mitigations and their prices:

Cost	Mitigation	Price of the mitigation
Big binaries	Git LFS	extra server, extra tooling
Deep history size	<code>--depth</code> clone	limited history locally
Blob bloat	<code>--filter=blob:none</code>	fetches on demand
Bad past commits	<code>filter-repo</code>	every later hash changes

4. `core.bigFileThreshold`, default 512 MiB, controls when git stops attempting delta compression. Below it, git still tries, and for compressed media it still fails to save anything.
5. Rename detection is a display-time heuristic controlled by `diff.renameLimit` and a similarity threshold, by default 50 percent. It is not stored, it is recomputed, and on very large changesets git may give up entirely and report the rename as a delete plus an add.
6. Where experts disagree: whether git’s monorepo behaviour at very large scale is a flaw in the model or an implementation gap. Facebook chose Mercurial in 2013 partly over this, and Microsoft built a virtual filesystem layer for the Windows repository, later replaced by scalar and partial

clone in git itself. Both camps agree the model is sound; they disagree about how far it scales without special tooling.

7. Established fact: the object model has not changed since 2005, other than the addition of the optional SHA-256 format. Active work: the SHA-256 transition and the refable ref back-end. Marketing claim territory: any statement that one hosting provider makes git itself faster. Hosting affects the network path, not the object model.

■ 38.13.6 WORDS - remember these

1. Monorepo — one repository holding many projects — a scaling pattern that stresses git's whole-history clone model.
2. Git LFS — a way to keep big files out of git — Large File Storage, which commits a small pointer file and stores the bytes on a separate server.
3. Partial clone — a clone that skips file contents until needed — enabled with `--filter=blob:none`, fetching blobs on demand.
4. Shallow clone — a clone with truncated history — `--depth <n>`, which omits older commits and their objects.
5. Rename detection — noticing a file moved — a similarity heuristic computed at diff time, never stored in any object.

38.98 Common wrong ideas

1. Wrong: a commit stores a diff, the changes you made. Right: a commit names one tree, which is a complete snapshot of every file. The second version of `docs/intro.md` in this chapter is stored as all 38 bytes of the new file, not as “add one line”.
2. Wrong: a branch contains commits. Right: a branch is a 41-byte file holding one commit's hash. The commits you see are the ones reachable by walking parent links backwards from there, and they may be reachable from twenty other branches too.
3. Wrong: git compresses by storing diffs between versions of a file. Right: git compresses in two independent ways. zlib compresses each object separately, and packfiles store some objects as deltas against any similar object, chosen by a size and window heuristic, not by version order. Neither is part of the history model.
4. Wrong: deleting a branch deletes its commits. Right: it deletes one small file. The commits stay until nothing references them, their reflog entries expire, and garbage collection runs, which by default is at least 30 days.
5. Wrong: `git commit --amend` edits the last commit. Right: it builds a new commit object with a new hash and moves the branch to it. The original is still on disk and is listed in the reflog.
6. Wrong: detached HEAD is an error state. Right: it is a normal state meaning HEAD names a commit instead of a branch. Every CI checkout runs this way. The only risk is losing sight of commits you make there.
7. Wrong: `origin/main` shows what is on the server. Right: it shows what was on the server the last time you fetched or pushed. Only `git ls-remote` or a fresh `git fetch` asks the server.
8. Wrong: rebasing moves commits onto a new base. Right: it creates new commit objects with new parents, new trees and new committer timestamps, therefore new hashes. The originals remain until they are collected.
9. Wrong: because git uses SHA-1, and SHA-1 is broken, git repositories can be forged. Right: SHA-1 collision resistance is broken in general, but since Git 2.13 in May 2017 git uses a collision-detecting SHA-1 that refuses known attack patterns, and a useful attack must also survive review and transport. The risk is real but it is not “anyone can forge a commit”.

10. Wrong: a tag is just a branch that does not move. Right: a lightweight tag is close to that, but an annotated tag is a separate stored object with its own hash, tagger, date, message and optional signature, and `git describe` treats the two differently.

38.99 Chapter summary in 20 lines

1. Git names every stored thing by hashing the thing itself. That single decision explains almost everything else.
2. The name is SHA-1 of `<type> <size>\0<content>`, printed as 40 hexadecimal characters, and you can reproduce it with `printf` and `sha1sum`.
3. SHA-1's collision resistance was publicly broken by CWI Amsterdam and Google on 23 February 2017, at about $2^{63.1}$ evaluations.
4. Git responded in version 2.13, May 2017, by making the collision-detecting SHA-1 of Marc Stevens and Dan Shumow the default; a SHA-256 object format exists but is still not the default in 2026.
5. There are four object types. A blob is file content with no name. A tree is one directory listing with modes. A commit names one tree and zero or more parents. A tag object is an annotated pointer.
6. Tree entries store the mode in ASCII, the name, a zero byte, and 20 raw bytes of hash. Only five modes are legal, including 120000 for symlinks and 160000 for submodules.
7. Changing one file creates one new blob, one new tree per directory level up to the root, and one new commit. Everything else is pointed at again.
8. In the worked repository, editing `docs/intro.md` created 4 new objects and reused 4 existing ones.
9. A commit's hash covers its parent's hash, so one tip hash seals the entire history behind it. History is immutable because names are derived from content.
10. History is a directed acyclic graph, not a line. Merge commits have two or more parents, and `^1` and `^2` select between them.
11. A branch is a file of 40 hexadecimal characters and a newline. Creating one writes 41 bytes; 1,000 branches took 2.28 seconds and 41,000 bytes.
12. Refs may be packed into `.git/packed-refs`, in which case the individual files vanish. A loose file always wins over the packed entry.
13. `HEAD` normally holds `ref: refs/heads/main`. When it holds a raw hash you are detached, which is normal, not an error, and recoverable.
14. Other refs live under `refs/tags`, `refs/remotes` and `refs/notes`, plus pseudo-refs such as `ORIG_HEAD` and `FETCH_HEAD`.
15. The reflog records every ref movement locally, keeps reachable entries 90 days and unreachable ones 30, and turns a catastrophic `git reset --hard` into a one-line recovery with `git reset --hard main@{1}`.
16. Plumbing commands show the machinery: `cat-file`, `rev-parse`, `hash-object`, `ls-tree`, `rev-list`, `count-objects`, `verify-pack`. Porcelain commands are for people and their output may change.
17. Storage is loose objects first, then packfiles. In the worked example 21.42 MiB of object content became one packfile of 85,423 bytes, with 198 of 200 blobs stored as deltas up to depth 50.
18. Deltas are storage only. Git's model is still whole snapshots, and the object ids are identical either way.
19. The reader's `origin/main` of `0a95cc8` was a cached local memory, not a live fact; only `git ls-remote` or a fresh fetch asks the server.
20. The rebased branch had to get a new hash, because its parent, its tree and its committer timestamp all changed, and all three go into the hash.

The Index, Push, Fetch, Merge and Rebase

39.0 What this chapter gives you

1. You will be able to name the three places a file can live in git, working directory, index and object database, and say which command moves content between which pair.
2. You will be able to open `.git/index`, read its header by hand, and explain why it is a full snapshot with stat data and not a list of differences.
3. You will be able to prove that `git add` writes a real object to disk immediately, before any commit exists, and find that object yourself.
4. You will be able to describe the three steps `git commit` performs, write a tree, make a commit, move the branch ref, and do all three by hand with plumbing commands.
5. You will be able to choose correctly between `git restore`, `git reset` in its three modes, `git revert`, `git clean` and `git stash`, and say for each one whether it can lose work.
6. You will be able to describe exactly what crosses the network on a push: capability advertisement, have and want negotiation, one packfile, pkt-line framing, and three sideband channels.
7. You will be able to explain the reader's own failure, `send-pack: unexpected disconnect while reading sideband packet`, say which stage it happened at, and say why it tells you nothing about whether the write landed.
8. You will be able to state the rule for non-idempotent operations over unreliable transports, and apply it beyond git.
9. You will be able to explain merge base, three-way merge, fast-forward, conflict markers, and why a clean text merge can still produce broken code.
10. You will be able to explain why rebase changes a branch's SHA even though the changes are identical, and decide when rebasing is safe.

39.1 The three states and three places

■ 39.1.1 PLAIN – in simple words

1. A file that git is tracking exists in three different places at once.
2. The first place is the **working directory**. That is the ordinary folder on your disk, holding the files you open and edit.
3. The second place is the **index**, also called the staging area. It holds the exact version of every file that your next commit will contain.
4. The third place is the **object database**, inside `.git/objects`. That is the permanent store of every version git has ever been told to keep.
5. A fourth thing sits alongside these three, called **HEAD**. It is a pointer saying which commit you currently have checked out.

6. The three copies of a file are often identical. When they are, git says the working tree is clean and prints nothing interesting.
7. When they differ, git tells you which pair differs. That is the whole of `git status`.
8. "Changes to be committed" means index differs from HEAD.
9. "Changes not staged for commit" means working directory differs from index.
10. "Untracked files" means the file is in the working directory and in neither of the other two places.

■ 39.1.2 PLAIN – a picture in your head

1. Think of posting a parcel at a counter.
2. Your desk at home is the working directory. Things lie around, half sorted, in whatever state you left them.
3. The counter at the post office is the index. You put on the counter only the items you actually want to send.
4. You can put one item on the counter, go home, change your mind about a second item, and come back. The counter keeps what you already placed.
5. The sealed and stamped parcel is the commit. Once sealed, its contents are fixed forever.
6. The archive room behind the counter is the object database. Every parcel ever sealed is stored there.
7. The clerk's note saying which parcel you are currently working from is HEAD.

Where this comparison breaks:

8. At a real post office the item leaves your desk when you put it on the counter. In git, staging a file copies it. Your working file stays put.
9. A real counter holds items. The git index holds a complete list of every tracked file, not only the changed ones.
10. A real parcel is opened by the receiver. A git commit is never opened and changed. It is replaced by a new one.

■ 39.1.3 PLAIN – a worked example

1. Here is a real repository with one change of every kind in it, and its real `git status` output.

```
$ git status
On branch main
Changes to be committed:
  (use "git restore --staged <file>..." to unstage)
    new file:   TODO.md
    modified:   calc.py
    deleted:    notes.txt

Changes not staged for commit:
  (use "git add <file>..." to update what will be committed)
  (use "git restore <file>..." to discard changes)
    modified:   README.md

Untracked files:
  (use "git add <file>..." to include in what will be committed)
    out.log
```

2. Map every line onto the three places.
3. `new file: TODO.md`. Not in HEAD. Present in the index. So index differs from HEAD, and the difference is an addition.

- Nothing in this picture ever edits a stored object. Objects are written once and never modified.

■ 39.1.5 TECHNICAL – the engineer’s version

- The three states are formally: modified, staged, committed. The three storage locations are the working tree, the index, and the object store.
- The index is a single binary file at \$GIT_DIR/index, by default .git/index. Its location can be overridden by GIT_INDEX_FILE.
- git status is implemented as two diffs: diff-index --cached HEAD for the staged column and diff-files for the unstaged column, plus a directory walk for untracked paths.
- The machine-readable form is git status --porcelain=v2, stable across versions and intended for scripts. Here is the same repository state.

```
$ git status --porcelain=v2 --branch
# branch.oid 66b84b4f79e5cce670a6a2c0f739d5433403423e
# branch.head main
1 .M N... 100644 100644 100644 1af06666... 1af06666... README.md
1 A. N... 000000 100644 100644 00000000... 1333ed77... TODO.md
1 M. N... 100644 100644 100644 4693ad3c... 6cddd28b... calc.py
1 D. N... 100644 000000 000000 fb188b9e... 00000000... notes.txt
? out.log
```

- Columns after the XY code are: submodule state, mode in HEAD, mode in index, mode in worktree, object name in HEAD, object name in index, path. Hashes are abbreviated here to fit the page; the real output prints all 40 digits.
- Note TODO.md has HEAD mode 000000 and HEAD hash all zeros. That is how git encodes “not present in HEAD”.

Status word	Which two places differ	Direction
to be committed	index vs HEAD	staged
not staged	worktree vs index	unstaged
untracked	in worktree only	unknown to git
ignored	worktree, matched gitignore	suppressed

- Commands that observe this: git status, git diff (worktree vs index), git diff --cached (index vs HEAD), git diff HEAD (worktree vs HEAD), git ls-files -s, git diff-index, git diff-files.

■ 39.1.6 WORDS – remember these

- Working directory — the files you edit — the checked-out worktree on the filesystem, outside .git.
- Index — the counter where you put things to send — the binary staging file .git/index holding the next commit’s full snapshot.
- Object database — the archive of everything kept — .git/objects, holding loose and packed blob, tree, commit and tag objects.
- HEAD — the note saying where you are — a symbolic ref, usually pointing at a branch ref under refs/heads/.
- Staged — placed on the counter — present in the index with content differing from HEAD.
- Untracked — git has never been told about it — a path in the worktree with no index entry and no HEAD entry.

39.2 What the index actually is

■ 39.2.1 PLAIN – in simple words

1. The index is not an idea. It is a real file on your disk, and you can look at it.
2. It is at `.git/index`. It is binary, so opening it in a text editor shows rubbish, but its structure is documented and simple.
3. It holds one entry per tracked file. Not one entry per changed file. Every single tracked file, always.
4. Each entry stores the file's path, the name of its stored content, its permission bits, and a copy of what the operating system said about the file the last time git looked.
5. That last part is the clever bit. Git remembers the file's size, its last modified time, and its position on disk.
6. Next time you run `git status`, git asks the operating system for those same facts again. If they match, git assumes the file did not change and does not read it at all.
7. That is why `git status` is fast even in a project with tens of thousands of files. Most files are never opened.
8. The index stores whole snapshots, not differences. There is no "diff" anywhere in it.

■ 39.2.2 PLAIN – a picture in your head

1. Think of a hotel cloakroom with a big register book.
2. Every guest's coat has a ticket. The register lists, for each coat, the ticket number, the peg it hangs on, its colour, and its weight.
3. When you come back, the clerk does not take every coat down and inspect it.
4. The clerk glances at the register and at the pegs. If the weights and colours still match, nothing has changed and the clerk says so instantly.
5. Only if something looks different does the clerk take a coat down and check it properly.
6. The register is the index. The weights and colours are the stat data. The coats themselves are the stored objects.

Where this comparison breaks:

7. A clerk could be fooled by two coats of identical weight and colour. Git can be fooled too, and this is real: if a file changes within the same second and keeps the same size, git can miss it. Git has a "racy timestamp" rule to handle that case, described later in this section.
8. A cloakroom register lists only coats currently held. The git index lists every tracked file, even ones you have not touched in years.

■ 39.2.3 PLAIN – a worked example

1. Here is a small repository with five tracked files. First its size, then its contents.

```
$ ls -l .git/index
-rw-r--r-- 1 root root 479 .git/index

$ git ls-files -s
100644 1af06666...9965 0    README.md
100644 1333ed77...ee69 0    TODO.md
100644 6cddd28b...7159 0    calc.py
100644 b04e7afa...7b19 0    docs/guide.md
100644 11b15b1a...a0d5 0    src/main.py
```

2. The columns are: file mode, object name of the content, stage number, path. Stage 0 means "not conflicted". Hashes shortened here to fit the page.

3. Note docs/guide.md and src/main.py. The index has no directories. It has flat paths with slashes in them.
4. Now the stat cache. The --debug flag prints it.

```
$ git ls-files --debug | head -7
README.md
  ctime: 1786606646:156685960
  mtime: 1786606646:156685960
  dev: 65024    ino: 1049252
  uid: 0      gid: 0
  size: 13    flags: 0
TODO.md
```

5. mtime is when the content last changed. ctime is when the file's metadata last changed. ino is the inode number, the file's identity on the filesystem. size is 13 bytes.
6. Every one of those numbers came from a single stat call to the operating system, which is far cheaper than reading and hashing the file.
7. Here is the header of that binary file, byte by byte.

```
$ head -c 16 .git/index | od -A d -t x1z
00000000 44 49 52 43 00 00 00 02 00 00 00 05 >DIRC.....<
```

8. 44 49 52 43 is the ASCII letters DIRC. Then 00 00 00 02 is version 2. Then 00 00 00 05 is five entries.

■ 39.2.4 PLAIN – what is really happening inside

1. The file has three parts: a 12-byte header, then the entries, then optional extra sections, then a checksum at the end.
2. Each entry begins with 40 bytes of numbers copied from the operating system's stat call: two timestamps with nanoseconds, device, inode, mode, user, group and size.
3. Then 20 bytes holding the content's SHA-1 name. Then 2 bytes of flags, including the path length and the merge stage.
4. Then the path itself, followed by at least one zero byte, padded so the whole entry length is a multiple of eight.
5. The entries are sorted by path, as raw bytes. That sorting is what lets git find an entry by binary search instead of scanning.
6. Let us add it up for the five-file repository above. Fixed part is 62 bytes. README.md is 9 characters, so 62 plus 9 is 71, padded up to 72.
7. Doing that for all five paths gives 72, 72, 72, 80 and 80, which is 376.
8. Add the 12-byte header and the 20-byte trailing checksum and we have 408. The file is 479. The missing 71 bytes are one extension section.
9. That section is the cached tree, signature TREE, 63 bytes of data plus its own 8-byte header. It remembers tree objects already computed, so a commit does not have to rebuild trees for unchanged directories.
10. When git status runs, for each entry git calls lstat on the path. If size, mtime, ctime and inode all match, git marks the file unchanged without reading a single byte of it.

■ 39.2.5 TECHNICAL – the engineer’s version

1. The format is specified in the git documentation page `git format-index`. The signature is the four bytes DIRC, standing for “directory cache”.
2. Supported versions are 2, 3 and 4. Version 3 adds a second flags word for skip-worktree and intent-to-add. Version 4 prefix-compresses path names.
3. All multi-byte numbers are big-endian (“network byte order”). The trailing checksum is a hash over everything before it.

Field group	Bytes	Contents
header	12	DIRC, version, entry count
entry, fixed part	62	stat data, OID, flags
entry, variable	var	path, NUL, pad to 8
trailer	20	SHA-1 of the whole file

4. Here is that exact five-entry index parsed by a short script, showing the real numbers.

```
total size: 479
signature: DIRC version: 2 entries: 5
  README.md    mode=100644 size= 13 stage=0 bytes=72
  TODO.md      mode=100644 size=  5 stage=0 bytes=72
  calc.py       mode=100644 size= 65 stage=0 bytes=72
  docs/guide.md mode=100644 size= 12 stage=0 bytes=80
  src/main.py   mode=100644 size= 15 stage=0 bytes=80
offset after entries: 388
extension: TREE size: 63
```

5. Only two file modes are legal for regular files, 100644 and 100755. 120000 is a symbolic link and 160000 is a gitlink (a submodule).
6. The stat cache is a cache, so it can be wrong. The known hazard is the “racy index” problem: a file written in the same second as the index itself may have a matching mtime yet different content. Git handles this by treating any entry whose mtime is not strictly older than the index’s own mtime as suspect, and re-reading it.
7. Real measurements, taken on a Linux sandbox with git 2.43.0, on a repository with 10,000 tracked files totalling 2,850,000 bytes:

Situation	git status time
stat cache valid	20 to 25 ms
every mtime invalidated	89 to 103 ms
hashing all 10,000 files	77 ms

8. The index for those 10,000 entries was 801,570 bytes, about 80 bytes per entry. The honest version: this repository is tiny, so the gap is only about four times. On a repository with large files the gap is far larger, because the cost of re-reading grows with total bytes while the stat calls do not.
9. Since git 2.36, released 18 April 2022, git ships a built-in filesystem monitor daemon, enabled with `git config core.fsmonitor true`. It replaces the per-file `lstat` scan with change notifications from the operating system, and matters most on macOS and Windows.
10. Sparse-checkout with a sparse index, `extensions.sparseIndex`, allows directory entries in the index with mode `040000`, so that a huge repository does not need an index entry per file.

■ 39.2.6 WORDS – remember these

1. Index entry — one line in the register — a 62-byte fixed record plus a padded path, holding stat data, OID, mode and flags.
2. Stat data — what the filesystem says about a file — `st_mtime`, `st_ctime`, `st_dev`, `st_ino`, `st_size` and mode from `lstat(2)`.
3. Stat cache — remembering that so you need not re-read — the mechanism that makes `git status` skip unchanged files.
4. DIRC — the four letters at the start — the index file signature, short for “directory cache”, present since git’s first commit in April 2005.
5. Stage number — which side of a conflict — 0 for normal, 1 for merge base, 2 for ours, 3 for theirs.
6. Cached tree — the remembered directory hashes — the TREE index extension that lets `git write-tree` skip unchanged directories.

39.3 What `git add` really does

■ 39.3.1 PLAIN – in simple words

1. Most people believe `git add` marks a file for later. It does much more than that, and it does it at once.
2. When you run `git add`, git reads the file, compresses its content, works out its name from the content, and writes that content into `.git/objects` straight away.
3. Then it writes an entry in the index recording that name against the path.
4. So the content is already safely stored before you type `git commit`. The commit does not copy your files; the copy has already happened.
5. This is why staging a file and then editing it again gives you three different versions at once: the committed one, the staged one, and the one on disk.
6. It also means you can stage part of a file. Git can build a version that exists nowhere on disk, store it, and put that in the index.
7. That partial staging is done with `git add -p`, which walks you through each chunk of change and asks yes or no.

■ 39.3.2 PLAIN – a picture in your head

1. Imagine a photocopier next to your desk that also files things.
2. When you say “add this page”, the machine does not put a sticky note on your page. It photocopies it immediately and files the copy in a cabinet.
3. It then writes in a ledger: “for the page called `report.txt`, use copy number `eb2fc3ca`”.
4. You can now scribble all over your original. The copy in the cabinet is untouched.
5. If you later say “add this page” again, a new copy is made and the ledger line is updated to point at the new copy. The old copy stays in the cabinet, unreferenced.

Where this comparison breaks:

6. A photocopier makes a new copy every time. Git checks first: if a copy with that exact content already exists, it stores nothing and reuses it.
7. The ledger in this picture holds one line per page you added. The real index holds one line per tracked file, added or not.

■ 39.3.3 PLAIN – a worked example

1. Start a completely empty repository and prove that `git add` writes to `.git/objects` before any commit exists.

```
$ git init -q .
$ find .git/objects -type f
(nothing)

$ printf 'hello index\n' > greeting.txt
$ git hash-object greeting.txt
eb2fc3ca2f129a710df1a6c0fd5ebfd088a10bfd

$ git add greeting.txt

$ find .git/objects -type f
.git/objects/eb/2fc3ca2f129a710df1a6c0fd5ebfd088a10bfd

$ git log --oneline
fatal: your current branch 'main' does not have any commits yet

$ git ls-files -s
100644 eb2fc3ca2f...bfd 0    greeting.txt
```

2. Read that carefully. There is no commit. There is no branch tip. Yet the content is already a permanent object in the database.
3. `git hash-object` printed the name before the add, without writing anything. It is the same name, because the name is computed from the content.
4. Now the three-version demonstration. Take a file with two separate changes and stage only the first.

```
$ git add -p
@@ -1,6 +1,6 @@
    import os

    -PORT = 8080
    +PORT = 9090
    DEBUG = False

(1/2) Stage this hunk [y,n,q,a,d,j,J,g,/,e,?]? y
@@ -8,3 +8,4 @@ def start():
    def stop():
        print("stopping")
+    print("goodbye")
(2/2) Stage this hunk [y,n,q,a,d,K,g,/,e,?]? n
```

5. Now ask git for the name of `server.py` in all three places.

```
committed : 6802ebd3762732a47322b13ed2d9510a9145a23f
index      : 345790221885e55f73d7e6c21d54fffc51998330
working dir: 154a7a3ee775a1746b842017a179c42cee649a30
```

6. Three different names, so three different contents. The middle one exists nowhere on your disk as a file. It is a real object in `.git/objects`.

■ 39.3.4 PLAIN – what is really happening inside

1. `git add path` performs these steps, in order, for each path.
2. Call `lstat` on the path to get size, mode and timestamps.

3. Read the file's bytes. Apply any content filters that are configured, for example line-ending conversion or a clean filter.
4. Build the object header: the word `blob`, a space, the byte count in decimal, and one zero byte. Put the content after it.
5. Compute SHA-1 over header plus content. That 40-character result is the object name.
6. Check whether an object with that name already exists. If it does, do nothing more; the content is already stored.
7. If it does not, compress the header-plus-content with `zlib` and write it to `.git/objects/ab/cdef...`, where `ab` is the first two characters.
8. Write or update the index entry: path, the new object name, the mode, and the freshly captured stat data.
9. Write the whole index back out, atomically, by writing `.git/index.lock` and renaming it over `.git/index`.
10. For `git add -p`, `git` first computes the diff, splits it into hunks, and for each accepted hunk applies it to a copy of the staged version. The result of applying the accepted subset is what gets hashed and stored.

■ 39.3.5 TECHNICAL - the engineer's version

1. The plumbing equivalents are `git update-index --add --cacheinfo` and `git hash-object -w`. The porcelain `git add` is a wrapper over both.
2. `git hash-object` without `-w` computes and prints the OID without writing. With `-w` it writes the loose object.
3. Loose objects are `zlib`-compressed with the default compression level set by `core.compression`, default `-1` meaning `zlib`'s own default of 6.
4. Useful `git add` variants:

Command	Effect
<code>git add -p</code>	interactive per-hunk staging
<code>git add -u</code>	stage changes to tracked files only
<code>git add -A</code>	stage everything, including deletions
<code>git add -N</code>	record intent to add, no content
<code>git add -e</code>	edit the diff by hand before staging

5. `git add -N` sets the intent-to-add flag, which requires index version 3. It makes an untracked file appear in `git diff` output without staging content.
6. In `git add -p`, the keys are: `y` stage, `n` skip, `q` quit, `a` stage this and all remaining in the file, `d` skip this and all remaining in the file, `s` split the hunk, `e` edit the hunk, `j/k` move without deciding.
7. `git add --interactive` was written by Junio C Hamano and merged on 18 December 2006; it shipped in `git 1.5.0` on 14 February 2007.
8. Filters that change content on the way in are set by `gitattributes`: `text` and `eol` for line endings, and `filter.<name>.clean` for custom transforms such as Git LFS. The honest version: with a clean filter configured, the blob stored is not the bytes on your disk.
9. To see what would be staged without staging it, use `git diff` for unstaged changes and `git add --dry-run -A`.

■ 39.3.6 WORDS – remember these

1. Blob — the stored content of one file — a git object of type blob, containing raw bytes with no filename.
2. Hunks — one chunk of change in a diff — a @@ section with its context lines, the unit `git add -p` operates on.
3. Loose object — one file per object — an object stored individually under `.git/objects/xx/`, as opposed to inside a packfile.
4. Intent to add — “this file is coming” — the index flag set by `git add -N`, registering a path with no content.
5. Clean filter — a transform applied on the way in — `filter.<name>.clean` from `gitattributes`, run before hashing.
6. Atomic index write — no half-written index — the lock-file-and-rename sequence git uses for `.git/index`.

39.4 What `git commit` really does

■ 39.4.1 PLAIN – in simple words

1. `git commit` does exactly three things, in this order.
2. First, it turns the index into tree objects. One tree for the top folder, and one for each subfolder, each listing names, modes and object names.
3. Second, it creates one commit object. That object holds the name of the top tree, the name of the commit you were on, who you are, when it is, and your message.
4. Third, it changes one small text file, the branch file, so it holds the new commit’s name.
5. That is all. No files are copied. The blobs were already written when you ran `git add`.
6. Because the branch file is the last thing to change, the commit is either fully there or not there at all.
7. If a step fails halfway, the objects written so far are simply unreferenced and will be cleaned up later. Nothing is corrupted.

■ 39.4.2 PLAIN – a picture in your head

1. Think of publishing an edition of a newspaper.
2. All the articles are already typeset and stored, one file each. That happened when you staged them.
3. Making the edition means writing a contents page listing which article file goes on which page. That is the tree.
4. Then you write a cover sheet: edition number, date, editor’s name, a sentence about what is in it, and the number of the previous edition. That is the commit.
5. Then you update the single sign on the wall that says “current edition”. That is the branch file.

Where this comparison breaks:

6. A newspaper’s contents page is written fresh each time. Git reuses tree objects for any folder whose contents did not change at all.
7. A newspaper edition can be recalled and reprinted. A commit object can never be edited. `git commit --amend` makes a completely new one.

■ 39.4.3 PLAIN – a worked example

1. Here is a commit done by hand, one plumbing command per step, so you can see the three stages separately.

```
$ git add greeting.txt

$ git write-tree
14a7508225642503557d7347c657e485225656a1

$ git commit-tree 14a75082... -p HEAD -m "second line"
d5d96f0f76b0571dd21802be5196808779e4b9ba

$ git update-ref refs/heads/main d5d96f0f...

$ git log --oneline
d5d96f0 second line
8c96e11 add greeting
```

2. Step one made a tree from the index. Step two made a commit pointing at that tree and at the old HEAD. Step three moved the branch.
3. `git commit` is those three commands with a message editor bolted on.
4. Now watch the three objects appear for a first commit in an empty repository. Before the commit there is one object, the blob.

```
before commit:
  eb2fc3ca... (blob)

after commit:
  856b2713... (tree)
  8c96e114... (commit)
  eb2fc3ca... (blob)
```

5. The commit object itself is plain text. Here it is.

```
$ git cat-file -p HEAD
tree 856b271361271d5c57e0ac557a10cc6961ea6806
author Reader <reader@example.com> 1772429400 +0530
committer Reader <reader@example.com> 1772429400 +0530

add greeting
```

6. And the branch file went from not existing at all to holding 40 characters plus a newline.

■ 39.4.4 PLAIN – what is really happening inside

1. Step one, `write-tree`, walks the index in sorted path order.
2. Whenever the path prefix changes, it knows a directory ended, so it builds the tree object for that directory and adds it as an entry in its parent.
3. If the cached tree extension says a directory is unchanged, git skips all of that and reuses the remembered tree name.
4. Step two builds the commit's bytes: the word `tree` and the tree name, then one parent line per parent, then author, then committer, then a blank line, then the message.
5. That text is hashed the same way a blob is, with a header saying `commit` and the byte count, and stored.
6. Step three writes the new commit's name into `.git/refs/heads/<branch>` and appends a line to `.git/logs/HEAD` and `.git/logs/refs/heads/<branch>`. Those log files are the reflog.

7. If HEAD is detached, meaning it holds a commit name directly rather than a branch name, step three writes to `.git/HEAD` instead.
8. Why does the index exist at all? Because it lets you decide what goes in a commit separately from what is on your disk.
9. Without it, either every commit contains everything you have changed, or the tool must ask you a list of files every single time.
10. The honest counter-argument: other systems manage without it. Mercurial has no staging area by default and uses `hg commit --interactive` for the same job. Subversion and Perforce have change lists instead. Fossil and Darcs ask about patches at commit time. So the index is a design choice, not a necessity, and reasonable people call it an unnecessary extra concept.

■ 39.4.5 TECHNICAL – the engineer’s version

1. The three plumbing commands are `git write-tree`, `git commit-tree` and `git update-ref`. Every porcelain commit path goes through equivalents.
2. `git commit --amend` does not modify the current commit. It builds a new commit with the same parents and moves the branch. The old commit remains reachable only through the reflog.
3. The commit object’s canonical byte layout, in order: `tree <oid>`, zero or more parent `<oid>`, author `<name> <email> <unix-ts> <tz>`, committer ..., optional headers such as `gpgsig`, a blank line, message.
4. Author and committer differ whenever a commit is replayed. `Rebase`, `cherry pick` and `git am` all keep the author and rewrite the committer.
5. Ref updates go through the ref transaction machinery. With the files backend this is a `.lock` file plus rename per ref. An alternative `reftable` backend was integrated in git 2.45, released April 2024, and is selected at creation time with `git init --ref-format=reftable`.
6. Commit-related knobs worth knowing:

Setting or flag	Effect
<code>commit.gpgSign</code>	sign every commit
<code>git commit -a</code>	stage tracked modifications first
<code>git commit --amend</code>	replace the tip commit
<code>git commit --fixup X</code>	message that autosquash recognises
<code>core.hooksPath</code>	where pre-commit hooks live

7. Hooks that run: `pre-commit`, `prepare-commit-msg`, `commit-msg`, `post-commit`. A non-zero exit from the first three aborts the commit.
8. Historical note: the index was in git’s very first commit. On 7 April 2005 Linus Torvalds committed `cache.h`, containing `#define CACHE_SIGNATURE 0x44495243 /* "DIRC" */`, and the object store then lived in `.dircache/objects`. The tools were called `update-cache`, `write-tree` and `commit-tree`. The names changed; the design did not.

■ 39.4.6 WORDS – remember these

1. Tree object — a folder listing — a git object mapping names to modes and object IDs, one per directory.
2. Commit object — the cover sheet — a git object naming one tree, zero or more parents, author, committer and message.
3. Ref — the sign on the wall — a file under `.git/refs` (or a line in `packed-refs`) holding an object name.

4. Amend — replace the top edition — create a new commit with the old commit's parents and move the branch to it.
5. Committer versus author — who applied it versus who wrote it — two separate identity and timestamp fields in every commit.
6. Reflog — the local diary of ref movements — append-only files under `.git/logs`, local only, never pushed.

39.5 Undoing things, laid out clearly

■ 39.5.1 PLAIN - in simple words

1. Git has many undo commands because there are many different things to undo.
2. The trick is to ask: which of the three places do I want to change?
3. `git restore <file>` changes the working directory only. It copies the staged version over your file, throwing your edits away.
4. `git restore --staged <file>` changes the index only. It copies the HEAD version into the index, so the file is no longer staged.
5. `git reset --soft <commit>` moves HEAD and the branch only. Index and working directory are untouched.
6. `git reset --mixed <commit>`, which is the default, moves HEAD and the branch and resets the index. Working directory untouched.
7. `git reset --hard <commit>` moves all three. Your uncommitted work is gone.
8. `git revert <commit>` changes nothing that already exists. It makes a new commit that undoes an old one. This is the safe undo for shared history.
9. `git clean` deletes untracked files. Nothing about them was ever stored, so they cannot be recovered.
10. `git stash` puts your uncommitted changes aside as hidden commits and gives you a clean tree.

■ 39.5.2 PLAIN - a picture in your head

1. Think of a kitchen with a chopping board, a tray, and a fridge.
2. The chopping board is the working directory. The tray is the index. The fridge is the object database.
3. `git restore` wipes the board and re-copies from the tray.
4. `git restore --staged` empties the tray and refills it from the fridge.
5. `git reset --soft` only moves the label saying which meal you are making. Board and tray keep everything.
6. `git reset --mixed` moves the label and clears the tray.
7. `git reset --hard` moves the label, clears the tray, and scrapes the board into the bin.
8. `git revert` does not touch anything. It cooks a new dish that cancels out an old one, and puts that in the fridge too.

Where this comparison breaks:

9. Scraping the board into a bin is final. `git reset --hard` losing a commit is not final, because the reflog remembers where the branch used to point for 90 days. Losing uncommitted edits, though, really is final.

■ 39.5.3 PLAIN – a worked example

1. Three commits, c1, c2, c3, where the file goes A, then A B, then A B C. Now watch each reset mode from the same starting point.

```

BASELINE (at c3)
  HEAD    = c3    index = "A B C"    workdir = "A B C"    status: clean

git reset --soft HEAD~1
  HEAD    = c2    index = "A B C"    workdir = "A B C"
  status: M f.txt      (staged modification)

git reset --mixed HEAD~1
  HEAD    = c2    index = "A B"      workdir = "A B C"
  status: M f.txt      (unstaged modification)

git reset --hard HEAD~1
  HEAD    = c2    index = "A B"      workdir = "A B"
  status: clean        (the "C" line is gone)

```

2. Read the three status lines. Soft leaves the change staged. Mixed leaves it unstaged. Hard destroys it.
3. Now the other four, in one real session.

```

$ git status --short
A  staged.txt
M  work.txt
?? build.tmp

$ git restore --staged staged.txt
M  work.txt
?? build.tmp
?? staged.txt

$ git restore work.txt
?? build.tmp
?? staged.txt

$ git clean -n
Would remove build.tmp
Would remove staged.txt

$ git clean -f
Removing build.tmp
Removing staged.txt

```

4. Note the -n dry run. Always run that first. `git clean -f` deletes files that git has never stored, so there is nothing to recover from.

■ 39.5.4 PLAIN – what is really happening inside

1. Here is the table. Read the middle column as “which of the three places does this touch”.

Command	What it changes	Can lose work
<code>git restore <f></code>	working dir only	yes, edits
<code>git restore --staged</code>	index only	no
<code>git reset --soft</code>	HEAD and branch	no

Command	What it changes	Can lose work
<code>git reset --mixed</code>	HEAD, branch, index	staged only
<code>git reset --hard</code>	HEAD, branch, index, wd	yes, badly
<code>git reset <f></code>	index entry for one path	no
<code>git revert <c></code>	adds a new commit	no
<code>git clean -f</code>	deletes untracked files	yes, forever
<code>git clean -fdx</code>	deletes ignored files too	yes, forever
<code>git stash</code>	wd and index into a stash	rarely
<code>git checkout <c></code>	HEAD only (detaches)	no

- Only two rows in that table can destroy something that git has never stored: `git reset --hard` and `git clean`. Everything else is recoverable.
- `git stash` is not magic. It makes real commits. One commit records the index, another records the working tree, and a ref called `refs/stash` points at the second one.

```
$ git stash list
stash@{0}: On main: half finished idea

$ git log --oneline --graph refs/stash
*   69aa036 On main: half finished idea
|\
| * 77c7641 index on main: b068de2 three hours of important work
|/
* b068de2 three hours of important work
```

- Now the recovery guide. Suppose you ran `git reset --hard HEAD~1` and threw away a commit.

```
$ git log --oneline
f74729c base                                <- the good commit is gone

$ git reflog
f74729c HEAD@{0}: reset: moving to HEAD~1
b068de2 HEAD@{1}: commit: three hours of important work
f74729c HEAD@{2}: commit (initial): base

$ git reset --hard 'HEAD@{1}'

$ git log --oneline
b068de2 three hours of important work
f74729c base
```

- The reflog is a local diary of every value HEAD and each branch has held. It is written on every commit, checkout, reset, merge, rebase and pull.
- Because the commit object was never deleted, only unreferenced, pointing a ref at it again brings it straight back.

■ 39.5.5 TECHNICAL - the engineer's version

- `git reset` has a fourth and fifth mode. `--merge` resets the index and updates worktree files that differ between HEAD and target while keeping unstaged changes. `--keep` is similar but aborts on conflict.
- `git reset <paths>` never moves HEAD. Path form and commit form are different operations sharing a name, which is a known wart. `git restore` and `git switch`, introduced in git 2.23 on

16 August 2019, exist to split those roles. They were marked experimental at introduction and remain so in the documentation as of git 2.43.

3. Reflog retention defaults: `gc.reflogExpire` is 90 days for reachable entries, `gc.reflogExpireUnreachable` is 30 days. `gc.pruneExpire` is 2 weeks, so unreachable objects survive at least that long before deletion.
4. Recovery ladder, in the order to try:

Situation	Command
branch moved wrongly	<code>git reflog then reset</code>
commit lost, not in reflog	<code>git fsck --lost-found</code>
dropped a stash	<code>git fsck --unreachable</code>
bad rebase, want the old branch	<code>git reset --hard ORIG_HEAD</code>
bad merge, not committed	<code>git merge --abort</code>
bad rebase, mid-flight	<code>git rebase --abort</code>

5. `ORIG_HEAD` is written by merge, rebase, reset and pull before they move HEAD. `git reset --hard ORIG_HEAD` is the fastest undo for those four.
6. Since git 2.36 (April 2022), `git branch --recurse-submodules` and related plumbing exist, but stash and submodules still interact badly; `git stash` does not stash submodule changes by default.
7. `git stash push --staged`, added in git 2.35 (24 January 2022), stashes only what is in the index. `git stash -u` includes untracked files; `git stash -a` includes ignored files.
8. `git stash` was added to git on 30 June 2007 and shipped in git 1.5.3 on 2 September 2007.

■ 39.5.6 WORDS – remember these

1. Soft reset — move the label only — move HEAD and branch, leave index and worktree.
2. Mixed reset — move the label and clear the tray — move HEAD and branch and reset the index; the default mode.
3. Hard reset — move everything and discard — overwrite index and worktree from the target commit.
4. Revert — undo by adding, not removing — create a new commit whose diff is the inverse of an existing commit.
5. `ORIG_HEAD` — where I was before that big operation — a ref written by merge, rebase, reset and pull.
6. Reflog — the local diary — per-ref append-only history of previous values, kept 90 days by default and never transferred over the network.

39.6 What actually crosses the wire on a push

■ 39.6.1 PLAIN – in simple words

1. When you push, git does not send files. It sends objects, and it sends only the ones the other side does not already have.
2. The first thing that happens is a conversation. Your git starts a program on the server called `receive-pack`.
3. The server speaks first. It lists every branch and tag it has, with the object name each one points at, and a list of features it supports.
4. Your git compares that list with what you are pushing. It works out which objects the server is missing.

5. Your git bundles those objects into one compressed file called a packfile, and sends it, together with a line saying “move branch main from this old name to this new name”.
6. The server reads the packfile, checks that nothing is missing or corrupt, then updates the branch.
7. Then the server sends a short report: whether the pack unpacked, and whether each branch update succeeded.
8. All of that is one connection and, for the object transfer, one round trip. Twenty commits cost the same number of round trips as one.

■ 39.6.2 PLAIN - a picture in your head

1. Think of sending documents to a records office by courier.
2. You phone first. The clerk reads out an index of everything already filed, and says which formats they accept.
3. You compare against your own shelf and put only the missing documents into one box. You do not send twenty separate envelopes.
4. On the box you write one instruction slip: “file these, then change the pointer for folder main from document 1c8a3b1 to document 9978003”.
5. The courier carries the box. The clerk unpacks it, checks nothing is missing, files everything, updates the pointer, and phones you back.
6. That phone call back is the report. It is a separate thing from the box.

Where this comparison breaks:

7. A courier can tell you the box arrived. Over a network there is no such guarantee. If the return phone call is cut off, you have no idea whether the clerk filed the documents. That is the whole of section 39.7.

■ 39.6.3 PLAIN - a worked example

1. This is a real push, traced with `GIT_TRACE_PACKET=1`. Lines are trimmed to fit the page; `>` means sent and `<` means received.

```

receive-pack> 9978003f... refs/heads/main\0report-status
                report-status-v2 delete-refs side-band-64k quiet
                atomic ofs-delta object-format=sha1 agent=git/2.43.0
receive-pack> 0000
push>          9978003f... e60afb23... refs/heads/main\0
                report-status-v2 side-band-64k quiet
                object-format=sha1 agent=git/2.43.0
push>          0000
                [ packfile bytes travel here ]
receive-pack> unpack ok
receive-pack> ok refs/heads/main
receive-pack> 0000
sideband<      \1000eunpack ok0017ok refs/heads/main0000

```

2. Line one is the advertisement. The server says what it has and what it can do. `0000` ends that list.
3. Line five is the command. Old name, new name, ref name, then the capabilities the client accepts.
4. Then the packfile is streamed.
5. Then the report: `unpack ok` and `ok refs/heads/main`.
6. Now look at the last line very carefully, because it shows the raw framing.
7. `\1` is the sideband channel number: channel 1, meaning real data.
8. `000e` is hexadecimal 14: this packet is 14 bytes long including its own 4-byte length. So 10 bytes of payload: `unpack ok` plus a newline.

9. 0017 is hexadecimal 23: 19 bytes of payload, ok refs/heads/main plus a newline.
10. 0000 is the flush packet, meaning “end of this stream”.
11. Now the round-trip claim, measured. Twenty commits, each changing one file.

```
$ git rev-list --count origin/main..main
20
$ git rev-list --objects origin/main..main | wc -l
60
$ git push --progress origin main
Enumerating objects: 62, done.
Counting objects: 100% (62/62), done.
Delta compression using up to 2 threads
Compressing objects: 100% (20/20), done.
Writing objects: 100% (60/60), 3.95 KiB | 674.00 KiB/s, done.
Total 60 (delta 0), reused 0 (delta 0), pack-reused 0
To file:///tmp/gw/srv.git
1c8a3b1..9978003 main -> main
```

12. Twenty commits became sixty objects, twenty commits plus twenty trees plus twenty blobs, in one packfile of 3.95 KiB, in one exchange.

■ 39.6.4 PLAIN – what is really happening inside

1. Everything on the wire is wrapped in a frame called a **pkt-line**.
2. A pkt-line is four hexadecimal characters giving the total length, then that many bytes minus four of payload.
3. So 0009hello is a complete packet: length 9, payload hello which is 5 bytes, plus the 4 length characters.
4. Three lengths are special. 0000 means flush, end of a section. 0001 is a delimiter used in the newer protocol. 0002 marks the end of a response.
5. On top of pkt-line sits the **sideband**. When both ends agree to it, the first byte of each packet’s payload is a channel number.
6. Channel 1 is real data, the packfile or the report. Channel 2 is progress text, which your git prints with the prefix remote:. Channel 3 is a fatal error, after which the stream stops.
7. This is why, on a real clone, you see lines beginning with remote:. Those came over channel 2.

```
$ git clone https://github.com/octocat/Hello-World.git
Cloning into 'Hello-World'...
remote: Enumerating objects: 13, done.
remote: Total 13 (delta 0), reused 0, pack-reused 13 (from 1)
Receiving objects: 100% (13/13), done.
```

8. remote: Enumerating objects is the server talking on channel 2. Receiving objects is your own git counting what it reads from channel 1.
9. For fetching, the two sides negotiate. The client says want <oid> for what it needs and have <oid> for tips it already holds. The server replies ACK for the ones it recognises.
10. That is how the server learns the common ancestor without either side sending the whole history.

■ 39.6.5 TECHNICAL – the engineer’s version

1. Transports: SSH runs git-upload-pack or git-receive-pack as a remote command on port 22. Smart HTTP uses two requests on port 443. The git:// daemon protocol uses port 9418 and has no authentication or encryption.
2. Real smart-HTTP trace against github.com, taken with GIT_TRACE_CURL=1, trimmed to the git-relevant headers.

```
=> GET /octocat/Hello-World.git/info/refs?service=git-upload-pack
=> User-Agent: git/2.43.0
=> Git-Protocol: version=2
<= HTTP/1.1 200 OK
<= Content-Type: application/x-git-upload-pack-advertisement

=> POST /octocat/Hello-World.git/git-upload-pack
=> Content-Type: application/x-git-upload-pack-request
=> Git-Protocol: version=2
<= HTTP/1.1 200 OK
<= Content-Type: application/x-git-upload-pack-result
<= Transfer-Encoding: chunked
```

3. The GET fetches the advertisement, the POST carries the negotiation and receives the packfile. Push uses the same shape with `git-receive-pack`.
4. Real negotiation for a fetch, over protocol v2, trimmed:

```
fetch> command=fetch
fetch> thin-pack
fetch> no-progress
fetch> ofs-delta
fetch> want fec0e27c2650e36592a05049f34cae60fc2966c0
fetch> have 9f1a39e109aca3fc1cce3033a70a43553ebd2bb1
fetch> have f27fb125fe41194710c653bb5b43870a725be980
fetch> 0000
fetch< acknowledgments
fetch< ready
fetch< 0001
fetch< packfile
```

5. Exact framing limits, from the `gitprotocol-common` specification: maximum pkt-line data is 65,516 bytes; maximum total packet length is 65,520 bytes.
6. Sideband limits, from `gitprotocol-capabilities`: side-band allows up to 1,000 bytes per packet, 999 of payload plus one band byte. side-band-64k allows up to 65,520 bytes, 65,519 of payload plus one band byte.

Capability	Meaning
report-status	send a per-ref result after push
report-status-v2	adds proc-receive rewrite reporting
side-band-64k	multiplex data, progress and errors
ofs-delta	deltas may reference by pack offset
atomic	all refs update or none do
delete-refs	zero OID means delete this ref
quiet	suppress server-side progress

7. Protocol v2 was introduced in git 2.18 on 21 June 2018, made default in git 2.26 on 22 March 2020, demoted again in 2.27 after bugs, and made default once more in git 2.29 on 19 October 2020.
8. Push still uses the v0-style advertisement in the trace above, taken with git 2.43.0. Since git 2.32 (6 June 2021), `push.negotiate=true` lets push use v2 negotiation to avoid sending objects the server already has.
9. Smart HTTP itself dates from git 1.6.6, released 23 December 2009, written largely by Shawn O. Pearce. Before that, HTTP fetch was a “dumb” walker that downloaded loose objects one at a time.

10. Observation tools: `GIT_TRACE_PACKET=1`, `GIT_TRACE=1`, `GIT_TRACE_CURL=1` with `GIT_TRACE_CURL_NO_DATA=1`, `GIT_SSH_COMMAND` with `ssh -v`, and `git ls-remote` for a pure read of the server's refs.
11. Be clear about what kind of rule each of these is. The pkt-line framing, the three sideband channels, the capability names and the smart-HTTP URL paths are a **standard**: they are written down in git's protocol documentation, and other implementations follow them.
12. The remote: prefix on band 2 output is an **implementation detail** of the git client, defined by `DISPLAY_PREFIX` in `sideband.c`. Nothing on the wire contains those eight characters.
13. Naming your main remote origin and your default branch main is a **convention**. Git does not care; the tooling around it often does.

■ 39.6.6 WORDS – remember these

1. pkt-line — a length-prefixed frame — 4 hex digits of total length followed by payload; 0000 is flush.
2. Sideband — three streams down one pipe — band 1 data, band 2 progress printed as `remote:`, band 3 fatal error.
3. Packfile — one compressed bundle of objects — the `.pack` format with deltas and an accompanying `.idx`.
4. receive-pack — the server side of push — the process that reads the pack and updates refs.
5. upload-pack — the server side of fetch — the process that negotiates and builds a pack for the client.
6. Capability advertisement — what each end can do — the space-separated list sent after a NUL byte on the first ref line.

39.7 The reader's own failure, analysed properly

■ 39.7.1 PLAIN – in simple words

1. Twice in one session, the reader's push stopped with this message.

```
send-pack: unexpected disconnect while reading sideband packet
fatal: the remote end hung up unexpectedly
```
2. Here is what that sentence means, word by word.
3. `send-pack` is the program on your own machine that does the pushing. So the complaint is coming from your side, not the server's.
4. `reading sideband packet` means your git had finished sending and had switched to listening for the answer.
5. `unexpected disconnect` means the connection went silent while it was listening. Not an error message. Silence.
6. So the stage is exactly this: the pack was already sent, and your git was waiting for the report that says whether it worked.
7. And now the crucial point. Your git never got the report. That is the only fact you have.
8. It does not tell you the push failed. It does not tell you the push succeeded. It tells you that the answer did not arrive.
9. The server may have taken the pack, checked it, moved the branch, and then died before it could say so.
10. Or the server may have died before doing any of that.
11. From your side those two look identical. The only way to find out is to ask the server again.

■ 39.7.2 PLAIN – a picture in your head

1. You post a signed contract by registered mail and wait for the receipt.
2. The receipt never comes.
3. Did the office receive and file your contract, and then lose the receipt in the post? Or did the envelope never arrive at all?
4. You genuinely cannot tell from your end. Both stories produce exactly the same experience: you sent something and heard nothing.
5. The only sane move is to phone the office and ask what they have on file.
6. Note what you must not do. You must not assume it failed and post a second contract, because if the first one landed you now have two.
7. And you must not assume it succeeded and move on, because if it did not you have lost the work.

Where this comparison breaks:

8. With a contract, a duplicate is a real problem. With a git push, re-pushing the identical commits is harmless, because the ref update either has already happened or will happen. That is a lucky property of git, not a general one.

■ 39.7.3 PLAIN – a worked example

1. This can be reproduced exactly. Here is a server that behaves normally, accepts the pack, updates the branch, and then drops the connection instead of delivering its report.

```
$ git ls-remote origin
(nothing: the server has no refs yet)

$ git push origin main
send-pack: unexpected disconnect while reading sideband packet
fatal: the remote end hung up unexpectedly
$ echo $?
128
```

2. That looks like a failure. Now ask the server.

```
$ git ls-remote origin
36e4614a1df6e4ff7839130240981cabb5b970ca    HEAD
36e4614a1df6e4ff7839130240981cabb5b970ca    refs/heads/main

$ git status -sb
## main...origin/main [gone]
```

3. The push worked. The branch is on the server. The error was about the reply, not about the write.
4. Also note origin/main [gone]. Your local copy of the server's state was never updated, because the report never arrived. Your machine still thinks nothing is there.
5. Now the second server, which dies before applying anything. Same client, same commit, same command.

```
$ git push origin main
send-pack: unexpected disconnect while reading sideband packet
fatal: the remote end hung up unexpectedly
$ echo $?
128

$ git ls-remote origin
(nothing)
```

6. Identical message. Identical exit code. Opposite outcome.
7. That is the whole lesson in one pair of transcripts. The error text carries no information about whether the write landed.
8. In the reader's own session, both failures had NOT applied. That was discovered by running `git ls-remote` and looking, not by reasoning from the error message. If it had been deduced from the message, the conclusion would have been luck, not knowledge.

■ 39.7.4 PLAIN – what is really happening inside

1. Sequence of events on a push, with the failure point marked.

```

1. client starts receive-pack on the server
2. server sends ref advertisement + capabilities -> flush
3. client sends "old new refname" -> flush
4. client streams the packfile
5. server reads pack, runs index-pack, verifies objects
6. server runs pre-receive hook
7. server updates refs/heads/main
8. server runs post-receive hook
9. server sends "unpack ok" and "ok refs/heads/main"
   <-- the connection dies anywhere from step 5 to step 9
10. client prints the report, updates origin/main

```

2. The client's error is raised in step 9. Everything from step 5 to step 8 may or may not have completed.
3. Concretely: in git's source, `send-pack.c` calls `recv_sideband("send-pack", ...)`. Inside `sideband.c`, when the packet reader returns end-of-file, it produces exactly the message the reader saw.
4. The word `send-pack` in the message is simply the name the caller passed in. It is a label, not a diagnosis.
5. Why does the connection die? Any of: an idle timeout on a middlebox, a carrier-grade NAT table entry expiring, a proxy closing an idle connection, the server process being killed, a load balancer draining, or a genuinely dropped path like the one in the reader's traceroute.
6. Note that step 4, streaming the pack, can take a long time with nothing coming back. That is exactly when idle-connection timers fire.
7. The general shape of the problem: a **non-idempotent** operation, meaning one where doing it twice is not the same as doing it once, sent over a transport that can fail after the request but before the reply.
8. Chapter 36 made the same point about HTTP APIs: `POST` is not idempotent, so a client that times out cannot safely retry, and that is precisely why idempotency keys exist. This is the same problem in a different suit.
9. Git is kinder than most, because pushing the same commits twice is harmless. But you still cannot know the state without asking.

■ 39.7.5 TECHNICAL – the engineer's version

1. The rule, stated properly: **a failure while reading a response tells you nothing about whether the request was applied**. Only the outcome of a fresh query does.
2. This is a two-generals situation. No number of extra acknowledgements makes the final one guaranteed to arrive.
3. Correct procedure after any interrupted push:

```

# what does the server actually hold right now?
git ls-remote origin refs/heads/<branch>

```

```
# what did I try to send?
git rev-parse HEAD

# refresh the remote-tracking refs, then read them
git fetch origin
git status -sb
```

- Do not use `git status` alone. Before a fetch, `origin/main` is a cached value written by the last successful exchange, not a live fact.
- Techniques that make this class of failure less likely or less painful:

Technique	What it buys you
<code>git push --atomic</code>	all-or-nothing across several refs
<code>--force-with-lease</code>	fails if the server moved unnoticed
<code>http.postBuffer</code> raise	fewer chunked-upload edge cases
<code>SSH ServerAliveInterval</code>	keeps NAT and proxy timers alive
<code>GIT_TRACE_PACKET=1</code>	shows the exact stage of failure
smaller pushes	shorter windows for a timeout

- `git push --atomic` uses the atomic capability so several ref updates land as one transaction. It does not solve the reporting problem; it only removes the partial-ref-update case.
- `--force-with-lease` is the strongest safety net here, because it encodes an expectation about the server's current value and fails if reality differs.
- Generalisation beyond git, worth memorising:

Operation type	Safe to blind-retry?	What to do instead
read (GET, fetch)	yes	just retry
idempotent write	yes	just retry
create (POST)	no	re-query, or use key
git push	in practice yes	re-query first

- The honest version: `git push` is described as “in practice safe to retry” because the second push either fast-forwards to the same value or reports “Everything up-to-date”. That is a property of the ref-update rule, not a guarantee written in a specification.
- In the reader's session, the diagnosis of the wider outage came from the same discipline: `curl -v https://github.com` printed `Trying 20.207.73.82:443...` and then timed out after 15 seconds with no reply of any kind, while the same request succeeded over mobile data. What was proven was “no response on this path”. What was not proven was who dropped it.

■ 39.7.6 WORDS – remember these

- Non-idempotent — doing it twice is not the same as once — an operation whose repetition changes the result.
- Two generals problem — you can never be sure the last message arrived — the classic impossibility result for agreement over a lossy channel.
- Re-query — go and look rather than guess — issue a fresh read to establish the true state after an ambiguous failure.
- Stale remote-tracking ref — your cached idea of the server — `origin/main` as written by the last successful fetch or push.

5. Atomic push — all refs or none — the `--atomic` flag, backed by the server's atomic capability.
6. Lease — an assertion about the server's current value — the expected old OID carried by `--force-with-lease`.

39.8 Fetch versus pull

■ 39.8.1 PLAIN – in simple words

1. `git fetch` downloads. That is all it does.
2. It brings any objects you are missing into `.git/objects`, and it updates your record of where the server's branches are.
3. It does not touch your files. It does not touch your branch. It does not touch your index. After a fetch, your working directory is byte for byte what it was before.
4. `git pull` is two commands in one: a fetch, then an integration step that combines the fetched work into your current branch.
5. That second step is where the surprises live, because it changes your files and can create commits or conflicts.
6. So `git fetch` is always safe to run. `git pull` is not always safe to run.
7. The usual advice is: fetch, look at what arrived, then decide how to integrate it.

■ 39.8.2 PLAIN – a picture in your head

1. Think of a shared noticeboard in an office, and your own copy of it in a folder.
2. `git fetch` is walking over, photographing the board, and filing the photo. Your desk is untouched. You now know what the board says.
3. `git pull` is walking over, photographing the board, and then immediately rewriting your own working notes to match it.
4. If your notes and the board disagree, that second act is where the mess happens, right there on your desk, without warning.

Where this comparison breaks:

5. A photograph is passive. A fetched object is not: it is a real object in your database that other commands can now reach and use.
6. Copying the board means overwriting. Git never overwrites your commits; it merges or replays. But it does overwrite your working files.

■ 39.8.3 PLAIN – a worked example

1. Here is a fetch, with the state of everything printed before and after.

```
before: HEAD=7f77069  origin/main=1303ba7
before: file f contains "A" and "from x1"

$ git fetch origin
From file:///tmp/gw/ff
 1303ba7..2c979a9  main      -> origin/main

after : HEAD=7f77069  origin/main=2c979a9
after : file f contains "A" and "from x1"

$ git status -sb
## main...origin/main [ahead 1, behind 1]
```

- Only one thing changed: origin/main. HEAD did not move. The file did not change. And now `git status` can tell you the truth: one commit each way.
- Now a pull in the same situation, on a modern git with nothing configured.

```
$ git pull
hint: You have divergent branches and need to specify how to
hint: reconcile them.
hint:
hint:   git config pull.rebase false  # merge
hint:   git config pull.rebase true   # rebase
hint:   git config pull.ff only       # fast-forward only
fatal: Need to specify how to reconcile divergent branches.
```

- That refusal is a good thing, and it is recent. Older git versions silently merged, which is how so many repositories acquired hundreds of commits reading “Merge branch ‘main’ of ...”.

■ 39.8.4 PLAIN – what is really happening inside

- `git fetch origin` does five things.
- Connect and get the ref advertisement.
- Work out which objects are missing, using want and have lines.
- Receive one packfile and store it under `.git/objects/pack/`.
- Update remote-tracking refs, that is `refs/remotes/origin/*`, to the server’s values.
- Write `FETCH_HEAD` and append to the reflog. Nothing else moves.
- `git pull` runs that, then runs either `git merge FETCH_HEAD` or `git rebase FETCH_HEAD`, depending on configuration.
- The surprise has three separate causes.
- First, the integration step is invisible in the command name. Nothing in the word “pull” says “and then merge”.
- Second, which integration happens depends on configuration that may differ between your machine and a colleague’s.
- Third, it acts on your working directory, so a bad outcome is immediately in your face, mid-task, possibly with conflicts.

■ 39.8.5 TECHNICAL – the engineer’s version

- `git pull` is documented as `git fetch` followed by either `git merge` or `git rebase`. The choice is made by `pull.rebase`, then `branch.<name>`. `rebase`, then the command-line flags.
- Recommended settings, with what each buys you:

Setting	Effect
<code>pull.ff only</code>	refuse to auto-merge
<code>pull.rebase true</code>	replay your work on top
<code>fetch.prune true</code>	delete gone remote-tracking
<code>push.default simple</code>	push only the current branch
<code>push.autoSetupRemote true</code>	first push sets upstream
<code>rebase.autoStash true</code>	stash and restore around it

- `push.default = simple` became the default in git 2.0, released 28 May 2014. `push.autoSetupRemote` arrived in git 2.37, released 27 June 2022.
- `git fetch --prune` deletes remote-tracking refs whose branches no longer exist upstream. Without it, `origin/old-feature` lingers forever.

5. `git fetch --all` fetches from every remote. `git remote update` is the older spelling of the same thing.
6. `FETCH_HEAD` is a file listing everything the last fetch brought, with the ones marked “not-for-merge” excluded from the integration step.
7. The `refspec` controls what is fetched. The default for a clone is `+refs/heads/*:refs/remotes/origin/*`. The leading `+` means “allow non-fast-forward updates to my remote-tracking refs”, which is why a force-push upstream does not break your fetch.
8. Shallow and partial fetches change the object set: `--depth=N` truncates history, `--filter=blob:none` omits file contents until needed. Partial clone requires the server capability `filter`, which GitHub’s advertisement in the earlier trace does list.
9. The honest version: experts disagree about `pull.rebase`. `Rebase-by-default` gives a clean line but rewrites your local commits every pull, which is confusing if you have already shared the branch. `Merge-by-default` is truthful but noisy. `pull.ff` only sidesteps the argument by making you choose each time, and is the safest default to teach.

■ 39.8.6 WORDS – remember these

1. Fetch — download and record — transfer missing objects and update `refs/remotes/*` only.
2. Pull — fetch plus integrate — fetch followed by merge or rebase into the current branch.
3. Remote-tracking ref — your note of where the server was — a ref under `refs/remotes/<remote>/`, updated only by fetch, push or remote commands.
4. Refspec — a mapping of their refs to mine — `+<src>:<dst>`, where `+` allows non-fast-forward updates.
5. `FETCH_HEAD` — what the last fetch brought — a file listing fetched tips, some marked not-for-merge.
6. Prune — forget branches that no longer exist — `git fetch --prune` or `fetch.prune true`.

39.9 Merge

■ 39.9.1 PLAIN – in simple words

1. Merging combines two lines of work into one.
2. Git starts by finding where the two lines split apart. That shared ancestor is called the **merge base**.
3. It then has three versions of every file: the base version, your version, and their version.
4. For each file it asks: did I change it, did they change it, or both?
5. If only one side changed a file, take that side. If neither changed it, keep the base. If both changed it, look closer.
6. If both changed different parts of the file, take both changes.
7. If both changed the same part, git stops and asks you. That is a conflict.
8. The result is stored as a new commit with two parents, one for each line that was joined.
9. There is one special case. If your branch has not moved at all since the split, there is nothing to combine. Git just moves your branch forward. That is called a **fast-forward**, and it creates no commit.

■ 39.9.2 PLAIN – a picture in your head

1. Two people are given identical copies of a report and go away to edit it.
2. When they come back, an editor puts three copies on the desk: the original, copy A and copy B.
3. For each paragraph the editor compares all three. If only A touched it, take A’s. If only B touched it, take B’s.

4. If both touched the same paragraph in different ways, the editor cannot decide and leaves both versions marked up for a human.
5. If B never actually changed anything, the editor simply hands over A's copy and calls it done. That is fast-forward.

Where this comparison breaks:

6. A human editor reads for meaning. Git compares lines of text and nothing else. Two changes that read fine together can still be wrong together, and git will never notice. Section 39.10 gives a real example.

■ 39.9.3 PLAIN – a worked example

1. Fast-forward first. Branch feature is ahead; main has not moved.

```
$ git log --oneline --graph --all
* 80b9042 C: feature file
* 3fc5061 B: on main
* 0a83b6e A: base

$ git merge-base main feature
3fc5061b9e3a37928186aab85f0c7ed2fc6b73c4

$ git merge-base --is-ancestor main feature && echo "ancestor"
ancestor

$ git merge feature
Updating 3fc5061..80b9042
Fast-forward
 feature.txt | 1 +
 1 file changed, 1 insertion(+)

$ git rev-list --merges --count HEAD
0
```

2. Zero merge commits were created, because main was already an ancestor of feature. Moving the label forward is enough.
3. Now a real three-way merge. Both branches changed the same file in different places.

```
BEFORE
* 1f96d1d B: rename header      (main)
| * 8681015 C: add contact line (feature)
|/

Merge branch 'feature'

```

■ 39.9.4 PLAIN – what is really happening inside

1. Finding the merge base is a graph problem, not a guess. Git walks backwards from both tips, marking which commits are reachable from which side.
2. The merge base is a commit reachable from both tips with no descendant that is also reachable from both. `git merge-base A B` prints it.
3. Sometimes there is more than one such commit. Git's default strategy then merges the bases together first, recursively, and uses the result as the base. That is why the old strategy was called recursive.
4. Fast-forward is detected by a single question: is the current tip an ancestor of the target? `git merge-base --is-ancestor A B` answers it with an exit code.
5. If yes, there is nothing to combine, so git writes the target's tree into the index and worktree and moves the branch. No new object is created.
6. `--no-ff` forces a merge commit even when a fast-forward is possible. The reason to use it is that the merge commit is the only record that these commits were a group.

```

with --no-ff:
* a78fc04 Merge branch 'feature'
|\
| * 52ee392 C (feature)
| * 9aa4587 B (feature)
|/
* 7c451a3 A

$ git log --oneline --first-parent
a78fc04 Merge branch 'feature'
7c451a3 A

```

7. That last command is the payoff of `--no-ff`. `--first-parent` follows only the mainline, so a two-year history of merges reads as one line per feature.

8. The three-way merge itself is applied per file, comparing base, ours and theirs, then per region within the file.

■ 39.9.5 TECHNICAL - the engineer's version

1. Strategies: `ort` is the default, `recursive` is the old default, `resolve` handles a single base only, `octopus` merges more than two heads, `ours` discards the other side's content entirely, `subtree` shifts paths.
2. `ort`, short for "ostensibly recursive's twin", became the default in git 2.34, released 15 November 2021. GitHub reported it outperforming `recursive` by roughly 500 times on rename-heavy merges and by more than 9,000 times on some rebases, largely because it does not use the index as its working data structure.
3. Do not confuse the `ours` strategy with the `-X ours` option. The strategy throws away the other branch's changes. The option only decides conflicting hunks in your favour.

Thing	Effect
<code>-s ours</code>	keep our tree entirely
<code>-X ours</code>	our side wins conflicting hunks only
<code>-X theirs</code>	their side wins conflicting hunks
<code>-X ignore-all-space</code>	ignore whitespace when merging
<code>--no-ff</code>	always create a merge commit
<code>--ff-only</code>	refuse anything but a fast-forward
<code>--squash</code>	stage the result, make no merge link

4. Rename detection is on by default, controlled by `merge.renameLimit` and `diff.renames`. It is why moving a file on one side and editing it on the other usually merges correctly.
5. `git merge --abort` restores the pre-merge state using `MERGE_HEAD` and `ORIG_HEAD`. It is safe while a merge is in progress.
6. During a conflicted merge, `.git/MERGE_HEAD`, `.git/MERGE_MSG` and `.git/MERGE_MODE` exist. Their presence is how git knows a merge is unfinished and why `git status` prints "You have unmerged paths".
7. An octopus merge with more than two parents is legal and appears in the Linux kernel history. It refuses to run if any pair conflicts.

■ 39.9.6 WORDS - remember these

1. Merge base — where the two lines split — the best common ancestor of two commits in the DAG.
2. Three-way merge — compare base, ours, theirs — the algorithm that decides per region which side's change to keep.
3. Fast-forward — just move the label — an update where the old tip is an ancestor of the new one, so no merge commit is needed.
4. Merge commit — the join — a commit with two or more parents.
5. `ort` — the modern merge engine — the default merge strategy since git 2.34, November 2021.
6. First-parent history — the mainline only — `git log --first-parent`, which treats each merge as one entry.

39.10 Conflicts at the file level

■ 39.10.1 PLAIN – in simple words

1. A conflict is not git failing. It is git refusing to guess.
2. Git compares text line by line. It works on regions of lines, not on meaning.
3. If your change and their change are in different regions of the file, git takes both without asking.
4. If they overlap, git cannot know which one you want, so it writes both into the file surrounded by markers and stops.
5. The markers are ugly on purpose. They are meant to be impossible to miss and impossible to leave in by accident.
6. Your job is to edit the file until it is what you actually want, delete the markers, and tell git you are done with `git add`.
7. There is a second, nastier kind of conflict that git will never report. Two changes that merge perfectly as text, but break the program.
8. Git cannot see that, because git does not know what your code means.

■ 39.10.2 PLAIN – a picture in your head

1. Two proofreaders mark up the same page.
2. One changes a word in paragraph two. The other adds a sentence to paragraph nine. The typesetter applies both without a thought.
3. Both change the same sentence in paragraph five, differently. The typesetter stops, prints both versions one above the other with a big line between them, and puts the page in the “needs a decision” tray.
4. Now the nasty case. One proofreader renames a character from Anna to Anya throughout chapter one. The other adds a new scene in chapter nine mentioning Anna.
5. No paragraph overlaps. The typesetter merges happily. The book is now inconsistent, and nothing in the process caught it.

Where this comparison breaks:

6. A typesetter might notice the name change by reading. Git never reads. It will merge a file into nonsense with complete confidence, every time.

■ 39.10.3 PLAIN – a worked example

1. Both branches change the same line of a config file.

```

BASE           OURS (main)    THEIRS (feature)
PORT = 8080     PORT = 3000    PORT = 9090

$ git merge feature
Auto-merging config.py
CONFLICT (content): Merge conflict in config.py
Automatic merge failed; fix conflicts and then commit.

$ cat config.py
HOST = "localhost"
<<<<<<< HEAD
PORT = 3000
=====
PORT = 9090
>>>>>> feature
TIMEOUT = 30

```

2. Line by line. <<<<<<< HEAD opens the conflicted region and names your side. Everything until ===== is your version.
3. ===== is the divider. Everything after it until >>>>>>> is their version. >>>>>>> feature closes the region and names their side.
4. The unconflicted lines, HOST and TIMEOUT, are outside the markers and have already been merged.
5. The default marker style hides the base. Turning on diff3 shows it, which is much more useful.

```
$ git checkout --conflict=diff3 config.py
$ cat config.py
HOST = "localhost"
<<<<<<< ours
PORT = 3000
||||||| base
PORT = 8080
=====
PORT = 9090
>>>>>>> theirs
TIMEOUT = 30
```

6. Now you can see that the original was 8080, so both sides changed it, and neither side is a superset of the other.
7. Meanwhile, the index holds all three versions at once.

```
$ git ls-files -u
100644 5c03df4f...9181 1    config.py
100644 bd085f95...ca9b 2    config.py
100644 ee2a92c1...4f85 3    config.py
```

8. Stage 1 is the base, stage 2 is ours, stage 3 is theirs. Resolving means replacing those three entries with one stage-0 entry, which is exactly what `git add` does.

■ 39.10.4 PLAIN – what is really happening inside

1. Now the semantic conflict. This one is real, run end to end.
2. Start with two files. `lib.py` defines `get_user`. `app.py` calls it.
3. On a branch called `refactor`, rename the function to `fetch_user` and fix the one call site that exists.
4. On `main`, add a brand new file `report.py` that calls `get_user`.
5. Neither side touched a line the other touched. Watch `git`.

```
$ git merge refactor
Merge made by the 'ort' strategy.
 app.py | 4 +--
 lib.py | 2 +-
 2 files changed, 3 insertions(+), 3 deletions(-)

$ python3 -c "import report; report.report()"
File "/tmp/gw/sem/report.py", line 1, in <module>
    from lib import get_user
ImportError: cannot import name 'get_user' from 'lib'
```

6. Zero conflicts. Zero warnings. Broken program.
7. This is not a bug. Git did exactly what it promises: combine text changes that do not overlap. It never promised the result would compile.
8. The only defence against semantic conflicts is a test suite that runs on the merge result, not on either branch alone. That is precisely what continuous integration on the merged head is for.

9. Binary files are the other special case. Git cannot combine regions of a JPEG or a spreadsheet, so any change on both sides is a whole-file conflict.

```
$ git merge designer
warning: Cannot merge binary files: logo.png (HEAD vs. designer)
CONFLICT (content): Merge conflict in logo.png

$ git status --short
UU logo.png
```

10. There are no markers in the file. The working copy is left as one of the two versions. You choose a side with `git checkout --ours` or `--theirs`, then `git add`.

■ 39.10.5 TECHNICAL – the engineer’s version

1. Conflict styles, set by `merge.conflictStyle`:

Style	Shows	Since
merge	ours and theirs only	always (default)
diff3	ours, base, theirs	long-standing
zdiff3	diff3 with common lines out	git 2.35, 2022

2. `zdiff3` arrived in git 2.35, released 24 January 2022. It hoists lines common to both sides out of the conflict region, making the real disagreement smaller.
3. The resolution workflow, in full:

```
git status          # which paths are unmerged
git diff            # combined diff of conflicts only
git mergetool       # optional three-pane editor
<edit files, remove markers>
git add <path>      # collapses stages 1,2,3 into stage 0
git status          # confirm nothing is unmerged
git commit          # message is prefilled from MERGE_MSG
```

4. `git mergetool` drives an external tool named by `merge.tool`. It creates `*.BASE`, `*.LOCAL` and `*.REMOTE` temporary files from index stages 1, 2 and 3, and removes them afterwards unless `merge-tool.keepBackup` is set.
5. `git checkout --ours <path>` and `--theirs <path>` pull stage 2 or stage 3 out of the index. During a rebase these are reversed relative to intuition, because the commit being replayed is “theirs”.
6. **rerere** stands for “reuse recorded resolution”. Enable it with `git config rerere.enabled true`. Git then records the conflict text and your resolution, and replays it automatically next time the same conflict appears.

```
$ git config rerere.enabled true
$ git merge feature
Recorded preimage for 'cfg.py'
<resolve by hand, git add, git commit>
Recorded resolution for 'cfg.py'.

$ git reset --hard HEAD~1
$ git merge feature
Resolved 'cfg.py' using previous resolution.

$ cat cfg.py
PORT = 3000
```

7. The recordings live in `.git/rr-cache/<hash>/preimage` and `postimage`. The hash is computed from the normalized conflict text, so an identical conflict anywhere gets the same resolution.
8. `rerere` was written by Junio C Hamano and merged on 6 February 2006, with the commit message “git-rerere: reuse recorded resolve”. It is most valuable during long rebases, where the same conflict recurs on every replayed commit.
9. For binary formats, `.gitattributes` with `*.png binary` or a custom `merge=` driver is the practical answer. Git LFS stores a pointer file, so conflicts appear on the pointer rather than the payload, which is smaller but no easier to merge.

■ 39.10.6 WORDS – remember these

1. Conflict — git refusing to guess — overlapping changes recorded as index stages 1, 2 and 3 with markers in the worktree.
2. Conflict marker — the ugly fence — `<<<<<<, =====, >>>>>>`, plus `|||||` for the base in `diff3` style.
3. Semantic conflict — merges fine, breaks anyway — a logically incompatible pair of changes that do not overlap textually.
4. `rerere` — remember how I fixed this — recorded conflict resolutions replayed automatically.
5. Unmerged path — a file still in dispute — a path with index entries at stages other than 0.
6. Merge driver — custom combining logic for a file type — a program named in `gitattributes` via `merge=<name>`.

39.11 Rebase

■ 39.11.1 PLAIN – in simple words

1. Rebase means: take my commits, and pretend I had started from somewhere else.
2. Git works out which commits are mine, sets them aside, moves my branch to the new starting point, and applies each of my changes again, one at a time.
3. Each time it applies one, it makes a **new commit**. Not the old one moved. A new object, with a new name.
4. It must be a new object, because a commit records the name of its parent, and the parent is now different. Change any byte and the name changes.
5. So after a rebase your work looks the same but every commit has a different identifier.
6. The result is a straight line instead of a fork, which many teams prefer to read.
7. Rebase can also edit history as it replays: reorder commits, reword messages, squash several into one, or drop one entirely. That is interactive rebase.

■ 39.11.2 PLAIN – a picture in your head

1. You wrote three pages of notes on top of page 10 of a shared notebook.
2. Meanwhile the shared notebook grew to page 14.
3. Merging means gluing your three pages in as a side branch, with a note saying where they joined.
4. Rebasing means copying your three pages out by hand onto fresh sheets, placing them after page 14, and burning the originals.
5. The words on your new sheets are identical. The sheets are not the same sheets.

Where this comparison breaks:

6. Copying by hand can introduce mistakes. Rebase reapplies changes exactly, but it can hit conflicts, because the surrounding text is now different.

7. The originals are not really burned. They stay in the reflog for 90 days.

■ 39.11.3 PLAIN – a worked example

1. A branch with two commits, and main has moved on.

```
BEFORE
* a91e93d M1: main moved on          (main)
| * 9ca2c92 F2: extend feat.txt      (feature)
| * 26e79b3 F1: add feat.txt
|/
* c32f284 A: base

$ git switch feature
$ git rebase main
Successfully rebased and updated refs/heads/feature.

AFTER
* 6a7f276 F2: extend feat.txt        (feature)
* 003972b F1: add feat.txt
* a91e93d M1: main moved on          (main)
* c32f284 A: base
```

2. The hashes side by side.

Commit	Before rebase	After rebase
F1	26e79b3	003972b
F2	9ca2c92	6a7f276
tip	9ca2c92	6a7f276

3. Two commits went in, two came out, and not one identifier survived.

4. Interactive rebase on a messy branch. This is the todo list git presents.

```
$ git rebase -i HEAD~4
pick 7644785 add parser
pick bd687cc wip
pick 894e838 fix typo in parser
pick 0ec5c9b add tests
```

5. Edit it to this, and save.

```
pick    7644785 add parser
fixup   bd687cc wip
fixup   894e838 fix typo in parser
reword  0ec5c9b add tests
```

6. The result: five commits become three, the file content is byte for byte identical, and the last message was rewritten.

```
$ git log --oneline
c868f3c add unit tests for the parser
4dcdb2e add parser
292e19e base
```

■ 39.11.4 PLAIN – what is really happening inside

1. `git rebase <upstream>` runs these steps.
2. Work out the commit list: everything reachable from HEAD but not from upstream, oldest first. That is `git rev-list upstream..HEAD --reverse`.
3. Check out the upstream tip, with HEAD detached.
4. For each commit in the list, compute its change against its own parent and apply that change to the current state.
5. Create a new commit with the same message, the same author and author date, a **new committer date**, and the new parent.
6. When the list is finished, move the branch ref to the last new commit and re-attach HEAD to it.
7. Step 5 is why the hash changes: the parent line differs, the tree usually differs, and the committer timestamp differs. Chapter 38 showed that the hash is computed over exactly those bytes.
8. If applying a change fails, the rebase stops and asks you to fix it, then `git rebase --continue`. `git rebase --abort` restores everything.
9. Interactive rebase is the same loop, but the list is written to a todo file you may edit first.

Verb	What it does
pick	replay this commit unchanged
reword	replay it, open the editor for the message
edit	replay it, then stop so you can amend
squash	fold into the previous, combine both messages
fixup	fold into the previous, discard this message
drop	do not replay it at all
exec	run a shell command at this point
break	stop here, continue later

10. `git commit --fixup <sha>` writes a message starting `fixup!`. Running `git rebase -i --autosquash` then reorders that commit next to its target and marks it `fixup` for you, with no editing by hand.

■ 39.11.5 TECHNICAL – the engineer’s version

1. Two backends exist. The `apply` backend uses `format-patch` and `git am`. The `merge` backend replays with the merge machinery and is the default since git 2.26 (March 2020). `--empty`, `--keep-empty` and `--reapply-cherry-picks` control what happens to commits that become empty.
2. `git rebase --onto <newbase> <upstream> <branch>` moves only the commits that are on branch but not on upstream. It is the tool for detaching a topic built on another topic.

```
| $ git rebase --onto main topic1 topic2
```
3. `git rebase -i --autosquash` was added by Nanako Shiraishi on 6 January 2010 and shipped in git 1.7.0 on 12 February 2010. Set `rebase.autoSquash true` to make it automatic.
4. `git rebase --exec 'make test'` runs a command after each replayed commit, so you can prove every commit in the branch builds, not just the tip.
5. `rebase.autoStash true` stashes uncommitted work before the rebase and restores it afterwards.
6. History: `git-rebase-script` was added by Junio C Hamano on 25 June 2005, with the message “rebase local commits to new upstream head”. Interactive mode was added by Johannes Schindelin on 24 June 2007 and shipped in git 1.5.3 on 2 September 2007.

7. `git rebase` sets `ORIG_HEAD` to the pre-rebase tip, and writes reflog entries labelled `rebase (start)`, `rebase (pick)`, `rebase (fixup)` and `rebase (finish)`, so every intermediate state is recoverable.

■ 39.11.6 WORDS – remember these

1. Rebase — replay my work on a new base — create new commits with the same changes and different parents.
2. Upstream — the thing I am rebasing onto — the commit that becomes the new parent of the first replayed commit.
3. Interactive rebase — edit the plan before replaying — `git rebase -i` with a todo list of verbs.
4. Autosquash — fold marked fixes automatically — reorder and mark `fixup!` and `squash!` commits during `rebase -i`.
5. Committer date — when this object was made — rewritten on every replay, unlike the author date.
6. Todo list — the rebase plan — the editable file of `pick`, `squash`, `fixup` and other verbs.

39.12 The reader's rebase, explained

■ 39.12.1 PLAIN – in simple words

1. In the reader's session, a local branch was rebased onto a `main` that had moved, and the branch's SHA changed.
2. Nothing went wrong. That is the only possible outcome.
3. A commit's name is computed from its exact bytes. Those bytes include the name of its parent.
4. Rebasing gives every replayed commit a different parent. Different parent means different bytes, which means a different name.
5. So the changes are the same and the commits are not the same objects.
6. The old commits still exist. They are simply no longer pointed at by the branch.

■ 39.12.2 PLAIN – a picture in your head

1. Two identical recipes, each written on a card that also says which card comes before it in the box.
2. Move one recipe to a different position in the box and the “comes after” line must change.
3. The ingredients are identical. The card is not the same card, because the card includes that line.

Where this comparison breaks:

4. You could rub out the line on a real card. A git object's name is derived from its bytes, so editing the bytes produces a different object rather than an edited one.

■ 39.12.3 PLAIN – a worked example

1. The same commit, before and after rebase, printed in full.

```
OLD F1 (26e79b3)
tree    d18b4ea7a3728589bfef3b1836e869ac1db45faf
parent  c32f2845c02885738408ebd404b13b9f2e3c7c4e
author   Reader <reader@example.com> 1772941200 +0530
committer Reader <reader@example.com> 1772941200 +0530

NEW F1 (003972b)
tree    ed1a2fa48bd51d2a79edc8c6e3628c892e5d4c9b
parent  a91e93d9b813a53be8d8b7f51733815d0de72dea
author   Reader <reader@example.com> 1772941200 +0530
committer Reader <reader@example.com> 1772942400 +0530
```

2. Three of the four lines differ. The parent is a different commit. The tree is different because it now also contains main's new version of `core.txt`. The committer timestamp is when the replay happened.
3. Only the author line survived, which is why `git log` still shows your original date.
4. Now recompute the new name by hand, exactly as Chapter 38 did.

```
$ git cat-file commit 003972b > c.raw
$ wc -c < c.raw
219
$ { printf 'commit %d\0' 219; cat c.raw; } | shasum
003972bffe4b385f957000613aa02ea8e5208924
$ git rev-parse 003972b
003972bffe4b385f957000613aa02ea8e5208924
```

5. The hash is not stored anywhere. It is arithmetic over those 219 bytes, and anyone can repeat it.

■ 39.12.4 PLAIN - what is really happening inside

1. The change each commit introduces really is identical. Git can prove that with a patch identifier, a hash of the diff with line numbers and whitespace normalized away.

```
$ git show 26e79b3 | git patch-id --stable
3644a7626a72280f69af9830a10cf2f013748966 26e79b3d...
$ git show 003972b | git patch-id --stable
3644a7626a72280f69af9830a10cf2f013748966 003972bf...
```

2. Same patch identifier on the left. Different commit identifier on the right. That is the whole story in two lines.
3. The old commits are still in the object database, reachable through the reflog.

```
$ git reflog feature
6a7f276 feature@{0}: rebase (finish): onto a91e93d
9ca2c92 feature@{1}: commit: F2: extend feat.txt
26e79b3 feature@{2}: commit: F1: add feat.txt
c32f284 feature@{3}: branch: Created from HEAD
```

4. So the pre-rebase branch is one command away: `git reset --hard feature@{1}`.
5. Practical consequence for the reader: after that rebase, the branch on the server and the branch on the machine had no commits in common past the base. A plain push would be refused as non-fast-forward, and a forced push would be required. Section 39.13 covers when that is acceptable.

■ 39.12.5 TECHNICAL - the engineer's version

1. The invariant: SHA-1 over `commit <len>\0` plus the commit body. Any change to tree, parent, author, committer or message yields a different object ID.
2. `git patch-id --stable` produces a diff-content identity that survives rebase, cherry-pick and reordering. `git cherry` and `git rebase` use it to skip changes already present upstream.
3. `git range-diff <base>..<old> <base>..<new>` compares two versions of the same series and is the correct tool for reviewing a rebased branch. It was added in git 2.19, September 2018.
4. What survives and what does not:

Property	Survives a rebase?
author name and date	yes
commit message	yes, unless edited
the diff (patch-id)	yes

Property	Survives a rebase?
tree object ID	usually not
parent object ID	no
committer date	no
commit object ID	no
GPG signature	no, must re-sign

- Signed commits are invalidated by rebase, because the signature covers the commit bytes. `git rebase -S` re-signs each replayed commit.
- Because remote-tracking refs are updated only by network operations, a rebase makes `git status` report a large “diverged” count immediately. That is arithmetic on the graph, not a warning about anything being wrong.

■ 39.12.6 WORDS – remember these

- Patch identifier — the fingerprint of a change — a hash of the normalized diff, unchanged by rebase.
- Rewritten history — the same work, new objects — a series replaced by a replayed series with different IDs.
- Diverged — no longer a straight line — two refs whose merge base is behind both of them.
- range-diff — compare two versions of a series — `git range-diff`, added in git 2.19, September 2018.
- Re-signing — the signature does not follow — GPG signatures must be recreated after any rewrite, with `git rebase -S`.
- Reflog recovery — the pre-rebase tip is still there — `branch@{1}` names the value the branch held before the last update.

39.13 When rebasing is safe and when it destroys work

■ 39.13.1 PLAIN – in simple words

- There is one rule, and it is short. Do not rebase commits that other people already have.
- Rebasing your own branch, before anyone else has fetched it, is safe and good practice. It makes your work easy to read and easy to review.
- Once you have pushed a branch and a colleague has fetched it, their machine holds those exact commit objects.
- If you rebase and force-push, the server now has different objects with the same branch name.
- Your colleague’s git still has the originals, plus anything built on top of them. Their next pull tries to combine two versions of the same work.
- The result is duplicated commits, avoidable conflicts, and confusion about which version is real.
- Main, master, develop and release branches are shared by definition. Never rebase those.

■ 39.13.2 PLAIN – a picture in your head

- You hand out photocopies of a chapter to five reviewers.
- Then you rewrite the chapter and renumber every paragraph.
- Each reviewer’s comments now point at paragraph numbers that mean something different, or nothing at all.
- Nobody’s work is destroyed, but reconciling it is now manual and tedious for five people instead of one.

Where this comparison breaks:

- Reviewers can see that the chapter changed. Git cannot. It sees two unrelated sets of commits with the same branch name and tries to merge them, which is how duplicate commits appear in the log.

■ 39.13.3 PLAIN – a worked example

- Alice and Bob both have commit B. Bob builds C on top of it. Alice amends B, which is a one-commit rewrite, and force-pushes.

```
Alice: 2bd9139 B: with a better message    (rewritten)
        fac214d A

Bob:    4370404 C: bob's work on top of B
        426111e B                        (the original)
        fac214d A
```

- Bob fetches, and his repository now contains both versions.

```
* 2bd9139 B: with a better message    (origin/main)
| * 4370404 C: bob's work on top of B  (main)
| * 426111e B
|/
* fac214d A
```

- Bob pulls with the default merge behaviour, and gets a conflict in a file neither of them meant to fight over.

```
$ git pull
Auto-merging f
CONFLICT (content): Merge conflict in f
```

- The fix Bob needs is `git pull --rebase`, which replays only his own C onto the new B.

```
$ git pull --rebase
Successfully rebased and updated refs/heads/main.
$ git log --oneline
0b6514b C: bob's work on top of B
2bd9139 B: with a better message
fac214d A
```

- Note that Bob had to know what happened. Git gave him no message saying “the upstream branch was rewritten”.

■ 39.13.4 PLAIN – what is really happening inside

- A normal push is only allowed if the old value on the server is an ancestor of the new value. That is the fast-forward rule.

```
$ git push origin main
! [rejected]        main -> main (fetch first)
error: failed to push some refs
hint: Updates were rejected because the remote contains work
hint: that you do not have locally.
```

- `--force` switches that check off entirely. Whatever the server had is replaced, and any commit only reachable from the old value becomes garbage.

3. `--force-with-lease` replaces the check with a different one: the server's current value must equal what your remote-tracking ref says it is.
4. So `--force-with-lease` says "overwrite, but only if nobody has pushed since I last looked". Here is it refusing.

```
my origin/main says : 2bd9139
the server really has: 0b6514b

$ git push --force-with-lease origin main
! [rejected]        main -> main (stale info)
error: failed to push some refs

$ git push --force origin main
+ 0b6514b...a848939 main -> main (forced update)
```

5. The plain `--force` succeeded and Bob's commit C is now unreachable on the server. Only Bob's own clone still has it.
6. One honest warning: `--force-with-lease` compares against your remote-tracking ref, and a background `git fetch` updates that ref without you noticing. Then the lease is satisfied and the protection is gone. Use `--force-with-lease=<ref>:<expected-oid>` when it matters.

■ 39.13.5 TECHNICAL – the engineer's version

1. The decision table:

Situation	Rebase?	Then push with
local branch, never pushed	yes	plain push
pushed, nobody else uses it	yes	<code>--force-with-lease</code>
open PR, reviewers on it	prefer not	<code>--force-with-lease</code>
shared feature branch, 2+ people	no	merge instead
main, master, develop, release	never	never force
tags already published	never	never move

2. `--force-if-includes`, added in git 2.30 (December 2020), strengthens the lease by also requiring that your local history includes everything your remote-tracking ref has seen. Turn it on with `push.useForceIfIncludes true`.
3. Server-side defences: `receive.denyNonFastForwards`, and on hosted services, protected branches that reject force pushes outright.
4. Recovery when a force push destroys a colleague's commit: the commit is still in that colleague's clone, and on GitHub-style services it is often still reachable through the reflog on the server or through the events API.
5. `git rebase` on a branch that has an open pull request is common practice, and opinions differ. One camp rebases and force-pushes to keep the series clean; the other adds fixup commits during review and squashes at merge time so that review comments stay anchored. Both are defensible.
6. `git range-diff` makes the first camp's approach reviewable, because it shows what changed between the old series and the new one.

■ 39.13.6 WORDS – remember these

1. Published history — commits other people have — anything that has been pushed and fetched by someone else.

2. Fast-forward rule — you may only extend — the default push check that the old tip is an ancestor of the new one.
3. Force push — replace whatever is there — `--force`, which switches the ancestry check off.
4. Lease — only if it is still what I saw — `--force-with-lease`, which compares against your remote-tracking ref.
5. Protected branch — the server says no — a hosting-service rule rejecting force pushes and deletions.
6. Duplicate commits — the same work twice — the visible symptom of merging a rewritten branch with its original.

39.14 Merge versus rebase as a team policy

■ 39.14.1 PLAIN – in simple words

1. Both merge and rebase produce a repository containing the same final files. Neither is more correct than the other.
2. The argument is about what the history looks like afterwards, and how easy it is to work with.
3. Merging keeps a true record: this work happened on a side branch, and it was joined on this date.
4. Rebasing produces a straight line that reads like a story, but the story is tidied. It never happened quite that way.
5. Squash merging goes further: an entire branch becomes one commit on the mainline, and the individual steps are discarded.
6. Teams pick one, write it down, and enforce it with a setting on the hosting service. The worst outcome is a repository where everyone does something different.

■ 39.14.2 PLAIN – a picture in your head

1. Three ways to write up a two-week experiment.
2. Merge: the full lab notebook, every dead end included, with dates.
3. Rebase: the same experiment rewritten as a clean sequence of steps that leads to the result.
4. Squash: a one-paragraph abstract.
5. All three are honest about the result. They differ in what you can go back and inspect a year later.

Where this comparison breaks:

6. A lab notebook cannot be rewritten without fraud. Git history is a tool for communication, and tidying it is normal and legitimate.

■ 39.14.3 PLAIN – a worked example

1. The same feature, three policies, as `git log --oneline --graph`.

```

MERGE (--no-ff)
*   a78fc04 Merge branch 'feature'
| \
| * 52ee392 C (feature)
| * 9aa4587 B (feature)
| /
* 7c451a3 A

REBASE then fast-forward
* 6a7f276 C (feature)
* 003972b B (feature)
* 7c451a3 A

```

SQUASH

- * 400e7f2 Add the whole feature (squashed)
- * 040d29f A

2. One extra fact about squash merging that surprises people.

```
$ git merge-base --is-ancestor feature main && echo yes || echo no
no
```

3. After a squash merge, git does not know the branch was merged. Merging it again would try to replay B, C and D. Delete squashed branches immediately.

■ 39.14.4 PLAIN – what is really happening inside

1. The arguments for merge.
2. It records what actually happened, including when parallel work existed.
3. It never rewrites objects, so nothing anybody has fetched ever becomes invalid.
4. `git log --first-parent` collapses each feature to one line, giving a clean mainline view on demand.
5. Reverting a whole feature is one command, `git revert -m 1 <merge>`.
6. The arguments for rebase.
7. A linear history is easier to read, and `git log` needs no graph rendering.
8. Every commit on the mainline was tested against the code it actually sits on top of, which makes bisect more reliable.
9. There are no merge commits whose diff is confusing to review.
10. The arguments for squash.
11. One commit per feature is the simplest possible mainline.
12. Reviewers' intermediate "fix typo" commits never reach the main branch.
13. The cost: bisect lands on a large commit, and the intermediate steps are gone unless the branch is kept.
14. The honest summary: this is a readability and bisect-ability argument, not a correctness argument. Every option produces identical file contents. Experts disagree, and both large, successful projects and small teams run all three policies happily.

■ 39.14.5 TECHNICAL – the engineer's version

1. Comparison of the three:

Property	Merge	Rebase	Squash
rewrites objects	no	yes	yes
mainline is linear	no	yes	yes
keeps step-by-step	yes	yes	no
bisect granularity	fine	fine	coarse
revert whole feature	easy	manual	easy
force push needed	no	often	no

2. The Linux kernel merges: Linus Torvalds pulls from maintainers, producing a deeply merged history, and explicitly asks maintainers not to rebase published trees. Many web and application teams squash-merge every pull request.
3. `git config merge.ff false` on a specific branch forces merge commits. `git config pull.ff` only prevents accidental merges on pull.

4. On hosting services the equivalent settings are the allowed merge methods for pull requests: merge commit, squash and merge, rebase and merge.
5. Bisect interacts with policy. With merge-based history, `git bisect` can land on a commit inside a feature branch that was never tested alone. `git bisect --first-parent`, added in git 2.29 (October 2020), restricts the search to the mainline and avoids that.
6. Commit hygiene matters more than the policy. A branch of ten commits each of which builds and passes tests is valuable under any of the three; a branch of ten commits named “wip” is not.

■ 39.14.6 WORDS - remember these

1. Linear history — one line, no forks — a history where every commit has exactly one parent.
2. Squash merge — one commit per feature — combine a branch into a single commit with no merge link.
3. First-parent view — the mainline only — following only the first parent of each merge.
4. Bisect-ability — how precisely a search can land — a property of how large and how independently testable each commit is.
5. Merge method — the button the service offers — merge commit, squash and merge, or rebase and merge.
6. Commit hygiene — each commit is a whole, working step — the practice that makes any policy work.

39.15 Cherry-pick, revert, bisect and the rest

■ 39.15.1 PLAIN - in simple words

1. `git cherry-pick` copies one commit’s change onto your current branch. Use it to move a single fix without moving everything around it.
2. `git revert` creates a new commit that undoes an old one. Use it when the bad commit is already public.
3. `git bisect` finds which commit introduced a bug, by testing a shrinking range automatically.
4. `git blame` shows which commit last changed each line of a file.
5. `git log -S“text”` finds commits where a piece of text was added or removed.
6. `git worktree` gives you a second checked-out directory sharing one object database, so you can look at another branch without stashing.

■ 39.15.2 PLAIN - a picture in your head

1. Bisect is the game of guessing a number between 1 and 1000 with yes-or-no questions.
2. Ask “is it above 500?” and half the possibilities vanish, whatever the answer.
3. Ten questions cover a thousand numbers; twenty cover a million.
4. Git plays the same game over commits. Each test halves the range.

Where this comparison breaks:

5. The number game assumes one answer. Bisect assumes the bug appeared once and stayed. If it comes and goes, bisect will mislead you. Mark such commits `git bisect skip`.

■ 39.15.3 PLAIN – a worked example

1. Thirty-one commits. Somewhere in there, `average([1,2,4])` started returning 2.0 instead of 2.333.

```
$ ./test.sh
AssertionError: average([1,2,4]) gave 2.0
```

2. Give git a known-bad commit and a known-good commit, and a script that exits 0 for good and non-zero for bad.

```
$ git bisect start HEAD 8c84483
$ git bisect run ./check.sh
Bisecting: 14 revisions left to test (roughly 4 steps)
[e07d528] c015: routine change
running './check.sh'
Bisecting: 7 revisions left to test (roughly 3 steps)
[56821a0] c022: routine change
running './check.sh'
Bisecting: 3 revisions left to test (roughly 2 steps)
[bb1e2b9] c018: routine change
running './check.sh'
Bisecting: 0 revisions left to test (roughly 1 step)
[a83bd2e] c017: routine change
running './check.sh'
bb1e2b9ca8de5e3324381ae15dec599b8c409a9f is the first bad commit
```

3. Four tests over thirty commits, because log base 2 of 30 is about 4.9.
4. And the guilty change, which was hidden among unrelated edits.

```
- return sum(nums) / len(nums)
+ return sum(nums) // len(nums) + 0.0
```

5. Finish with `git bisect reset`, which puts you back where you started.

■ 39.15.4 PLAIN – what is really happening inside

1. Cherry-pick computes the diff of one commit against its parent, applies it here, and makes a new commit. The change is the same; the object is new.

```
original S    = 9e25370ab0a266f7b25787b2a08e719f8dd9d964
copy on main = d673ae20eb28f1b43254cad402c16571ec99e9b3

patch-id of both = c92b260713d372c3c1c2babe11f8384d5319ef45
```

2. `git cherry -v main hotfix` uses that patch identifier to say which commits on hotfix are already on main. A leading - means already there, + means not yet.
3. Revert computes the inverse diff and commits it. Reverting a merge needs `-m 1` to say which parent's line of history to keep.

```
$ git revert HEAD
error: commit 88e4ee8... is a merge but no -m option was given.

$ git revert -m 1 --no-edit HEAD
```

4. Bisect works on the graph. `git rev-list --bisect` picks the commit that splits the remaining candidates most evenly, so each answer removes about half regardless of which answer it is.
5. `git bisect run <cmd>` automates it. Exit code 0 means good, 1 to 124 and 126 to 127 mean bad, and exit code 125 means “cannot test, skip this one”.

■ 39.15.5 TECHNICAL – the engineer’s version

1. The wider toolbox:

Command	Use it when
<code>git cherry-pick -x</code>	you want a “cherry picked from”
<code>git cherry-pick -n</code>	stage without committing
<code>git revert -n</code>	revert several as one commit
<code>git bisect skip</code>	this revision cannot be tested
<code>git bisect log/replay</code>	save and rerun a bisect session
<code>git blame -C -M</code>	follow copies and moves
<code>git log -S<string></code>	find when a string appeared
<code>git log -G<regex></code>	find diffs matching a pattern
<code>git worktree add</code>	second checkout, one object store
<code>git reflog expire</code>	prune the local diary

2. History: `git rev-list --bisect` was added by Linus Torvalds on 17 June 2005, and `git-bisect-script` followed on 30 July 2005 with the commit message “Making it easier to find which change introduced a bug”.
3. `git bisect run` takes any command, so the test can be a unit test, a build, a grep on the output, or a shell one-liner. It is the highest-value five minutes in this chapter.
4. `git bisect --first-parent` (git 2.29, October 2020) confines the search to the mainline, which matters in merge-heavy repositories.
5. `git worktree` shares `.git/objects` and refs across checkouts, so a second worktree costs disk space for files only, not for history.
6. `git log -S` is a “pickaxe” search on the number of occurrences of a string; `git log -G` matches the diff text with a regular expression. They answer different questions, and `-S` is usually the one you want.

■ 39.15.6 WORDS – remember these

1. Cherry-pick — copy one change here — apply one commit’s diff and create a new commit for it.
2. Revert — undo by adding — commit the inverse of an earlier commit.
3. Bisect — binary search over history — halve the candidate range with each test until one commit remains.
4. Pickaxe — find when text appeared — `git log -S<string>`.
5. Worktree — a second checkout of one repository — an extra working directory sharing the same object database.
6. Skip — this one cannot be judged — `git bisect skip`, or exit code 125 from a `bisect run` script.

39.98 Common wrong ideas

1. Wrong: `git add` only marks a file for later. Right: it hashes the content and writes a real object into `.git/objects` immediately.
2. Wrong: the index stores differences. Right: it stores a complete snapshot, one entry per tracked file, with stat data and object IDs.
3. Wrong: `git commit` copies your files. Right: the blobs already exist; commit writes trees, one commit object, and moves a ref.
4. Wrong: a push failure means nothing was written. Right: a disconnect while reading the response says nothing about the write. Re-query with `git ls-remote`.

5. Wrong: `git status` shows the server's current state. Right: it compares against a cached remote-tracking ref that only a fetch or push updates.
6. Wrong: `git fetch` can mess up my work. Right: fetch changes only refs/remotes/* and the object database. `git pull` is the one to be careful with.
7. Wrong: rebase moves my commits. Right: it creates new commit objects with new identifiers, and leaves the old ones in the reflog.
8. Wrong: a clean merge means the code works. Right: `git` merges text, not meaning. Two non-overlapping changes can break the program completely.
9. Wrong: `git reset --hard` loses commits forever. Right: commits survive in the reflog for 90 days. Uncommitted edits, however, are gone.
10. Wrong: `--force-with-lease` is always safe. Right: it compares against your remote-tracking ref, which a background fetch can silently refresh.

39.99 Chapter summary in 20 lines

1. A tracked file exists in three places: working directory, index, object database. HEAD says which commit you are on.
2. `git status` is nothing more than two comparisons: index against HEAD, and working directory against index.
3. The index is a real binary file, `.git/index`, starting with the four bytes DIRC, present in `git`'s first commit on 7 April 2005.
4. It holds one entry per tracked file: path, object ID, mode, and cached stat data from the filesystem.
5. That stat cache is why `git status` is fast: most files are never opened, only asked about.
6. `git add` hashes the content and writes the object at once, then records its name in the index. `git add -p` can stage a version that exists nowhere.
7. `git commit` writes trees from the index, writes one commit object, and moves one ref. Three steps, in that order.
8. The index exists so you can choose what goes in a commit. Other systems manage without one; it is a design choice, not a necessity.
9. `git restore`, `git reset --soft/--mixed/--hard`, `git revert`, `git clean` and `git stash` differ only in which of the three places they touch.
10. Only `git reset --hard` and `git clean` can destroy work that `git` never stored. Everything else is recoverable through the reflog.
11. A push sends one packfile of only the missing objects, framed in pkt-lines, with three sideband channels: data, progress, fatal error.
12. Twenty commits is one round trip, not twenty. In the real measurement, sixty objects in 3.95 KiB.
13. `send-pack`: unexpected disconnect while reading sideband packet means the pack was sent and the reply never arrived.
14. That error is identical whether the server applied the write or not. Both cases were reproduced. Only `git ls-remote` can tell you which happened.
15. In the reader's session both pushes had not applied, and that was established by re-querying, not by reading the error.
16. `git fetch` changes only remote-tracking refs and the object store. `git pull` adds an integration step that touches your files.
17. Merge finds the common ancestor and does a three-way merge; fast-forward needs no commit because the old tip is already an ancestor.
18. Conflicts are `git` refusing to guess about overlapping text. Semantic conflicts merge cleanly and still break the code.

19. Rebase replays each commit onto a new parent, so every commit gets a new identifier even though the patch identifier is unchanged.
20. Rebase your own unpushed work freely; never rewrite history other people already hold, and prefer `--force-with-lease` when you must force.

Your Own Git Server, and What GitHub Adds

40.0 What this chapter gives you

1. You will be able to say, in one sentence, what a git server is, and prove it by building one in an empty folder in under a second.
2. You will be able to explain what `--bare` means, what a bare repository contains, what it deliberately lacks, and why pushing into a normal repository's checked-out branch is refused by default.
3. You will be able to run the whole loop yourself: create a server repository, push to it, clone it somewhere else, commit there, push back, and pull the change into the first copy, with real output at every step.
4. You will be able to do the same thing over SSH and see that a remote URL is nothing but a path plus a way of getting to it.
5. You will be able to read and write a refspec, and say exactly what `+refs/heads/*:refs/remotes/origin/*` does, character by character.
6. You will be able to write a server-side hook that deploys a website on every push, and say why a client-side hook is a helper and never a rule.
7. You will be able to state precisely what GitHub is: hosting for bare repositories, plus a web interface, plus identity and permissions, plus automation, founded in 2008 and bought by Microsoft in 2018 for 7.5 billion United States dollars.
8. You will be able to sort every feature you use into "this is git" or "this is GitHub", and defend each answer.
9. You will be able to explain the reader's own outage exactly: why git kept working while the GitHub API did not, using a three-column table of operations.
10. You will be able to choose between GitHub, a self-hosted Forgejo or GitLab, and a plain SSH remote with no web interface at all, and say what you gain and what you take on.
11. You will be able to mirror, migrate and back up a repository properly, and say what a backup of git does not cover.

40.1 A git server is just another repository

■ 40.1.1 PLAIN – in simple words

1. Here is the whole idea of this chapter in one line.
2. A git "server" is just another git repository that other machines can reach.
3. That is all. There is no server program that must be bought. There is no special file format. There is no central authority.
4. Every copy of a git repository holds the full history. Every copy can send history to another copy and receive history from another copy.

5. So a “server” is only a copy that everybody agrees to treat as the meeting point.
6. We call it the server because of where it sits and who can reach it, not because of what it is made of.
7. The one thing a meeting-point copy usually does differently is that it has no working files. Only the history. We will see why in the next section.
8. Everything else in this chapter is proof of that single claim.

■ 40.1.2 PLAIN – a picture in your head

1. Think of a study group of four students who each keep a notebook of the same lecture course.
2. Each notebook is complete. Any student can copy pages from any other student.
3. The group decides to leave one spare notebook in the department office, because the office is open to all four and nobody has to chase anybody.
4. The office notebook is not magic. It is the same kind of notebook. It has the same pages. It is special only because everyone can walk to it.
5. If the office burns down, the course is not lost. Four complete notebooks still exist in four bags.
6. That is exactly the relationship between your laptop’s repository and the one you call the server.

Where this comparison breaks:

7. Copying pages by hand is slow and error-prone. Git copies exactly, and it copies only the pages the other side is missing.
8. Two students writing on the same page at the same time makes a mess. Git refuses that case rather than making a mess: it rejects the push and makes you combine the work first.
9. And a notebook has one order of pages. Git history is a graph, so two students can genuinely have two different valid orders at once.

■ 40.1.3 PLAIN – a worked example

1. We will use three folders on one machine for the whole chapter. One machine is enough to prove the point, because git does not know or care whether the other repository is across the room or across the world.
2. The layout is this.

/tmp/lab/proj	your working copy, folder number one
/tmp/lab/srv/proj.git	the "server", a repository with no files
/tmp/lab/copy	a second working copy, folder number three

3. Here is a real repository being created and given two commits. Every block in this chapter is real output from a real run, not an illustration.

```
$ git init proj
Initialized empty Git repository in /tmp/lab/proj/.git/

$ git add README.md && git commit -m "First commit: add README"
[main (root-commit) 041c4ad] First commit: add README
1 file changed, 1 insertion(+)
create mode 100644 README.md

$ git add app.py && git commit -q -m 'Add app.py' && git log --oneline
08391eb Add app.py
041c4ad First commit: add README
```

4. Two commits exist. Nothing has touched a network. Nothing has touched a server, because there is not one yet.

5. In the next section we will make the server, and it will take one command and about ten milliseconds.

■ 40.1.4 PLAIN – what is really happening inside

1. When two git repositories talk, one of them runs a small program that reads history out, and the other runs a small program that writes history in.
2. The reading program is called `git-upload-pack`. It says “here are all the names I have and what they point to”, and then sends whatever objects the other side asks for.
3. The writing program is called `git-receive-pack`. It accepts a bundle of objects and a list of name changes, and applies them.
4. When you type `git fetch`, your git starts `git-upload-pack` on the other side and reads from it.
5. When you type `git push`, your git starts `git-receive-pack` on the other side and writes to it.
6. That is the entire client and server story. Two small programs and a way to connect their inputs and outputs.
7. If the other repository is a folder on the same disk, git simply runs the program directly. No network at all.
8. If it is on another machine, git needs some way to run that program over there and pipe bytes back and forth. That is what SSH does. That is what HTTPS does, with a small wrapper. That is what the git protocol does.
9. So the phrase “git server” really means “a machine willing to run `git-upload-pack` and `git-receive-pack` on a repository for you”.

■ 40.1.5 TECHNICAL – the engineer’s version

1. Git’s wire protocol is a framed byte stream called **pkt-line**. Each frame begins with four hexadecimal digits giving the frame’s total length, including those four digits. The value `0000` is a flush packet and marks the end of a section.
2. We can see the raw advertisement by running the server program by hand over SSH. This is the real output, trimmed on the right to fit the page.

```
$ ssh gitbox 'git upload-pack --advertise-refs \
/tmp/lab/srv/proj.git' | cat -A | head -3
010b64952410dab49907fec630138e55e7504834b082 HEAD^@multi_ack
thin-pack side-band side-band-64k ofs-delta shallow ...
symref=HEAD:refs/heads/main object-format=sha1
agent=git/2.43.0$
003d64952410dab49907fec630138e55e7504834b082 refs/heads/main$
0000
```

3. Read the first line. `010b` is hexadecimal for 267, the length of that frame. Then a 40-character SHA-1, a space, the ref name `HEAD`, a NUL byte (shown by `cat -A` as `^@`), and then the capability list.
4. The second frame is `003d`, hexadecimal for 61: four length digits, 40 hash characters, one space, `refs/heads/main` at 15 characters, and one newline. That is $4 + 40 + 1 + 15 + 1 = 61$. The framing is exact.
5. `0000` ends the advertisement.
6. Protocol versions: version 0 is the original, version 1 adds a version string, and **protocol v2** was introduced in Git 2.18 (June 2018) and made the default for fetch in Git 2.26 (March 2020). Version 2 lets the client ask for a filtered ref list instead of receiving every ref up front, which matters on repositories with tens of thousands of refs.
7. The four transports and how the server program is started:

Transport	How the program starts	Default port
local path	run directly by your git	none
ssh	remote shell command	22
https	git-http-backend via CGI	443
git	git-daemon	9418

- Port 9418 is registered with IANA for the git protocol. The git protocol has no authentication and no encryption, which is why GitHub permanently disabled unencrypted `git://` access on 15 March 2022.
- Commands that observe this layer: `git ls-remote`, `GIT_TRACE=1 git fetch`, `GIT_TRACE_PACKET=1 git fetch`, and `git daemon --verbose`.

■ 40.1.6 WORDS – remember these

- Repository — a project’s full history plus its settings — a directory containing an object database, a ref namespace and a configuration file.
- Server — the copy everybody can reach — any repository exposed through a transport that can start upload-pack or receive-pack.
- upload-pack — the program that sends history out — the server side of fetch and clone, which advertises refs and streams a packfile.
- receive-pack — the program that takes history in — the server side of push, which validates ref updates and runs the receive hooks.
- pkt-line — git’s way of cutting a stream into labelled chunks — a framing format with a four-hex-digit length prefix and 0000 as flush.
- Transport — the road the bytes travel on — the mechanism (file, ssh, http, git) that connects the two programs’ standard input and output.

40.2 Bare repositories

■ 40.2.1 PLAIN – in simple words

- A normal repository has two parts: the files you edit, and a hidden folder called `.git` that holds the history.
- A **bare repository** is the second part on its own. The history, with no files to edit.
- You make one with `git init --bare`. By convention its folder name ends in `.git`, for example `proj.git`.
- A bare repository is what you use for a server, because a server has nobody sitting at it editing files.
- It is missing two things on purpose: a working tree (the actual editable files) and an index (git’s staging list of what will go into the next commit).
- Those two things only make sense when a human is working. A server has no human working in it.
- You cannot run `git status` usefully in a bare repository, because there is no working tree to compare against.
- You can run `git log`, `git show`, `git cat-file` and everything else that only reads history, because all of the history is right there.

■ 40.2.2 PLAIN – a picture in your head

1. Think of a normal repository as a desk. On the desk are the pages you are writing. In a drawer under the desk is the complete archive of every version ever saved.
2. A bare repository is the drawer, on its own, in a storeroom. No desk.
3. You can pull any past version out of the drawer. You just cannot scribble on anything, because there is no desk surface.
4. When somebody pushes, they are handing new folders into the drawer and updating the labels on the front.

Where this comparison breaks:

5. A drawer takes more space as you add papers. Git's drawer stores each distinct version once and stores similar versions as small differences, so it grows far more slowly than the total of all versions.
6. And a real drawer does not check what you put in it. Git verifies every object against its hash on the way in and on the way out.

■ 40.2.3 PLAIN – a worked example

1. Here are the two kinds side by side, from a real run.

```
$ git init --bare srv/proj.git
Initialized empty Git repository in /tmp/lab/srv/proj.git/

$ ls -l /tmp/lab/proj/.git      $ ls -l /tmp/lab/srv/proj.git
COMMIT_EDITMSG                HEAD
HEAD                          branches
branches                      config
config                        description
description                   hooks
hooks                         info
index                         objects
info                          refs
logs
objects
```

2. Look at what matches. HEAD, branches, config, description, hooks, info, objects, refs are in both. That is the whole history machinery.
3. Look at what only the normal repository has: index, logs and COMMIT_EDITMSG. Those are all about a person doing work here.
4. And the normal repository has one more thing that the bare one does not: the actual files, one level up.

```
$ ls -l /tmp/lab/proj
README.md
app.py
```

5. Git records the difference in one configuration setting.

```
$ git -C /tmp/lab/proj config --get core.bare
false

$ git -C /tmp/lab/srv/proj.git config --get core.bare
true
```

```
$ cat /tmp/lab/srv/proj.git/config
[core]
    repositoryformatversion = 0
    filemode = true
    bare = true
```

6. That is the entire difference at the configuration level. One boolean.

■ 40.2.4 PLAIN – what is really happening inside

1. Now the important part: why you cannot push into a normal repository's checked-out branch.
2. A checked-out branch means three things are supposed to agree: the branch pointer, the index, and the files on disk.
3. If somebody pushes new commits into that branch from outside, git would move the branch pointer but would not touch the index or the files.
4. The person sitting at that repository would then be told they have deleted everything that arrived, because their files no longer match their branch.
5. So git refuses. Here is the real refusal, with the long lines wrapped to fit this page and nothing else changed.

```
$ git push wt main
remote: error: refusing to update checked out branch:
refs/heads/main
remote: error: By default, updating the current branch in a
non-bare repository is denied, because it will make the
index and work tree inconsistent with what you pushed, and
will require 'git reset --hard' to match the work tree to
HEAD.
remote:
remote: You can set the 'receive.denyCurrentBranch'
configuration variable to 'ignore' or 'warn' in the remote
repository to allow pushing into its current branch;
however, this is not recommended unless you arranged to
update its work tree to match what you pushed in some
other way.
To /tmp/lab/wt
! [remote rejected] main -> main (branch is currently
checked out)
error: failed to push some refs to '/tmp/lab/wt'
```

6. Read the message closely. It does not say “you may not do this”. It says “this would make the index and work tree inconsistent”.
7. A bare repository has no index and no work tree, so there is nothing to make inconsistent, so the refusal never applies.
8. That is the real reason servers use bare repositories. Not policy. Arithmetic.

■ 40.2.5 TECHNICAL – the engineer's version

1. `git init --bare` sets `core.bare = true` and lays the repository contents directly in the given directory rather than in a `.git` subdirectory.
2. Contents of a bare repository, and what each part is:

Entry	What it holds
HEAD	symbolic ref, usually <code>refs/heads/main</code>
objects/	the object database

Entry	What it holds
refs/	loose refs, heads and tags
packed-refs	refs collapsed into one file
config	repository configuration
hooks/	executable hook scripts
info/	exclude file, alternates, http info

- Absent from a bare repository: index (the staging area, a binary file in the format documented as the git index format, version 2, 3 or 4), the working tree, logs/ unless `core.logAllRefUpdates` is turned on, and `COMMIT_EDITMSG`.
- The refusal above comes from `receive.denyCurrentBranch`, whose default is `refuse`. Related settings are `receive.denyDeleteCurrent`, default `refuse`, and `receive.denyNonFastForwards`, default `false`.
- Three ways to make a bare repository, all equivalent in result:

```
git init --bare proj.git
git clone --bare /path/to/proj proj.git
git clone --mirror /path/to/proj proj.git
```
- They differ in what refs come along. `--bare` from `init` starts empty. `clone --bare` copies branches and tags but sets no `fetch refspec`. `clone --mirror` copies every ref under `refs/*` and configures the repository to keep tracking them. We measure that difference in 40.10.
- There is a fourth arrangement worth knowing: a non-bare repository with `receive.denyCurrentBranch = updateInstead`. Then a push into the checked out branch also updates the working tree, provided the working tree is clean. This is useful for a small deploy target and is handled by the `push-to-checkout` hook.
- Observation commands: `git rev-parse --is-bare-repository`, `git rev-parse --git-dir`, `git count-objects -vH`.

■ 40.2.6 WORDS – remember these

- Bare repository — the history with no editable files — a repository with `core.bare = true`, containing the object database and refs at top level, with no working tree and no index.
- Working tree — the files you actually edit — the checked-out state of one commit, materialized on the filesystem.
- Index — git's list of what goes in the next commit — a binary file mapping paths to blob hashes and stat data, also used during merges.
- Checked-out branch — the branch you are currently on — the branch named by the symbolic ref `HEAD`.
- `denyCurrentBranch` — the rule that stops pushes into a busy branch — the `receive.denyCurrentBranch` configuration key, default `refuse`.

40.3 Doing it end to end

■ 40.3.1 PLAIN – in simple words

- We will now do the whole loop, with nothing hidden.
- Make a server repository. Tell your project about it. Send your history.
- Copy the server repository into a fresh folder as if you were a second person on a second machine.
- Make a commit in that fresh folder. Send it to the server.

5. Go back to the first folder. Bring the change down. Now both folders and the server agree.
6. Then we do the same thing again over SSH, to show that the only thing that changed is the address.
7. Here is the shape of the whole thing.

■ 40.3.2 PLAIN – a picture in your head

1. Think of a shared drop box in a corridor between two rooms.
2. You put a copy of your work in the box. The person in the other room takes a copy out.
3. They add a page and put their copy back in. You take the new page.
4. Nobody ever has to be in the corridor at the same time. The box holds the agreed state.
5. Git's box is smarter than a real one, because it never loses the older versions when a new one arrives. It stacks them all, in order, with each one pointing at the one before.

Where this comparison breaks:

6. A drop box has no opinion. Git's box refuses anything that would erase history it already holds, unless you force it explicitly.
7. And a drop box holds one thing at a time. Git's box holds many named lines of work at once, one name per branch.

■ 40.3.3 PLAIN – a worked example

1. Step one. Point the project at the server and push.

```

$ git remote add origin /tmp/lab/srv/proj.git

$ git remote -v
origin /tmp/lab/srv/proj.git (fetch)
origin /tmp/lab/srv/proj.git (push)

$ git push -u origin main
To /tmp/lab/srv/proj.git
 * [new branch]      main -> main
branch 'main' set up to track 'origin/main'.
  
```

2. The server now really has the history. Look inside it directly.

```

$ ls -l /tmp/lab/srv/proj.git/refs/heads
main

$ cat /tmp/lab/srv/proj.git/refs/heads/main
fa776d1882d36bdc0af68926f71ff710cdea281a

$ git -C /tmp/lab/srv/proj.git log --oneline
fa776d1 Change app.py
08391eb Add app.py
041c4ad First commit: add README
  
```

3. A branch on the server is one file containing one 40-character hash. That is all a branch has ever been.
4. Step two. Clone it into a third folder, as a second person would.

```
$ git clone /tmp/lab/srv/proj.git /tmp/lab/copy
Cloning into '/tmp/lab/copy'...
done.

$ git -C /tmp/lab/copy log --oneline
fa776d1 Change app.py
08391eb Add app.py
041c4ad First commit: add README

$ git -C /tmp/lab/copy branch -a
* main
remotes/origin/HEAD -> origin/main
remotes/origin/main
```

5. Step three. Commit in the copy and push it back. This is the terminal view, where the percentage counters overwrite themselves in place.

```
$ git add NOTES.md && git commit -q -m 'Add NOTES.md'

$ git push --progress origin main
Enumerating objects: 4, done.
Counting objects: 100% (4/4), done.
Delta compression using up to 2 threads
Compressing objects: 100% (2/2), done.
Writing objects: 100% (3/3), 328 bytes | 328.00 KiB/s, done.
Total 3 (delta 0), reused 0 (delta 0), pack-reused 0
To /tmp/lab/srv/proj.git
fa776d1..249b3ed main -> main
```

6. Three objects and 328 bytes went across: one commit, one tree, one blob. Nothing else was sent, because the server already had everything else.
7. Step four. Back in folder one, fetch first so you can see the two halves of a pull separately.

```
$ git status -sb
## main...origin/main

$ git fetch origin
From /tmp/lab/srv/proj
fa776d1..249b3ed main -> origin/main

$ git status -sb
## main...origin/main [behind 1]

$ ls
README.md
app.py
```

8. Read that carefully. After fetch, git knows about the new commit and says you are behind by one. But ls shows no new file. Fetch changed nothing in your working tree. It only downloaded history.
9. Now pull, which is fetch plus merge.

```
$ git pull
Updating fa776d1..249b3ed
```

```
Fast-forward
NOTES.md | 1 +
1 file changed, 1 insertion(+)
create mode 100644 NOTES.md

$ ls
NOTES.md
README.md
app.py
```

10. The loop is closed. Three repositories, one history, no service, no account, no web page.

■ 40.3.4 PLAIN - what is really happening inside

1. Now the same thing over SSH, to prove the point of this chapter.
2. A remote URL has two parts: how to get there, and where it is once you arrive. Change the first part and nothing else changes.

```
$ git remote add ssh-origin \
    ssh://root@127.0.0.1:2222/tmp/lab/srv/proj.git

$ git ls-remote ssh-origin
249b3edc818ac4a38fc39b982e19a880675326de    HEAD
249b3edc818ac4a38fc39b982e19a880675326de    refs/heads/main
```

3. Exactly the same repository, reached a different way. Now push to it.

```
$ git commit -q -am 'Document how to run app'

$ git push ssh-origin main
To ssh://127.0.0.1:2222/tmp/lab/srv/proj.git
    249b3ed..6495241  main -> main

$ git -C /tmp/lab/srv/proj.git log --oneline -1
6495241 Document how to run app
```

4. And clone over SSH using the short form, which needs an entry in your SSH configuration file because the short form cannot carry a port number.

```
$ cat /root/.ssh/config
Host gitbox
    HostName 127.0.0.1
    Port 2222
    User root
    IdentityFile /root/.ssh/id_ed25519

$ git clone gitbox:/tmp/lab/srv/proj.git /tmp/lab/viassh
Cloning into '/tmp/lab/viassh'...

$ git -C /tmp/lab/viassh log --oneline -2
6495241 Document how to run app
249b3ed Add NOTES.md
```

5. What SSH actually did was log in and run one command. Here is git's own verbose trace of that decision, reproduced by running the command by hand.

```
$ ssh gitbox 'git upload-pack --advertise-refs \
    /tmp/lab/srv/proj.git' | head -c 60
010b64952410dab49907fec630138e55e7504834b082 HEAD
```

6. So SSH is not doing anything clever. It is a remote login that runs `git-upload-pack` or `git-receive-pack` and connects the pipes.
7. That is why an SSH remote needs no git-specific server software at all. If the account can log in and git is installed, you have a git server.

■ 40.3.5 TECHNICAL – the engineer’s version

1. The git protocol also works, which shows the third transport. Here is a real git daemon serving the same bare repository.

```
$ git daemon --reuseaddr --base-path=/tmp/lab/srv \
  --export-all --verbose

$ git ls-remote git://127.0.0.1/proj.git
a2648f3588da557802930bc984745c8a574b7a38      HEAD
8a65572b3a58cded170998be063e26b8cbea76e6      refs/heads/demo
0327736b4327edde443c3dfa9456555015d0b3f4      refs/heads/feature/login
a2648f3588da557802930bc984745c8a574b7a38      refs/heads/main
c541c6934d9bd45d02e86d902253422366134e87      refs/notes/commits
9ee3b0bda37deeffc6317b5dcda3c483895f490c      refs/tags/v1.0
```

2. The daemon log confirms protocol v2 and which program was requested.

```
[17254] Ready to rumble
[17260] Connection from 127.0.0.1:42896
[17260] Extended attribute "host": 127.0.0.1
[17260] Extended attribute "protocol": version=2
[17260] Request upload-pack for '/proj.git'
[17254] [17260] Disconnected
```

3. And the git protocol is read-only unless you go out of your way, because it has no authentication:

```
$ git push origin main
fatal: remote error: access denied or repository not exported:
/proj.git
```

4. Timings and sizes from this run, on a small repository:

Operation	Objects	Bytes on wire
push of one commit	3	328
bare repo, loose	41	164.00 KiB
bundle of all refs	all	3.1 KiB

5. Server-side authorization for SSH remotes is normally done by the account, not by git. The standard pattern on a self-hosted box is a single git user whose `~/.ssh/authorized_keys` has one line per developer key, each line prefixed with `command="git-shell -c \"$SSH_ORIGINAL_COMMAND\""` plus `no-port-forwarding,no-agent-forwarding,no-pty`.
6. `git-shell` is a restricted login shell shipped with git that only permits `git-upload-pack`, `git-upload-archive` and `git-receive-pack`. It has existed since the early git releases and is the simplest real access control you can deploy.
7. Useful environment variables for debugging transports: `GIT_TRACE=1`, `GIT_TRACE_PACKET=1`, `GIT_SSH_COMMAND`, `GIT_CURL_VERBOSE=1`.

■ 40.3.6 WORDS – remember these

1. Remote — a saved nickname for another repository — a named set of configuration keys holding one or more URLs and one or more refsspecs.
2. origin — the usual nickname for where you cloned from — a convention, set automatically by `git clone`, changeable with `git clone -o name`.
3. Fetch — download history without touching your files — updating remote-tracking refs and the object database only.
4. Pull — fetch and then combine — `git fetch` followed by `git merge` or `git rebase`, depending on `pull.rebase`.
5. Fast-forward — moving a branch pointer along a straight line — an update where the old commit is an ancestor of the new one, so no merge is needed.
6. git-shell — a login shell that only allows git — a restricted shell that rejects every command except the three git transport programs.

40.4 Remotes in depth

■ 40.4.1 PLAIN – in simple words

1. A remote is a saved nickname for another repository.
2. Instead of typing a long address every time, you say `origin` and git looks up the address.
3. You can have as many remotes as you like. They are just entries in a text file inside your repository.
4. The address can take four shapes: a plain folder path, an SSH address, an HTTPS address, or a `git://` address.
5. You can add a remote, rename it, change its address and delete it, and none of that touches your history at all. It is only a phone book entry.
6. A remote also carries a rule that says which of the other side's names get copied into which of your names. That rule is called a **refspec**.
7. The refspec is the part that most people never read, and it is the part that explains almost every confusing thing about push and fetch.

■ 40.4.2 PLAIN – a picture in your head

1. Think of the contacts list in a phone.
2. `origin` is a contact name. Behind it sits a number.
3. Changing the number does not change any of your past conversations. It only changes where the next call goes.
4. Deleting the contact does not delete the conversations either.
5. Now imagine each contact also has a filing rule attached: “anything this person sends me goes in the folder named after them”. That is the refspec.
6. So messages from Anita land in a folder called Anita, and messages from Bala land in a folder called Bala, and they never overwrite each other even if both send a file with the same name.

Where this comparison breaks:

7. A phone contact has one number. A git remote can have one address for reading and several different addresses for writing.
8. And a filing rule in a phone is your private business. A refspec is negotiated with the other side, because the other side must agree that the names you ask for exist.

■ 40.4.3 PLAIN – a worked example

1. Everything about a remote lives in the repository's configuration file. Here is the real file after adding two remotes.

```
$ cat .git/config
[core]
    repositoryformatversion = 0
    filemode = true
    bare = false
    logallrefupdates = true
[remote "origin"]
    url = /tmp/lab/srv/proj.git
    fetch = +refs/heads/*:refs/remotes/origin/*
[branch "main"]
    remote = origin
    merge = refs/heads/main
[remote "ssh-origin"]
    url = ssh://root@127.0.0.1:2222/tmp/lab/srv/proj.git
    fetch = +refs/heads/*:refs/remotes/ssh-origin/*
```

2. Now the refspec, character by character. The value is:

```
| +refs/heads/*:refs/remotes/origin/*
```

3. It splits at the colon into a source and a destination.

Part	Meaning
+	allow a non-fast-forward update
refs/heads/*	source: every branch over there
:	separator
refs/remotes/origin/*	destination: my copy of them

4. In plain words: “take every branch on the other side, and store it under a name of mine that begins with refs/remotes/origin/, and let it move backwards or sideways if it has to.”
5. So the other side's main becomes your refs/remotes/origin/main, which you normally type as origin/main.
6. This is why origin/main is not a branch you can commit on. It is a read-only copy of a name that lives somewhere else.
7. Watch the destination folder appear on disk after fetching from two different remotes.

```
$ ls -R .git/refs
.git/refs:
heads
remotes
tags

.git/refs/heads:
main

.git/refs/remotes:
origin
ssh-origin

.git/refs/remotes/origin:
main
```

```
.git/refs/remotes/ssh-origin:
main
```

- Now push with an explicit refspec, which lets you send a local branch to a differently named remote branch.

```
$ git push origin HEAD:refs/heads/wip-login
To /tmp/lab/srv/proj.git
 * [new branch]      HEAD -> wip-login

$ git ls-remote origin
64952410dab49907fec630138e55e7504834b082    HEAD
64952410dab49907fec630138e55e7504834b082    refs/heads/main
0327736b4327edde443c3dfa9456555015d0b3f4    refs/heads/wip-login
```

- And an empty source means “delete the destination”. That is the whole trick behind deleting a remote branch.

```
$ git push origin :refs/heads/wip-login
To /tmp/lab/srv/proj.git
 - [deleted]         wip-login

$ git ls-remote origin
64952410dab49907fec630138e55e7504834b082    HEAD
64952410dab49907fec630138e55e7504834b082    refs/heads/main
```

- `git push origin --delete wip-login` is a friendlier spelling of exactly the same refspec.

■ 40.4.4 PLAIN - what is really happening inside

- The leading `+` deserves its own demonstration, because it is the difference between “I refuse to lose history” and “overwrite it”.
- We put a commit on a branch, copy it with a refspec that has no `+`, then rewrite the commit on the server, then fetch again.

```
$ git fetch -q origin \
    '+refs/heads/demo:refs/remotes/nf/demo'
$ git rev-parse --short refs/remotes/nf/demo
4f4b9de
```

- Now the branch is rewritten on the server, with `git commit --amend` followed by a force push. The old commit `4f4b9de` becomes `8a65572`, and the two are not ancestors of each other.

```
$ git push --force origin demo
To /tmp/lab/srv/proj.git
 + 4f4b9de...8a65572 demo -> demo (forced update)
```

- Fetch with a refspec that has no `+`, and git refuses. Fetch with `+`, and git obeys. The same command, run twice, differing by one character.

```
$ git fetch origin refs/heads/demo:refs/remotes/nf/demo
From /tmp/lab/srv/proj
 ! [rejected]         demo -> nf/demo (non-fast-forward)
 + 4f4b9de...8a65572 demo -> origin/demo (forced update)

$ git fetch origin '+refs/heads/demo:refs/remotes/nf/demo'
From /tmp/lab/srv/proj
 + 4f4b9de...8a65572 demo -> nf/demo (forced update)
```

```
$ git rev-parse --short refs/remotes/nf/demo
8a65572
```

5. Notice something in the middle of the first result. `nf/demo` was rejected, and in the very same command `origin/demo` was force-updated.
6. That is because the default refspec for `origin` has the `+`, and the one we typed by hand did not. Two rules, one fetch, two different outcomes.
7. That single output block explains the whole meaning of the plus sign better than any paragraph could.

■ 40.4.5 TECHNICAL - the engineer's version

1. URL forms, all four, with real examples from this chapter's run:

Form	Example
local path	<code>/tmp/lab/srv/proj.git</code>
ssh, full	<code>ssh://root@host:2222/tmp/proj.git</code>
ssh, short	<code>gitbox:/tmp/lab/srv/proj.git</code>
https	<code>https://github.com/git/git</code>
git	<code>git://127.0.0.1/proj.git</code>

2. The short SSH form, `user@host:path`, is called the scp-like syntax. It cannot express a port number. If you need a non-default port you must use the `ssh://` form or a `Host` block in `~/.ssh/config`. That is a real limitation, not a style preference.
3. In the `ssh://` form the path is absolute. In the scp-like form the path is relative to the login user's home directory unless it starts with a slash. This trips people up constantly.
4. Remote management commands:

```
git remote add <name> <url>
git remote rename <old> <new>
git remote remove <name>
git remote set-url <name> <newurl>
git remote set-url --push <name> <pushurl>
git remote set-url --add --push <name> <another>
git remote show <name>
git remote prune <name>
```

5. Different fetch and push URLs are genuinely useful. Here we set one remote that reads from one place and writes to two, so a single push updates both a primary and a backup.

```
$ git remote -v
both    /tmp/lab/srv/proj.git (fetch)
both    /tmp/lab/srv/proj.git (push)
both    /tmp/lab/srv/mirror.git (push)

$ git push both main
Everything up-to-date
To /tmp/lab/srv/mirror.git
* [new branch]      main -> main
```

6. Common reasons to have several remotes:

Situation	Typical remotes
you forked a project	origin, upstream
migrating platforms	origin, newhost
offsite backup	origin, backup
internal plus public	origin, public

7. Refspec grammar, stated properly. A refspec is `[+]<src>[:<dst>]`. For fetch, `src` is a ref on the remote and `dst` is a ref in your repository. For push, `src` is a local ref or any expression that resolves to a commit, and `dst` is a ref on the remote. The `+` sets the force flag for that one mapping. An empty `src` on push means delete `dst`. An omitted `dst` on fetch means “download it but only record it in `FETCH_HEAD`”.
8. A remote may carry several fetch refs. Adding one is how you fetch GitHub pull-request refs:

```
git config --add remote.origin.fetch \
    '+refs/pull/*/head:refs/remotes/origin/pr/*'
```

9. URL rewriting is a useful production trick. `insteadOf` rewrites a prefix for all commands:

```
$ git config --global \
    url.'ssh://root@127.0.0.1:2222/tmp/lab/srv/'.insteadOf 'kb:'

$ git ls-remote kb:proj.git | head -1
a2648f3588da557802930bc984745c8a574b7a38    HEAD
```

10. `pushInsteadOf` does the same but only for pushes, which is the standard way to clone over HTTPS in continuous integration while pushing over SSH from a developer machine using the same recorded URL.

■ 40.4.6 WORDS – remember these

1. Refspec — the rule that maps their names onto your names — a string of the form `[+]<src>[:<dst>]` used by fetch and push.
2. Remote-tracking ref — your read-only copy of their branch — a ref under `refs/remotes/<remote>/`, updated only by fetch, push and remote prune.
3. Force flag — permission to lose history on one ref — the `+` prefix in a refspec, or `--force` on the command line.
4. Scp-like syntax — the short SSH address form — `user@host:path`, which cannot carry a port number.
5. `insteadOf` — a find-and-replace for remote addresses — configuration keys `url.<base>.insteadOf` and `url.<base>.pushInsteadOf`.
6. `FETCH_HEAD` — a scratch note of what the last fetch brought — a file listing the refs and hashes downloaded by the most recent fetch.

40.5 Hooks: server-side and client-side

■ 40.5.1 PLAIN – in simple words

1. A **hook** is a small program that git runs automatically at a certain moment.
2. Hooks live in the `hooks` directory of a repository. They are ordinary executable files. Shell, Python, anything the machine can run.
3. Git ships them as `.sample` files, which are inert. Rename one to remove the `.sample` and it becomes live.

4. There are hooks that run on your own machine, and hooks that run on the server when a push arrives.
5. The three important server hooks are pre-receive, update and post-receive.
6. pre-receive runs once for the whole push, before anything is saved. If it exits with a non-zero status, the entire push is rejected.
7. update runs once per branch or tag being changed. It can reject one branch and let the others through.
8. post-receive runs once after everything is saved. It cannot reject anything. It is for doing things afterwards: deploying, notifying, triggering a build.
9. Client hooks such as pre-commit and commit-msg run on your own machine. They are helpful, and they are not enforcement, because anybody can skip them with one flag.

■ 40.5.2 PLAIN – a picture in your head

1. Think of a building with a security desk at the entrance and a noticeboard inside.
2. pre-receive is the guard who checks the whole delivery at the door. If any item on the trolley is wrong, the whole trolley goes back.
3. update is a second guard who checks each box on the trolley separately. Some boxes may pass while others are turned away.
4. post-receive is the person who, once the delivery is inside, updates the noticeboard and phones the department that ordered it. That person cannot send the delivery back. It is already in.
5. Client hooks are the checklist taped to your own desk before you leave the house. Useful. Easy to ignore.

Where this comparison breaks:

6. A guard can be persuaded. A hook is a program and does exactly what it says, every time, with no judgement.
7. And a real guard sees the whole delivery. A hook sees only three pieces of text per ref: the old hash, the new hash and the ref name. Everything else it must look up for itself.

■ 40.5.3 PLAIN – a worked example

1. Here is a real, working post-receive hook that deploys a website. It is in the server repository at hooks/post-receive and is executable.

```
#!/bin/sh
# Deploy the site when main is updated.
DEPLOY_DIR=/tmp/lab/www
BRANCH=refs/heads/main

while read old new ref
do
    if [ "$ref" = "$BRANCH" ]; then
        echo "post-receive: deploying $ref"
        echo "post-receive: old=$(git rev-parse --short $old)"
        echo "post-receive: new=$(git rev-parse --short $new)"
        git --work-tree="$DEPLOY_DIR" --git-dir=. checkout -f main
        echo "post-receive: deployed to $DEPLOY_DIR"
    else
        echo "post-receive: ignoring $ref"
    fi
done
```

2. Line by line, because every line earns its place.
3. `#!/bin/sh` is the shebang. It tells the kernel which interpreter to run. Without it, git will try to execute the file directly and fail.
4. `DEPLOY_DIR` is where the website files should end up. In production this would be the directory your web server serves.
5. `BRANCH` is the only branch we deploy. Pushing a feature branch must not change the live site.
6. `while read old new ref` is the key line. Git feeds `post-receive` one line per updated ref on standard input, and each line has exactly three fields: the hash before, the hash after, and the full ref name.
7. The `if` compares the ref name to `refs/heads/main`. Note it is the full ref name, not the short name. A hook never sees `main` on its own.
8. `git rev-parse --short` turns a 40-character hash into a 7-character one for the log line. For a brand new branch the old hash is forty zeros.
9. The deploy line is the interesting one. `--work-tree` tells git to put the files somewhere other than the repository, and `--git-dir=.` says the history is right here. `checkout -f main` then writes every file of `main` into the deploy directory, overwriting whatever is there.
10. `echo` output from a server hook is sent back to the person pushing, prefixed with `remote:.` That is how you talk to your users.
11. Now the real push, with the hook live. The deploy directory was empty before this command.

```
$ git add index.html && git commit -q -m 'Add home page'

$ git push origin main
remote: post-receive: deploying refs/heads/main
remote: post-receive: old=6495241
remote: post-receive: new=adb4a16
remote: Already on 'main'
remote: post-receive: deployed to /tmp/lab/www
To /tmp/lab/srv/proj.git
    6495241..adb4a16  main -> main

$ ls -la /tmp/lab/www
-rw-r--r-- 1 root root  21 Aug 13 03:12 NOTES.md
-rw-r--r-- 1 root root  47 Aug 13 03:12 README.md
-rw-r--r-- 1 root root  18 Aug 13 03:12 app.py
-rw-r--r-- 1 root root  17 Aug 13 03:12 index.html

$ cat /tmp/lab/www/index.html
<h1>KedByte</h1>
```

12. That is a complete deployment system in fourteen lines of shell. No service, no agent, no vendor.

■ 40.5.4 PLAIN - what is really happening inside

1. Now the two hooks that can say no. First `pre-receive`, enforcing a branch naming policy.

```
#!/bin/sh
fail=0
while read old new ref
do
    case "$ref" in
        refs/heads/main)      ok=yes ;;
        refs/heads/feature/*) ok=yes ;;
        refs/tags/*)          ok=yes ;;
        refs/notes/*)         ok=yes ;;
        *)                    ok=no  ;;
    esac
done
```

```

esac
if [ "$ok" = "no" ]; then
    echo "policy: bad branch name: $ref"
    fail=1
fi
done
if [ "$fail" = "1" ]; then
    echo "policy: whole push rejected"
    exit 1
fi
exit 0

```

8. Here is a real force push being stopped by that rule.

```
$ git commit -q --amend -m 'Add about page (message fixed)'

$ git push --force origin main
remote: policy: main is fast-forward only
remote: error: hook declined to update refs/heads/main
To /tmp/lab/srv/proj.git
 ! [remote rejected] main -> main (hook declined)
error: failed to push some refs to
      '/tmp/lab/srv/proj.git'

$ git ls-remote origin refs/heads/main
a07dcbcd1fbb04efa6dbb8f6272a2aed8c361556      refs/heads/main
```

9. That is branch protection, built by hand, in twenty lines. GitHub's branch protection is the same idea with a web form in front of it.
10. One honest note from the same run. When we tried `git push origin :main` to delete the branch, git's own built-in `receive.denyDeleteCurrent` check fired before our hook did, because `main` is the branch that the bare repository's `HEAD` points at. Our hook line is still worth having, for every branch that is not the current one.

■ 40.5.5 TECHNICAL – the engineer's version

1. Server-side hooks, in the exact order git runs them on a push:

Hook	Runs	Can reject	Input
pre-receive	once per push	yes, all refs	stdin
update	once per ref	yes, that ref	argv
post-receive	once per push	no	stdin
post-update	once per push	no	argv

2. `post-update` is the oldest of these and its main modern use is running `git update-server-info`, which is only needed for the “dumb” HTTP transport, where a plain web server serves the repository files with no git-aware program behind it.
3. Client-side hooks that matter day to day:

Hook	When	Typical use
pre-commit	before message editor	linting, secret scanning
prepare-commit-msg	before editor opens	insert a template
commit-msg	after message written	enforce message format
pre-push	before push starts	run tests
pre-rebase	before a rebase	protect published branches

4. Here are two real client hooks and the real refusals they produce. First `pre-commit`, refusing a marker string:

```
#!/bin/sh
if git diff --cached -U0 | grep -q 'DO-NOT-COMMIT'; then
    echo "pre-commit: found DO-NOT-COMMIT marker"
    exit 1
fi
exit 0
```

```
$ git add secrets.py && git commit -m 'KB-42: add config'
pre-commit: found DO-NOT-COMMIT marker
```

5. Then `commit-msg`, enforcing a ticket prefix. Git passes the path of the file holding the message as the first argument.

```
#!/bin/sh
first=$(head -n 1 "$1")
if ! echo "$first" | grep -Eq '^KB-[0-9]+: .+'; then
    echo "commit-msg: need a KB-<number>: prefix"
    echo "commit-msg: you wrote: $first"
    exit 1
fi
exit 0

$ git commit -m 'add contact page'
commit-msg: need a KB-<number>: prefix
commit-msg: you wrote: add contact page

$ git commit -m 'KB-43: add contact page'
[main 40048a8] KB-43: add contact page
1 file changed, 1 insertion(+)
```

6. And now the honest part, demonstrated rather than asserted. One flag skips both hooks, and the resulting commit pushes perfectly happily.

```
$ git commit --no-verify -m 'whatever, no ticket, no checks'
[main a2648f3] whatever, no ticket, no checks
1 file changed, 1 insertion(+)
create mode 100644 leak.py

$ git push -q origin main && git ls-remote origin main
a2648f3588da557802930bc984745c8a574b7a38 refs/heads/main
```

7. The secret marker went in. The ticket prefix was skipped. Both hooks were bypassed by a single documented flag.
8. **Client hooks are not enforcement.** They are a convenience that catches honest mistakes. Three independent reasons: `--no-verify` exists, hooks are not committed to the repository so a fresh clone has none, and a hook file that is not executable is silently ignored.
9. Because hooks are not versioned, teams use a manager that installs them from a committed configuration. The common ones are `pre-commit` (a Python tool, first released in 2014), `Husky` for Node.js projects, and setting `core.hooksPath` to a directory that is committed. `core.hooksPath` arrived in Git 2.9 (June 2016) and is the plainest option.
10. Real enforcement lives on the server: `pre-receive` and `update` hooks on a self-hosted server, or branch protection plus required status checks on a hosted platform. Everything else is advice.

■ 40.5.6 WORDS – remember these

1. Hook — a program git runs at a set moment — an executable in the `hooks` directory or in `core.hooksPath`, invoked with a defined argument or `stdin` contract and judged by its exit status.
2. `pre-receive` — the all-or-nothing gate on a push — a server hook reading `old new ref` lines on `stdin`, whose non-zero exit rejects every ref.
3. `update` — the per-branch gate — a server hook called once per ref with three arguments, whose non-zero exit rejects that ref only.

4. post-receive — the after-the-fact action — a server hook that runs once the refs are updated and cannot reject anything.
5. no-verify — the flag that skips client hooks — `--no-verify` on commit and push, which is why client hooks are advice and not policy.
6. core.hooksPath — a way to share hooks with a team — a configuration key pointing at a directory of hooks, which can be committed to the repository.

40.6 What GitHub actually is

■ 40.6.1 PLAIN – in simple words

1. GitHub is four things stacked on top of each other.
2. One: hosting for bare repositories. Machines that hold your repositories and run `git-upload-pack` and `git-receive-pack` for you.
3. Two: a web interface. Pages that let you read code, history and differences in a browser, and comment on them.
4. Three: an identity and permission system. Accounts, organizations, teams, tokens, and rules about who may do what to which repository.
5. Four: automation. Servers that run your tests and builds when something happens, and store the results.
6. GitHub was founded in 2008 by Tom Preston-Werner, Chris Wanstrath and P. J. Hyett. The site opened to the public in April 2008.
7. Microsoft announced it would buy GitHub on 4 June 2018 for 7.5 billion United States dollars in Microsoft stock. The purchase completed on 26 October 2018.
8. Here is the sentence that matters most in this chapter: the git part of GitHub is not the valuable part.
9. Anybody can host bare repositories. It took us one command and ten milliseconds. What is hard to copy is the other three layers, and above all the fact that millions of developers already have an account there.

■ 40.6.2 PLAIN – a picture in your head

1. Think of a public library that also happens to have meeting rooms, a membership desk and a printing service.
2. Holding books is the easy part. Any building with shelves can hold books.
3. What makes the library useful is that you know where it is, everyone else uses it too, there is a catalogue, there is a librarian who checks membership cards, and there is a room you can book.
4. GitHub is that. The shelves are cheap. The catalogue, the membership system and the fact that everyone is already a member are the product.
5. That is also why leaving is harder than it looks. Your books come with you. Your reading room bookings, your notes in the margins and your library card do not.

Where this comparison breaks:

6. A library lends you one copy and keeps the original. Git gives you the whole collection every time, so the “original” has no special status.
7. And a library card is issued by the library. Your git history is not issued by GitHub. It is yours, complete, on your own disk.

■ 40.6.3 PLAIN – a worked example

1. Here is proof that GitHub's git layer is ordinary git, taken live during the writing of this chapter.

```
$ git ls-remote https://github.com/git/git | head -5
745601a9a94110d74769ab605ccd4f61339758d2    HEAD
165e5ad3169d0fd26637da3383a4514f1a9d1e72    refs/heads/bisect
426ec014a6630fb78c5a7334461bc33568f07743    refs/heads/jch
e9019fcafe0040228b8631c30f97aeladb61bcddc    refs/heads/maint
745601a9a94110d74769ab605ccd4f61339758d2    refs/heads/master

$ git ls-remote https://github.com/git/git | wc -l
5297
```

2. That is exactly the same command, producing exactly the same shape of output, as the one we ran against a folder in /tmp.
3. The git source repository on GitHub advertises 5,297 refs. Our little bare repository advertised seven. Same protocol, same program, different scale.
4. Now here is proof of the second layer, the part that is not git. GitHub stores pull requests as extra refs that plain git can see but that plain git never creates.

```
$ git ls-remote https://github.com/cli/cli 'refs/pull/*' \
| head -4
e9a3253762e768badaa1d4a5b3d267416d1e42f4    refs/pull/1/head
9966ca8bdb06ff86febbb49ff08480ef3fb4f790    refs/pull/10/head
24b83202679eeddb72bf9eb35752bf3f5ea737    refs/pull/100/head
b4b8e8a13bb99bae479929048ea5f64808d0bc32    refs/pull/10002/head

$ git ls-remote https://github.com/cli/cli 'refs/pull/*' \
| wc -l
5147
```

5. Five thousand one hundred and forty-seven pull-request refs. Git can list them, because they are refs. Git cannot create one, cannot comment on one, cannot approve one and does not know what “pull request” means.
6. That single distinction is the subject of the next two sections.

■ 40.6.4 PLAIN – what is really happening inside

1. When you `git push` to GitHub, this is the sequence.
2. Your git resolves `github.com` to an address. In the reader's own session it resolved to `20.207.73.82`, which is in a Microsoft-owned range, because GitHub is a Microsoft company and fronts traffic through Microsoft's network edge.
3. Your git opens a connection, either TCP port 22 for SSH or TCP port 443 for HTTPS.
4. It authenticates. Over SSH that is your key pair. Over HTTPS that is a personal access token or a credential helper.
5. GitHub's front end checks who you are and whether you may write to that repository. This check is GitHub's, not git's.
6. If allowed, GitHub runs `git-receive-pack` against the bare repository it holds for you. From this point the bytes are ordinary git.
7. GitHub's own pre-receive hooks then run. Branch protection, required signatures, push rules and secret scanning all live here.
8. If nothing objects, the refs update and GitHub's equivalent of post-receive fires. That is what creates the timeline entry, sends the notification, updates the pull request, and starts an Actions workflow.

9. Steps 4, 5, 7 and 8 are GitHub. Steps 3 and 6 are git. That is the whole boundary.

■ 40.6.5 TECHNICAL – the engineer’s version

1. Dates and figures worth committing to memory:

Event	Date
Git first released by Linux Torvalds	April 2005
GitHub launched publicly	April 2008
GitHub introduces Git LFS	April 2015
Microsoft announces acquisition	4 June 2018
Acquisition completes	26 Oct 2018
Password auth for git removed	13 Aug 2021
Unencrypted git:// disabled	15 Mar 2022

2. GitHub removed password authentication for git operations over HTTPS on 13 August 2021. Since then HTTPS pushes require a personal access token, an OAuth token, a GitHub App installation token, or SSH keys instead.
3. On 24 March 2023 GitHub replaced its RSA SSH host key after the private key was briefly exposed in a public repository. Every user with the old key in `known_hosts` saw a host key verification failure. This is a good reminder that host key pinning is real security with real operational cost.
4. GitHub’s git hosting uses a custom system for replication and routing. Publicly described pieces include Spokes, formerly called DGit, for three-way replication of repositories across servers, and a proxy layer in front of the git transports. The important engineering point is that nothing about this changes the wire protocol. Your git client cannot tell.
5. The scale of GitHub’s non-git surface is what makes it expensive to run: the REST API, the GraphQL API, webhooks, Actions runners, package registries, Pages hosting and code search. None of those are git.
6. Estimated user counts published by GitHub have grown from roughly 100 million developers reported in early 2023 to figures above that since. Treat any single number as approximate and dated, because the company publishes it as a marketing figure rather than an audited one.

■ 40.6.6 WORDS – remember these

1. Forge — a website that hosts repositories and adds collaboration — the general term covering GitHub, GitLab, Gitea, Forgejo and Bitbucket.
2. Hosting — somebody else runs the bare repository — a service that exposes upload-pack and receive-pack over authenticated transports.
3. Personal access token — a password made for programs — a revocable credential with a fixed set of scopes, used in place of a password.
4. Scope — the list of things a token is allowed to do — a named permission such as `repo`, `workflow` or `read:org` attached to a token.
5. `refs/pull` — GitHub’s storage for pull request heads — read-only refs created by GitHub, visible to `git ls-remote`, not creatable by git.

40.7 What GitHub adds that plain git does not have

■ 40.7.1 PLAIN – in simple words

1. Git has exactly one job: move history between repositories, exactly.
2. It has no idea what a pull request is. No idea what a review is. No idea what an issue, a label, a release, a package or a build is.
3. Every one of those is added by the website you happen to be using.
4. Here is the whole list, in plain words, one item per line.
5. Pull requests. A written request saying “please take my branch into yours”, with a conversation attached to it.
6. Code review. Named people reading the change and marking it approved, or asking for changes, or just commenting.
7. Branch protection. A rule saying “nobody may push straight into main”.
8. Required checks. A rule saying “the tests must pass before the merge button is allowed to work”.
9. CODEOWNERS. A file listing which people must review which folders.
10. Issues and projects. A shared to-do list, and a board of cards.
11. Releases. A named point in history with files attached, such as a compiled program somebody can download.
12. Packages. A place to publish libraries that other projects install.
13. Actions. Computers that run your tests and builds when something happens, and keep the logs.
14. Two programming interfaces, REST and GraphQL. Ways for programs to ask GitHub questions and give it orders.
15. Permissions. Accounts, organizations, teams, roles and tokens.
16. Not one of those is part of git. Git ships none of them, and would work exactly the same if GitHub had never existed.

■ 40.7.2 PLAIN – a picture in your head

1. Think of a shared workshop where people build furniture.
2. Git is one machine in the corner. It copies a design exactly, down to the last measurement, and hands the copy to somebody else.
3. That machine is superb at that job and does nothing else. It has no opinion about who you are or whether the design is any good.
4. The workshop around the machine is everything else. A pass reader on the door. A noticeboard of jobs to do. A sign-off sheet outside the paint room saying two people must approve the colour. An overnight test rig. A shelf of finished pieces with labels on them.
5. You can take the copying machine home and still build furniture.
6. You cannot take the noticeboard, the sign-off sheets, the pass reader or the test rig. They belong to the building.
7. GitHub is the building. Git is the machine.

Where this comparison breaks:

8. The building also stores the designs, so day to day the two feel like one thing. The split is in the protocol, not in the floor plan.
9. And the sign-off sheet is not decoration. On GitHub, branch protection really does stop the push at the door. It is a lock, not a note.

■ 40.7.3 PLAIN – a worked example

1. A pull request has two halves. One half is refs, which git can see. The other half is a database row, which git cannot see.

2. Here is the visible half, read live with plain git, no account, no token.

```
$ git ls-remote https://github.com/cli/cli 'refs/pull/10002/*'
b4b8e8a13bb99bae479929048ea5f64808d0bc32 refs/pull/10002/head

$ git ls-remote https://github.com/cli/cli 'refs/pull/*/head' \
  | wc -l
4981

$ git ls-remote https://github.com/cli/cli 'refs/pull/*/merge' \
  | wc -l
166
```

3. Read those two numbers. 4,981 pull requests have a head ref, which is the commit the author is proposing.
4. Only 166 have a merge ref. That is GitHub's pre-computed trial merge, kept only while a pull request is open and can be merged cleanly.
5. Now the invisible half. Git cannot answer any of these, at any price: who opened it, what the title says, who approved it, which comment sits on which line, whether the tests passed, whether the merge button works.
6. Proof by absence. Ask git for every command it has that mentions requests or reviews.

```
$ git help -a | tr ' ' '\n' | grep -iE 'request|review|issue'
request-pull
```

7. One result, and it is not what you think. `git request-pull` has existed since 2005 and prints an email for you to send to a maintainer by hand.

```
$ git request-pull main /tmp/mg/base feature/login
The following changes since commit cd18e975:

    Base commit (2026-08-13 07:43:39 +0000)

are available in the Git repository at:

    /tmp/mg/base feature/login

for you to fetch changes up to 00ee7d7c:

    Fix login typo (2026-08-13 07:43:39 +0000)

Reader (2):
    Start login
    Fix login typo

login.py | 2 ++
1 file changed, 2 insertions(+)
```

8. That is the true ancestor of the pull request. It produces text for a mailing list. It has no state, no approval, no button and no thread.
9. GitHub's version added the state, the approval, the button and the thread. That addition is the product.

■ 40.7.4 PLAIN – what is really happening inside

1. A pull request is three things glued together.
2. One: two ref names. A base, meaning where you want the work to land, and a head, meaning the work. Both are ordinary git refs.
3. Two: a row in a database, holding a number, a title, a body, a state (open, closed or merged) and an author.
4. Three: a conversation. Comments, review states, requested reviewers, labels, and links to issues.
5. When you press Merge, GitHub runs an ordinary git merge on its own server, into the base branch, using whichever strategy you picked.
6. Review states are values on that database row: APPROVED, CHANGES_REQUESTED, COMMENTED, DISMISSED, PENDING.
7. Branch protection is enforced by GitHub's own pre-receive hook. Earlier in this chapter we wrote a pre-receive hook by hand that rejected a push. GitHub runs a much larger version of the same thing.
8. A required status check is a record attached to a **commit SHA**, not to a branch. Something posts "the tests passed for this SHA" through the API.
9. The protection rule then asks one question: does the head SHA of this pull request carry a passing record with the required name?
10. That is exactly why, in the reader's own session, checking CI by run ID against the exact head SHA was stronger than trusting a green tick beside a branch name. The tick is drawn next to a name, and names move. The record is attached to a SHA, and a SHA never moves.
11. CODEOWNERS is the one hybrid. The file is a real blob inside your repository, so git stores and versions it. The rule "these owners must approve" is GitHub's, and git ignores the file completely.
12. Actions is a scheduler plus a fleet of machines. A push fires an internal event, a workflow file in the repository says what to run, and a runner picks up the job.
13. Releases and packages are file storage with a database index in front. The attached files are not git objects and are not in the history.
14. So the rule is short: refs and objects are git; anything with an opinion is GitHub.

■ 40.7.5 TECHNICAL – the engineer's version

1. The classification. "Truth lives in" means where the authoritative copy is.

Feature	git or GitHub	Truth lives in
Commit, tree, blob, tag	git	object database
Branch and tag refs	git	refs, packed-refs
Merge, rebase, cherry-pick	git	local repository
Push, fetch, clone	git	wire protocol
Server-side hooks	git	hooks directory
Submodules	git	gitlink plus file
Pull request	GitHub	GitHub database
Review state	GitHub	GitHub database
Branch protection rule	GitHub	GitHub database
Required status check	GitHub	GitHub database
CODEOWNERS file	git	a blob in the tree
CODEOWNERS behaviour	GitHub	rule engine
Issue, label, milestone	GitHub	GitHub database
Projects board	GitHub	GitHub database

Feature	git or GitHub	Truth lives in
Release and its assets	GitHub	object storage
Packages registry	GitHub	object storage
Actions workflow run	GitHub	runners plus DB
REST and GraphQL API	GitHub	GitHub servers
Teams, roles, tokens	GitHub	GitHub database
Fork, star, watch	GitHub	GitHub database

2. Dates, so you can see that every GitHub feature has a birthday and git has none of them.

GitHub feature	Date
Pull Requests 2.0 post	31 Aug 2010
Releases introduced	2 Jul 2013
Protected branches, checks	3 Sep 2015
GraphQL API announced	14 Sep 2016
CODEOWNERS introduced	6 Jul 2017
Actions announced	16 Oct 2018
Actions generally available	13 Nov 2019
Merge queue GA	12 Jul 2023

3. Rate limits, from GitHub's published documentation, current as of 2026. REST, unauthenticated: 60 requests per hour per IP address. REST, with a personal access token: 5,000 per hour. GitHub Apps and OAuth apps owned by a GitHub Enterprise Cloud organization: 15,000 per hour. GraphQL is budgeted in points, 5,000 points per hour for a user token.
4. The API keeps its own books, and will tell you so:

```
$ curl -s https://api.github.com/rate_limit
{ "resources": {
  "core": { "limit": 15000, "remaining": 15000 },
  "search": { "limit": 30, "remaining": 30 },
  "graphql": { "limit": 5000, "remaining": 5000 } } }
```

5. Honest note on that output: the request above ran through a proxy that attached an application credential, which is why core shows 15,000 and not 60. The number you see depends on how you authenticated.
6. Git has no equivalent of any of that, because git has no accounts. There is nothing in the git protocol to rate-limit against.
7. The permission model, as of 2026. Repository roles: Read, Triage, Write, Maintain, Admin. Organization roles: Member, Moderator, Billing manager, Owner, plus custom roles on paid plans. Teams can nest, and effective permission is the union of every grant a user receives.
8. Token types. Classic personal access tokens carry coarse scopes such as `repo`, `workflow`, `read:org` and `admin:repo_hook`. Fine-grained personal access tokens, generally available since 2022, are limited to chosen repositories, carry per-resource read or write permissions, and must have an expiry date.
9. The reader's own session shows why the scope list is not decoration. One push was refused because the token lacked the `workflow` scope and the push modified a CI workflow file. Git had already packed and sent the objects. GitHub's server-side rule refused the ref update.

10. GraphQL exposes fields with no git equivalent at all. The reader saw `mergeStateStatus` values `CLEAN`, `BLOCKED` and `UNKNOWN`; the full set also includes `BEHIND`, `DIRTY`, `DRAFT`, `HAS_HOOKS` and `UNSTABLE`.
11. Git cannot compute any of those values, because each depends on a rule git does not know exists.
12. Scale figures published by GitHub are marketing figures, not audited ones. Roughly 100 million developers were reported in early 2023, about 150 million for May 2025, and the repository count was reported to pass one billion in June 2025. Treat all three as approximate and dated.

■ 40.7.6 WORDS - remember these

1. Pull request — a request to merge one branch into another, with a discussion — a GitHub database object referencing a base ref and a head ref, exposed to git only as `refs/pull/N/head`.
2. Review state — the verdict a reviewer left — one of `APPROVED`, `CHANGES_REQUESTED`, `COMMENTED`, `DISMISSED`, `PENDING`.
3. Branch protection — a rule stopping direct pushes to a branch — a server-side policy implemented in GitHub's pre-receive path.
4. Required status check — the tests must pass before merging — a named check record that must exist and be successful for the head SHA.
5. Check run — one reported result for one commit — an API object attached to a SHA with a name, status, conclusion and output.
6. CODEOWNERS — a file saying who owns which folders — a versioned path pattern file whose enforcement is entirely the forge's, not git's.
7. Fork — your own server-side copy of somebody's repository — a GitHub database relationship plus a repository that may share object storage.
8. GraphQL API — one endpoint you send a shaped query to — GitHub's typed schema at a single endpoint, budgeted in points rather than requests.
9. `mergeStateStatus` — GitHub's summary of whether merging is allowed — a GraphQL enum with values such as `CLEAN`, `BLOCKED` and `BEHIND`.
10. Merge queue — a line that tests changes in order before merging — a GitHub service that builds candidate merges and merges only what passes.

40.8 The exact boundary, using the reader's own outage as evidence

■ 40.8.1 PLAIN - in simple words

1. During the reader's outage one sentence describes everything: git kept working, and the GitHub API did not.
2. Committing worked. Branching worked. Merging worked. Rebasing worked. Reading old history worked. Tagging worked.
3. Pushing failed. Fetching failed. Looking at a pull request failed. Checking a CI run failed.
4. That is not luck and not a coincidence. It follows from two facts the book has already given you.
5. Fact one: a git command needs the network if and only if it must read from, or write to, another repository. Everything else is reading and writing files inside the `.git` folder, and files need no network.
6. Fact two: every GitHub-specific feature is a network service. There is no local copy of a pull request, an issue, a review or a build result.
7. Put the two together and the boundary is exact. The local half of git kept working. The remote half of git, and the whole of GitHub, did not.

- Nothing here is special to GitHub. Point your remote at a self-hosted Forgejo and the same line falls in the same place.

■ 40.8.2 PLAIN – a picture in your head

- Imagine you keep a paper diary at home, and your office keeps a shared wall planner that everyone updates.
- The phone line to the office is cut.
- You can still write in your diary. Every page, any amount. The cut line does not touch your pen.
- You can still read every old page, because they are in your hands.
- You cannot see today's wall planner, and you cannot change it.
- Here is the sharp part. You can still look at the photo of the wall planner you took last Tuesday. It will show you Tuesday's planner, confidently, and it will be out of date.
- That photo is `origin/main`. During the outage the reader's machine reported `origin/main` as `0a95cc8`. That was a cached value from the last successful fetch, not a live fact about the server.

Where this comparison breaks:

- A photo obviously looks like a photo. A remote-tracking ref does not. `git log origin/main` prints normally, with no warning and no note saying how old the information is.
- And a wall planner suggests one true copy. Git has no true copy. During the outage `origin/main` was stale, but the reader's own `main` was not somehow less real.

■ 40.8.3 PLAIN – a worked example

- Here is the boundary as a table. Read the third column as the reason, not as an excuse.

Operation	Works offline	Why
<code>git commit</code>	yes	writes <code>.git</code> only
<code>git branch</code> , <code>git switch</code>	yes	writes a ref file
<code>git merge</code> , <code>git rebase</code>	yes	objects already local
<code>git log</code> , <code>git diff</code> , <code>blame</code>	yes	reads local objects
<code>git tag</code> , <code>git stash</code>	yes	local refs and objects
<code>git bisect</code>	yes	walks the local graph
<code>git show origin/main</code>	yes, but stale	cached tracking ref
<code>git fetch</code> , <code>git pull</code>	no	must read the remote
<code>git push</code>	no	must write remote refs
<code>git clone</code>	no	nothing local yet
<code>git ls-remote</code>	no	asks the other side
Open or merge a PR	no	GitHub database only
Read review comments	no	GitHub database only
Check a CI run result	no	GitHub service only
Create or close an issue	no	GitHub database only
Get a release asset	no	GitHub storage only
Branch protection verdict	no	server-side rule
Any gh CLI command	no	wraps the GitHub API

- Every row above was reproduced in a sandbox for this chapter. The remote was pointed at `203.0.113.9`, an address reserved by RFC 5737 for documentation, so nothing could answer. The outage was real, not faked with a flag.

```

git log --oneline -1      rc=0 f657694 First commit
git branch -a             rc=0 * main
git switch -c feature/x   rc=0
git commit --allow-empty  rc=0
git tag v0.9              rc=0
git diff HEAD~1 --stat    rc=0
git rev-parse origin/main rc=0 f6576945ec22d250a17a6fe3...
git status -sb            rc=0 ## feature/x

```

3. Note line seven. `git rev-parse origin/main` succeeded and printed a full SHA while the server was unreachable. That is the cached photo.
4. In the same second, on the same repository, the network commands:

```

$ git ls-remote origin
ssh: connect to host 203.0.113.9 port 22: Connection timed out
fatal: Could not read from remote repository.

$ git fetch origin
ssh: connect to host 203.0.113.9 port 22: Connection timed out
fatal: Could not read from remote repository.

$ git push origin main
ssh: connect to host 203.0.113.9 port 22: Connection timed out
fatal: Could not read from remote repository.

```

5. Three failures, all identical, all at the same layer: the connection never opened. Git never got as far as speaking git.
6. That is the same shape as the reader's own evidence. `curl -v https://github.com` printed Trying 20.207.73.82:443... and then timed out after 15 seconds with no response of any kind. No RST, no ICMP unreachable, silence.
7. What that proves: nothing on that path answered. What it does not prove: who dropped it. The same request succeeded instantly over mobile data, which is consistent with a silent drop somewhere on the fixed-line path, and not consistent with GitHub being down.

■ 40.8.4 PLAIN – what is really happening inside

1. Take the three cases apart, one at a time.
2. Case one, a local git command. `git commit` reads the index file, writes blob, tree and commit objects under `.git/objects`, and rewrites one 41-byte ref file. Zero sockets are opened. There is nothing to fail.
3. Case two, a remote git command. `git push` must change a ref on another machine. It resolves a name, opens TCP port 22 or 443, authenticates, runs the remote helper, and negotiates. Any broken step ends it.
4. Case three, a GitHub feature. Opening a pull request is an HTTPS request to `api.github.com`. There is no offline path, because there is no local copy of the data and no local code that understands it.
5. Now the important consequence for the reader. Because case one never touches a network, work does not stop. The reader committed to branches all through the outage and pushed them later, when the path came back.
6. Nothing had to be redone. The commits made during the outage were already complete, already hashed, already in the object database. Pushing later just copied objects that already existed.
7. That is the entire practical payoff of the distributed design, and the reader lived it.

8. One more piece from the same session. Twice, a push failed with `send-pack: unexpected disconnect while reading sideband packet`.
9. That message is different from the ones above. It means the connection was established, authentication passed, objects were sent, and the link died while git was reading the server's reply.
10. So the error tells you the answer never arrived. It tells you nothing about whether the server acted before the link died.
11. Both times the operation had not been applied. But that could not be known from the message. It had to be re-checked with `git ls-remote origin`, which asks the server what its refs are now.
12. The rule to carry away: a failure while reading a response is not evidence that the write did not happen. Only a fresh query is evidence.

■ 40.8.5 TECHNICAL – the engineer's version

1. What each operation actually needs on the wire.

Operation	Endpoint	Port
git over SSH	ssh to the host	22
git over HTTPS	the smart HTTP path	443
GitHub REST API	api.github.com	443
GitHub GraphQL API	api.github.com/graphql	443
gh CLI	the same two APIs	443
Web pages, PR view	github.com	443
Release asset download	objects storage host	443
Actions log fetch	a logs host	443

2. Note what that table means. Everything except plain SSH shares one port and often one path. When that path is silently dropped, git over HTTPS and the whole API fail together, which is what the reader observed.
3. Plain SSH on port 22 is a different destination and can survive when HTTPS does not. In the reader's session one transport worked while the other failed, in the same minute, on the same machine.
4. That asymmetry is a diagnostic, not a fix. If SSH works and HTTPS does not, the fault is path-specific or port-specific, not a dead server.
5. Failure taxonomy, with the exact signal for each:

Symptom	What it means	Proven or suggested
Connection refused	a host sent RST	server or firewall said no
Timed out, no reply	silent drop	proven: nothing answered
TLS handshake error	reached, policy fail	proven: TCP worked
403 from the API	authenticated, denied	proven: service is up
sideband disconnect	reply lost mid-stream	write status unknown

6. Only the last row is ambiguous, and it is the one that bites. The git protocol sends the `report-status` response inside sideband channel 1 during `receive-pack`. If the stream dies there, the client has no report.
7. The correct recovery is a re-query, never a retry decided by guesswork:

```
$ git ls-remote origin refs/heads/main
0a95cc8a5f0b... refs/heads/main
```

8. Compare that SHA with your local main. If they match, the push landed. If not, it did not. That is a fact from the server, not an inference.
9. There is a second reason the re-query matters. A push is not atomic across refs by default. Pushing several refs at once can leave some applied and some not, unless you use `--atomic`, added in Git 2.4 (April 2015), which makes the whole push succeed or fail as one unit on servers that support it.
10. Chapter 37 gave the local versus remote split. This chapter adds the second axis. Together they explain every row of the table in 40.8.3:

	needs no network	needs the network
pure git	commit, log, merge, rebase, tag, bisect	fetch, push, clone, ls-remote
forge feature	(nothing)	PR, review, CI, issues, releases

11. The bottom-left cell is empty, and that emptiness is the point. There is no such thing as an offline pull request.
12. Tools that appear to break this rule cache data locally, which is the same stale-photo problem as origin/main and should be treated the same way.

■ 40.8.6 WORDS – remember these

1. Local operation — anything git can do with your own files — a command whose entire working set is the object database, index and refs on this disk.
2. Remote-tracking ref — your last photo of the server — a ref under refs/remotes/ updated only by fetch, never live.
3. Silent drop — a packet vanishes with no reply — no RST and no ICMP time-exceeded, observed as a connection timeout.
4. Sideband — the channel carrying the server's messages — multiplexed stream inside the pack protocol, where the report-status reply travels.
5. Re-query — ask again instead of guessing — using `git ls-remote` to learn the server's current refs after an ambiguous failure.
6. Atomic push — all refs or none — `git push --atomic`, added in Git 2.4 (April 2015), requiring server support.

40.9 The self-hosted alternatives

■ 40.9.1 PLAIN – in simple words

1. If you do not want to use GitHub, you have four honest choices. Here they are from heaviest to lightest.
2. GitLab Community Edition. Close to GitHub in features, and heavy to run.
3. Gitea, or its community fork Forgejo. Most of what a small team needs, in a program small enough for a Raspberry Pi.
4. Bitbucket Data Center from Atlassian. Bought mainly by companies that already run Jira and want one supplier.
5. Plain SSH remotes with no web interface at all. A machine, an account, and git. Nothing else.
6. All four store bare repositories the same way and speak the same protocol. Every difference is in the layers above git.

7. What you gain by self-hosting: control over the rules, privacy for the code, and no lock-in to one company's features or prices.
8. What you lose is simpler than people admit. You become the operator. Backups are yours. Uptime is yours. Upgrades and security patches are yours. At three in the morning, it is you.

■ 40.9.2 PLAIN – a picture in your head

1. Compare eating in a canteen with cooking at home.
2. In the canteen, somebody else buys the food, cooks it, washes up and keeps the doors open. You accept their menu and pay their price.
3. Cooking at home, you choose everything. You know exactly what is in the food. Nobody can change the price or close the kitchen.
4. But you also shop, cook, wash up and mend the cooker. Every day. Including days you are ill and days you are away.
5. Most people cook at home for four and hire a caterer for four hundred.
6. Self-hosting scales the same way. It is genuinely easy for a small trusted group and genuinely hard for a large public project full of strangers.

Where this comparison breaks:

7. A broken cooker ruins one dinner. A broken git server does not lose your history at all, because every clone is a complete copy. The stakes are lower than the picture suggests.
8. What an outage really costs you is the meeting point, plus the metadata: issues, reviews and build results. Those are the parts with no second copy on anybody's laptop.

■ 40.9.3 PLAIN – a worked example

1. Here is the smallest useful server anyone can build, and it needs no software beyond git and an SSH daemon.
2. Make one account on a machine, called git. Set its login shell to `git-shell`, a program that ships with git and refuses everything except git's own transport commands.
3. Put each developer's public key in that account's `authorized_keys` file.
4. Proof that `git-shell` really is a lock and not a suggestion:

```
$ git-shell -c "ls -la"
fatal: unrecognized command 'ls -la'
```

5. And proof that the git commands still work through it. This is the real first bytes of a ref advertisement, wrapped to fit the page:

```
$ git-shell -c "git-upload-pack '/srv/git/proj.git'"
01032304fd03...16d6 HEAD multi_ack thin-pack side-band
side-band-64k ofs-delta shallow deepen-since deepen-not
no-progress include-tag multi_ack_detailed
symref=HEAD:refs/heads/main object-format=sha1
agent=git/2.43.0
0046a3bfdce1...3a refs/heads/feature/login
```

6. That is the whole server. Somebody who logs in with that key can clone, fetch and push, and cannot get a shell, list files or read other accounts.
7. Cost of running it: git itself. Measured in the sandbox for this chapter, peak memory of the git process during real work:

```
git clone (11,772 commits) 0.58 s peak RSS 42.1 MB
git gc (blobless clone) 0.93 s peak RSS 39.2 MB
```

```
git status (1,356 files)    0.29 s    peak RSS 16.5 MB
git log --oneline (all)     0.17 s    peak RSS 14.8 MB
```

8. Tens of megabytes, for a few seconds, per operation. That is why a plain SSH git server runs happily on the smallest machine you can rent.
9. Now compare that with what each option needs before it will start at all.

Option	Min RAM	Web UI	Effort
SSH plus git-shell	tens of MB	none	very low
Gitolite added	tens of MB	none	low
cgit or gitweb	~128 MB	read only	low
Gitea or Forgejo	1 GB	full	low
GitLab CE	8 to 16 GB	full	high
Bitbucket Data Center	8 GB and up	full	high, paid

10. And what you actually get for that memory.

Feature	SSH only	Gitea, Forgejo	GitLab CE
Push and pull	yes	yes	yes
Server-side hooks	yes	yes	yes
Web code browsing	no	yes	yes
Pull requests	no	yes	yes, called MRs
Issues, labels	no	yes	yes
Built-in CI	no	yes	yes
Package registry	no	yes	yes
Fine-grained roles	limited	yes	yes

■ 40.9.4 PLAIN – what is really happening inside

1. The four options differ in exactly one way: how many processes must be running before a developer can do anything.
2. Plain SSH: one process, and only while somebody is connected. `sshd` accepts the connection, `git-shell` checks the command, and `git-upload-pack` or `git-receive-pack` does the work and exits.
3. Nothing runs between pushes. There is no database, no queue, no web server and no cache. That is why it costs almost nothing.
4. Gitolite adds a single Perl program in front. It reads one configuration repository that lists users, repositories and per-branch rules, and it installs an update hook to enforce them.
5. Gitea and Forgejo are one compiled program written in Go. It contains the web server, the issue tracker, the review system and its own SSH server. Storage is SQLite for small installations, or PostgreSQL or MySQL.
6. GitLab is not one program. A standard installation runs a Ruby on Rails application, background job workers, PostgreSQL, Redis, a reverse proxy, a metrics stack, and Gitaly, which is GitLab's own service that every other part must call in order to touch git at all.
7. That list is the entire reason for the memory difference. It is not that GitLab is badly built. It is that it is many services, and each one has a floor.

8. In every case the bytes on the wire are identical. A developer cloning from plain SSH and a developer cloning from GitLab run the same client, speak the same protocol and get the same objects.

■ 40.9.5 TECHNICAL – the engineer’s version

1. Provenance and licensing, which matter more than feature lists when you are choosing something to depend on for ten years.

Project	Origin	Licence
Gogs	2014, by Jiahua Chen	MIT
Gitea	Nov 2016 fork of Gogs	MIT
Forgejo	Dec 2022 fork of Gitea	GPL since Aug 2024
GitLab CE	2011, D. Zaporozhets	MIT
GitLab EE	same codebase, add-ons	proprietary
Bitbucket	2008, by Jesper Nohr	proprietary

2. The Gitea and Forgejo split is a governance story, not a technical one. Gitea’s trademarks and operations were transferred to a company in 2022, contributors asked for community control, the request was refused, and Forgejo was forked in December 2022. Codeberg e.V., a German non-profit association, leads it.
3. Forgejo stopped tracking Gitea after Gitea 1.21, in February 2024, and became a hard fork. It relicensed from MIT to the GNU General Public Licence in August 2024. Code written before that remains MIT.
4. Bitbucket was founded in 2008 by Jesper Nohr, acquired by Atlassian on 29 September 2010, and dropped Mercurial support in July 2020. Support for the self-hosted **Bitbucket Server** product ended on 15 February 2024. Self-hosting now means Bitbucket Data Center, which is licensed and priced for larger organizations.
5. That last date is a lesson in its own right. A self-hosted product can be discontinued by its vendor. Self-hosting removes the hosting dependency; it does not by itself remove the vendor dependency. Only an open licence with a living community does that.
6. Hardware, from the projects’ own documentation as of 2026. Gitea states that “2 CPU cores and 1GB RAM is typically sufficient for small teams/projects” and that a Raspberry Pi 3 is enough for small workloads. GitLab’s single-node baseline is 8 vCPU and 16 GB of RAM, with 8 GB possible only with extra configuration. Older GitLab documentation quoted 4 GB, so check the version-specific page rather than trusting a number you remember.
7. That is a factor of roughly sixteen in memory between Gitea and GitLab for the same core job. It is the single most useful figure in this section.
8. Access control on a plain SSH server, in increasing order of precision: UNIX file permissions on the repository directory; one shared git account with git-shell; Gitolite for per-repository and per-branch rules; and server-side pre-receive or update hooks for anything else.
9. Read-only web browsing without a full forge: cgit, a C program, or gitweb, which ships with git itself. Both render a repository as HTML and neither has accounts, issues or reviews.
10. Honest trade-off summary. Self-hosting is a good decision when the group is small and trusted, when the code must not leave your control for legal reasons, when your costs at a hosted provider have become large, or when you need rules a hosted provider will not give you.

11. It is a poor decision when your project depends on drive-by contributions from strangers, when nobody on the team wants to be on call, or when the real cost of an engineer's time doing operations exceeds the subscription you were avoiding.
12. Experts disagree about the middle ground. One camp argues that a Forgejo instance is so cheap to run that any team should own its own. The other argues that discovery, and the fact that contributors already have GitHub accounts, outweighs everything else for public projects. Both are right about different projects, and the deciding question is whether strangers need to contribute.

■ 40.9.6 WORDS – remember these

1. Self-hosting — running the server yourself — operating the repository host, its storage, its backups and its upgrades on infrastructure you control.
2. git-shell — a login that can only do git — a restricted shell shipped with git that accepts only git-upload-pack, git-receive-pack and git-upload-archive.
3. Gitolite — a rules file in front of a git server — a Perl layer using one configuration repository and an update hook for per-branch access control.
4. Forge — a website around repositories — the general term for GitHub, GitLab, Gitea, Forgejo and Bitbucket.
5. Gitaly — GitLab's git service — the component every other GitLab process must call to read or write a repository.
6. Vendor lock-in — hard to leave — dependence on features whose data has no portable export, as opposed to the commit history, which always exports.
7. Operator — the person who is responsible when it breaks — the role you take on the moment you self-host, covering backups, uptime and patching.

40.10 Migrating and mirroring

■ 40.10.1 PLAIN – in simple words

1. Two jobs get confused with each other, so separate them first.
2. Mirroring means keeping a second copy that stays in step with the first. Both live. You did not leave anywhere.
3. Migrating means moving to a new home and shutting the old one, or leaving it as an archive.
4. For the git part, both jobs are easy and take one or two commands.
5. For everything else, both jobs are hard, and some of it simply cannot be moved at all.
6. Here is the sentence to remember, and it is the honest warning of this whole section: **your commit history is portable, and almost nothing else is.**
7. Commits, branches, tags and file contents move perfectly, byte for byte, with identical hashes.
8. Issues, pull requests, review approvals, build history, release downloads, stars, webhooks and protection rules do not move by themselves, because none of them is in git.

■ 40.10.2 PLAIN – a picture in your head

1. Think about moving house.
2. Your books, clothes and furniture go in boxes. They arrive exactly as they left. Nothing about them changes.
3. The fitted kitchen does not come. The neighbours do not come. Your children's school place does not come. The postal redirection has to be arranged, lasts a while, and then stops.
4. Git history is the boxes. Everything the website added is the fitted kitchen and the school place.
5. And notice which one people actually worry about on moving day. Not the boxes.

Where this comparison breaks:

6. Moving house removes things from the old place. Cloning does not. After you migrate, the old repository still exists, complete, and can still serve.
7. That is why a git migration is unusually safe. You can run both for weeks and switch back with one `git remote set-url`.

■ 40.10.3 PLAIN – a worked example

1. First, what `--mirror` actually gives you. This is a real run.

```
$ git clone --mirror proj mirror.git

$ git -C mirror.git config --get remote.origin.mirror
true

$ git -C mirror.git config --get remote.origin.fetch
+refs/*:refs/*

$ git -C mirror.git show-ref
a3bfdce1... refs/heads/feature/login
2304fd03... refs/heads/main
fb32611e... refs/tags/v1.0
```

2. Compare that with an ordinary clone of the same repository:

```
$ git clone proj plain
$ git -C plain show-ref
2304fd03... refs/heads/main
2304fd03... refs/remotes/origin/HEAD
a3bfdce1... refs/remotes/origin/feature/login
2304fd03... refs/remotes/origin/main
fb32611e... refs/tags/v1.0
```

3. Read the difference carefully. The ordinary clone has one local branch and puts the rest under `refs/remotes/origin/`. The mirror keeps every ref at its original name.
4. That is the whole point of a mirror: it is a copy of the ref namespace, not a copy for working in.
5. Second, keeping a mirror up to date. One command, and `--prune` matters:

```
$ git -C mirror.git remote update --prune
From /tmp/mir/up
- [deleted]    (none) -> hotfix/urgent
```

6. Third, pushing one commit to two servers with one command. Add a second push URL to the same remote:

```
$ git remote set-url --add --push origin /tmp/lab3/srv1.git
$ git remote set-url --add --push origin /tmp/lab3/srv2.git
$ git remote -v
origin /tmp/lab3/srv1.git (fetch)
origin /tmp/lab3/srv1.git (push)
origin /tmp/lab3/srv2.git (push)

$ git push origin main
To /tmp/lab3/srv1.git
  99b5afc..a98de55  main -> main
To /tmp/lab3/srv2.git
  * [new branch]    main -> main
```

- One `git push`, two servers, and both now hold the identical SHA `a98de5517c0e80180ed2a1ccd6795d47f155beb5`.
- Fourth, the trap. A mirror push is a replica, not a backup. Watch what happens when a branch is deleted upstream:

```
$ git -C up branch -D hotfix/urgent
Deleted branch hotfix/urgent (was d9a902a).

$ git -C mir.git remote update --prune
- [deleted] (none) -> hotfix/urgent

$ git -C mir.git push --mirror /tmp/mir/dest.git
To /tmp/mir/dest.git
- [deleted] hotfix/urgent
```

- The deletion was faithfully copied to the second server. A mirror reproduces mistakes exactly as well as it reproduces work. Keep that in mind for the backup section.

■ 40.10.4 PLAIN – what is really happening inside

- `git clone --mirror` does three things and nothing magical.
- It makes the new repository bare, so there is no working tree.
- It sets `remote.origin.mirror` to `true`.
- It sets the fetch refspec to `+refs/*:refs/*`, meaning “take every ref, of every kind, and store it under the same name, forcing where needed”.
- Compare that with the ordinary clone refspec, `+refs/heads/*:refs/remotes/origin/*`, which takes only branches and files them under a separate prefix.
- That single line of configuration is the entire difference between a copy you work in and a copy that stands in for the original.
- On the push side, `git push --mirror` sends every local ref and deletes every destination ref that you do not have. That is why the deletion propagated above.
- One consequence surprises everybody who mirrors a GitHub repository. `+refs/*:refs/*` includes GitHub’s pull request refs. Here is a real mirror clone of a public repository:

```
$ git clone --mirror https://github.com/octocat/Hello-World hw.git
$ git -C hw.git show-ref | wc -l
3439
$ git -C hw.git show-ref | grep -c refs/pull/
3436
```

- Three branches, and three thousand four hundred and thirty-six pull request refs. If you then push that mirror to a new host, you are trying to create three thousand refs the new host neither wants nor allows.
- The fix is to fetch or push only what you mean, using an explicit refspec such as `+refs/heads/*:refs/heads/*` and `+refs/tags/*:refs/tags/*`.

■ 40.10.5 TECHNICAL – the engineer’s version

- What actually travels, and what does not.

Thing	Inside git?	Copied by clone
Commits, trees, blobs	yes	yes
Branches	yes	yes, renamed

Thing	Inside git?	Copied by clone
Lightweight tags	yes	yes
Annotated tag objects	yes	yes
Notes in refs/notes	yes	only with refspec
Signatures on commits	yes	yes
Issues and comments	no	no
Pull requests, reviews	no	no
CI runs and logs	no	no
Releases and assets	no	no
Wiki content	separate repo	separate clone
Webhooks, secrets	no	no
Protection rules	no	no
Stars, forks, watchers	no	no

- The wiki row is worth knowing precisely: GitHub stores a repository wiki as a separate git repository, reachable at the repository address with `.wiki.git` on the end. So the wiki does migrate, but only if you deliberately clone it as a second repository.
- A correct migration of the git part, in full:

```
git clone --mirror https://github.com/you/proj.git
cd proj.git
git remote set-url --push origin git@newhost:you/proj.git
git push --prune origin \
    '+refs/heads/*:refs/heads/*' \
    '+refs/tags/*:refs/tags/'
```

- That is deliberate rather than clever. It moves branches and tags, prunes what is gone, and does not attempt to move `refs/pull/*`.
- Verify the move by comparing ref lists rather than by looking at a web page:

```
OLD=https://old/proj.git
NEW=git@newhost:you/proj.git
git ls-remote --heads --tags $OLD | sort > old.txt
git ls-remote --heads --tags $NEW | sort > new.txt
diff old.txt new.txt && echo "identical"
```

- Metadata is a separate project with separate tools, and no standard format exists. As of 2026 the realistic options are:

Source and target	Tool	What it carries
GitHub to Gitea, Forgejo	built-in migration	issues, PRs, labels
GitHub to GitLab	GitLab importer	issues, MRs, comments
GitLab to GitLab	project export file	most things
Anything to anything	the REST API	whatever you code

- For a do-it-yourself export the practical route is the API. The GitHub CLI can page through issues and write JSON, which you then store in the repository itself so it is versioned with the code:

```
gh api --paginate repos/OWNER/REPO/issues?state=all \
    > issues.json
gh api --paginate repos/OWNER/REPO/pulls?state=all \
    > pulls.json
```

8. GitHub also offers migration archives through its migrations API for organizations, producing a downloadable archive of repositories and associated metadata. Availability and contents depend on your plan, so check before you rely on it.
9. Now the honest warnings, which matter more than the commands.
10. Issue numbers will not survive. Every forge assigns its own numbering, so “fixes #42” in a commit message will point at the wrong thing after migration. The commit message is immutable, so this cannot be corrected without rewriting history.
11. Cross-references, mentions of users, and links between issues and pull requests are stored as identifiers that mean nothing on the new host.
12. Timestamps and authorship on imported issues usually become “imported by the migration account on the day of import” unless the importer has special support, because most APIs will not let you post as someone else.
13. Attachments in comments are files on the old host, served from the old host’s storage, and vanish when the repository does.
14. Build history and logs are effectively unmovable. Treat them as data with a retention period, not as a permanent record.
15. So the practical rule for anything you truly cannot lose: put it in the repository. A decision written in a Markdown file in docs/ migrates perfectly, forever, because it is a blob. The same decision written in an issue comment is the platform’s, not yours.

■ 40.10.6 WORDS – remember these

1. Mirror clone — a copy of every ref under its own name — `git clone --mirror`, which sets `remote.origin.mirror=true` and the `refspec+refs/*:refs/*` on a bare repository.
2. Mirror push — make the far side match me exactly — `git push --mirror`, which creates, updates and deletes refs to match the local set.
3. Prune — remove refs the other side no longer has — `--prune` on fetch, remote update or push.
4. Second push URL — one remote, two destinations — extra push URLs added with `git remote set-url --add --push`.
5. Migration — moving to another host — copying refs and objects with git, then copying metadata with each platform’s own tools, imperfectly.
6. Platform metadata — everything not in git — issues, reviews, runs, releases and rules, which have no interchange standard.

40.11 Working with others, practically

■ 40.11.1 PLAIN – in simple words

1. There are only two ways to arrange a team around a repository.
2. The shared repository model. Everyone can push to the same repository, and they push branches, not straight to main.
3. The fork model. Nobody outside the core team can push at all. Outsiders make their own server-side copy, push there, and ask for their work to be taken.
4. The shared model is for people you trust: a company team, a class group, a startup.
5. The fork model is for strangers: any public project where anyone in the world may send a change.
6. Both end at the same place, a pull request, so they look identical in the web interface. The difference is only in who may write where.
7. On top of that choice sits a second one: how branches are organized over time. There are three well-known answers, and they have real trade-offs.

8. And on top of that sits one rule everybody agrees on: protect main.

■ 40.11.2 PLAIN – a picture in your head

1. Think of a shared document at a college.
2. The shared repository model is a group project. Everyone has edit rights, but the agreement is that you work on your own page and ask before merging your page into the final report.
3. The fork model is a published book. You cannot write in the book. You make a photocopy, mark it up, and post your marked copy to the editor, who decides whether to take your change.
4. A publisher does not give edit rights to every reader. That would be absurd, and it is exactly why open-source projects use forks.
5. A group of four friends does not photocopy the report for each other. That would be pointless ceremony, and it is why company teams use the shared model.

Where this comparison breaks:

6. A photocopy goes out of date the moment the book changes. A fork does not have to. You can add the original as a second remote and pull from it, so your copy stays current.
7. And the editor in this picture merges by hand. A pull request merge is performed by the server, exactly, using git.

■ 40.11.3 PLAIN – a worked example

1. Here is the fork-and-pull-request path drawn out. Only two steps in it are git; the rest are the website.

2. In the shared repository model, the first two boxes disappear. You clone upstream/proj directly, push feature/login to it, and open the pull request from there.
3. Now branch names. Git's rules are stricter than people expect, and this is real output from git check-ref-format:

```

OK   feature/login
OK   feature/ABC-123-add-login
OK   release/1.0
OK   Feature/Login
BAD  feature/add login
BAD  feature//login
BAD  feature/login.lock
  
```

```
BAD feature/.hidden
BAD feature/login~1
BAD feature/login^
```

4. So a space is illegal, a double slash is illegal, a component starting with a dot is illegal, an ending of .lock is illegal, and the characters ~ ^ : ? * [\ are illegal.
5. Feature/Login is legal but a bad idea, because on macOS and Windows the filesystem usually ignores case and two branches differing only in case will collide.
6. And here is the trap that catches every team once:

```
$ git branch feature/login
$ git branch feature
fatal: cannot lock ref 'refs/heads/feature':
'refs/heads/feature/login' exists;
cannot create 'refs/heads/feature'
```

7. A loose ref is a file on disk, so feature cannot be both a file and a directory. Pick a prefix scheme and never use a bare prefix as a branch.
8. Finally, the three ways a pull request can land. All three of these are real graphs from the same starting point:

```
1. merge commit (--no-ff)
* 0685fe9 Merge pull request: login
|\
| * 00ee7d7 Fix login typo
| * 046ed60 Start login
* | ec53eed Unrelated work on main
|/
* cd18e97 Base commit

2. squash merge
* 23a1f88 Add login (#42)
* ec53eed Unrelated work on main
* cd18e97 Base commit

3. rebase then fast-forward
* 12a1676 Fix login typo
* 0ae1582 Start login
* ec53eed Unrelated work on main
* cd18e97 Base commit
```

9. Look at what each one costs. The merge commit keeps every step and the shape. The squash keeps one tidy commit and throws away the steps. The rebase keeps the steps and throws away the shape, and it made new SHAs: 046ed60 became 0ae1582.
10. That last point is the reader's own experience. Rebasing a local branch onto a moved main changed the branch's SHA, because rebase does not move commits. It creates new commit objects with new parents, and therefore new hashes.

■ 40.11.4 PLAIN - what is really happening inside

1. A fork, mechanically, is a repository on the server plus a database row saying "this came from that". Git has no idea it happened.
2. When you fork on GitHub, the new repository may share object storage with the original, which is why forking a huge repository is instant. That is an implementation detail of one product, not part of git.

3. A pull request from a fork works because both repositories are on the same server, so the server can read your head commit directly.
4. Now the three branching models, described by what they actually do to the graph.
5. Git flow, published by Vincent Driessen on 5 January 2010, keeps two permanent branches, `main` and `develop`, plus `feature/*`, `release/*` and `hotfix/*`. Work flows feature into `develop`, `develop` into a release branch, release into `main` and back into `develop`.
6. GitHub flow, published by Scott Chacon on 31 August 2011, keeps one permanent branch. Branch off `main`, open a pull request, get review, merge, deploy. There is no `develop` branch and no release branch.
7. Trunk-based development keeps one permanent branch and adds a rule about time: branches live hours, not days, and unfinished work is hidden behind feature flags rather than hidden on a branch.
8. Notice what the three actually disagree about. Not tooling. They disagree about how long a change may live away from the mainline.
9. Long-lived branches are the cost. Every day a branch lives, the mainline moves under it, and the merge gets harder. This is not an opinion; it is what a graph does when two lines diverge.
10. Protecting `main` is the mechanism that makes any of the three safe. A protected branch cannot be pushed to directly, cannot be force-pushed and cannot be deleted, and merges into it require whatever checks you set.
11. Without protection, all three models are just polite suggestions, exactly like a client-side hook.

■ 40.11.5 TECHNICAL – the engineer’s version

1. The two collaboration models compared on the things that actually differ.

Question	Shared repo	Fork model
Who may push branches	the team	only your fork
Write access needed	yes	no
Number of remotes	one	two
Suits	trusted teams	public projects
CI secrets exposure	trusted	needs care

2. The last row is a real security point. A workflow triggered by a pull request from a fork must not be given repository secrets, or any stranger could exfiltrate them. GitHub’s `pull_request` event withholds secrets from fork pull requests for exactly this reason, while `pull_request_target` runs with them and is dangerous if misused.
3. The three branching models, with honest trade-offs.

Model	Long-lived branches	Best for
Git flow	<code>main</code> and <code>develop</code>	versioned releases
GitHub flow	<code>main</code> only	continuous deploy
Trunk-based	<code>main</code> only	high-rate teams

4. Driessen added a note to his own 2010 article in March 2020 saying that if your team does continuous delivery you should adopt a much simpler workflow such as GitHub flow, and that git flow still fits software that is explicitly versioned or must support several versions in the wild.
5. That is the fairest summary available, and it comes from the author of the model people argue about.

6. The research position: the 2018 book *Accelerate*, by Nicole Forsgren, Jez Humble and Gene Kim, reports that high-performing teams have fewer than three active branches, branch lifetimes under a day, and rarely or never have code freezes.
7. Read that as a correlation found in survey data, not as a law. The critics' point is fair too: trunk-based development requires strong automated tests and feature flags, and a team without them will simply break main faster.
8. Recommended day-one setup for a small team, concretely. This is a working configuration, not a philosophy.
9. Set the default branch name once per machine, so nobody argues:

```
| git config --global init.defaultBranch main
```
10. That option arrived in Git 2.28, released 27 July 2020. GitHub changed the default branch for newly created repositories to `main` in October 2020. Older repositories were not renamed, which is why both names are still everywhere.
11. On the repository, turn on branch protection for `main` with these settings: require a pull request before merging, require at least one approving review, require status checks to pass, require branches to be up to date before merging, and block force pushes and deletions.
12. Choose one merge method and disable the others, so history has one shape. Squash merge is the usual choice for small teams because it makes `main` one commit per change and keeps `git log --oneline` readable.
13. Agree a branch prefix scheme and write it in the README. A workable one is `feature/`, `fix/`, `chore/`, `docs/`, plus the ticket identifier, giving names like `feature/ABC-123-add-login`.
14. Add a CODEOWNERS file even with three people. It costs two lines and it means nobody has to remember who reviews what.
15. Add one CI workflow that runs the tests on every pull request, and make it a required check. An unenforced test suite decays within weeks.
16. Turn on tag protection or use signed tags for anything you release, so a version number cannot be quietly repointed.
17. Verify CI by run identifier against the exact head SHA rather than by trusting a green tick beside a branch name. In the reader's own session that distinction was the difference between believing a result and knowing one.
18. Do not add: a `develop` branch, a release branch per version, or a rule that two people must approve, until you have a concrete reason. Each of those is a real cost paid every day.

■ 40.11.6 WORDS – remember these

1. Fork — your own server-side copy of a project — a forge-level repository copy plus a recorded parent relationship, invisible to git.
2. Upstream — the original project you forked from — conventionally a second remote named `upstream` alongside `origin`.
3. Shared repository model — everyone pushes branches to one repository — collaboration requiring write access, with policy enforced by protection rules.
4. Git flow — the two-permanent-branch model from 2010 — `main` plus `develop` with `feature/*`, `release/*` and `hotfix/*` branches.
5. GitHub flow — branch, pull request, merge, deploy — a single permanent branch model published in 2011.
6. Trunk-based development — branches measured in hours — mainline development with short-lived branches and feature flags instead of long branches.

7. Feature flag — a switch that hides unfinished work — a runtime condition allowing incomplete code to be merged but not executed.
8. Protected branch — main cannot be pushed to directly — a server-side rule blocking direct pushes, force pushes and deletion.
9. Squash merge — many commits become one — a merge that applies the combined change as a single new commit with one parent.
10. check-ref-format — the rules for legal ref names — `git check-ref-format`, which rejects spaces, `..`, `~`, `^`, `:`, `?`, `*`, `[`, trailing `.` lock and leading dots.

40.12 Monorepos and large repositories

■ 40.12.1 PLAIN - in simple words

1. A monorepo is one repository holding many projects that could have been separate repositories.
2. Big companies use them for one reason above all others: one commit can change a library and every user of that library at the same time.
3. That removes the hardest problem in large systems, which is not writing code but keeping many versions of many pieces compatible.
4. You also get one place to search, one build configuration, and no arguing about which repository a change belongs in.
5. The price is size, and size hurts git in specific, measurable ways.
6. Clones get slow, because a clone copies the whole history by default.
7. Everyday commands get slow, because git checks every file it tracks.
8. Tools get slow or give up, because editors and search programs were not written with a million files in mind.
9. Git has four answers, and you can combine them: shallow clone, partial clone, sparse checkout, and Git LFS for large files.
10. And one weakness has no good answer: binary files. Git stores them, but it stores them badly, and this section will show exactly how badly.

■ 40.12.2 PLAIN - a picture in your head

1. Think of a library that keeps every edition of every book it has ever held.
2. If you want to borrow one novel, the librarian hands you the entire archive on a trolley, including every draft of every book, and says “it is all yours now, take it home”.
3. That is `git clone`. It is wonderful once you have it and painful the first time.
4. A shallow clone is asking for only the newest edition of everything.
5. A partial clone is asking for the catalogue now and the actual pages later, only when you open a book.
6. A sparse checkout is taking the whole archive home but only unpacking the one shelf you work on.
7. Git LFS is the library keeping the heavy art books in a warehouse and giving you a slip of paper saying where each one is.

Where this comparison breaks:

8. Fetching a page later feels free in a library. In a partial clone it is a network round trip, and if you ask for thousands of pages one at a time it is dramatically slower than having taken the trolley. There are real numbers for this in the worked example, and they are worse than most people guess.

■ 40.12.3 PLAIN – a worked example

1. Every number here was measured for this chapter against one real public repository, the GitHub CLI source, which has 11,772 commits and 1,356 tracked files. It is a medium repository, not a giant one.
2. First, the three ways to clone it.

Clone type	.git size	Time	Commits
Full clone	81 MB	5.9 s	11,772
Blobless, blob:none	27 MB	3.4 s	11,772
Shallow, depth 1	15 MB	2.3 s	1

3. Read the middle row carefully. The blobless clone still has every commit and every tree. It has 11,772 commits, same as the full clone. What it does not have is old file contents.
4. That is usually the right trade, because history browsing needs commits, and commits are small. File contents are what is big.
5. Object counts make the same point:

```
full clone    in-pack 90,539    size-pack 79.75 MiB
blobless     in-pack 64,891    size-pack 25.66 MiB
shallow 1    in-pack 1,776    size-pack 14.58 MiB
```

6. Second, sparse checkout, which is about the working tree rather than the history. This checks out one directory only:

```
$ git sparse-checkout set --cone pkg/cmd/pr
$ git ls-files | wc -l
1356
$ find . -path ./.git -prune -o -type f -print | wc -l
115
```

7. Git still tracks all 1,356 files. Only 115 exist on disk. The working tree shrank from 27 MB to 1.4 MB.
8. The index shows how it is done. 1,241 entries are marked skip-worktree and 115 are present.
9. Third, the honest cost of a partial clone. The same command in both:

Command	Full clone	Blobless clone
git log -p -300	0.197 s	106 s

10. That is not a typo. Reading the patch text of the last 300 commits took a fifth of a second with all objects present, and one minute forty-six seconds when each missing blob had to be fetched over the network.
11. The .git directory grew from 27 MB to 29 MB during that command, and 51 extra pack files appeared, each marked .promisor, meaning “fetched lazily from the promising remote”.
12. So partial clone is not free speed. It moves cost from clone time to the first command that needs old content.
13. Fourth, Git LFS. Here is what git actually stores when a 1 MiB binary file is tracked by LFS:

```
$ git cat-file -p HEAD:blob.bin
version https://git-lfs.github.com/spec/v1
oid sha256:5e20a633da26ff9bceb11f08d4671c234
```

```
38c49362cefce5042e8c77bb58bbdf9
size 1048576

$ git cat-file -s HEAD:blob.bin
132
```

14. The object in git is 132 bytes of text. The real megabyte lives outside the object database, under `.git/lfs/objects`, and is fetched by a separate program over a separate protocol.
15. Note the oid line. It is a SHA-256 of the file contents, and it matches what `sha256sum` reports for the real file. The pointer is content-addressed, just like git itself.
16. Fifth, why binaries are git's weak point. Two repositories, ten commits each, both starting from nothing:

Repository, 10 revisions	Packed size
1 MiB random binary	10.01 MiB
2.1 MB text, tiny edits	148.27 KiB

17. Ten revisions of a one-megabyte binary cost ten megabytes. Ten revisions of a two-megabyte text file cost 148 kilobytes.
18. The text repository is fourteen times smaller while holding twice as much content per revision. That gap is the whole story of binaries in git.

■ 40.12.4 PLAIN – what is really happening inside

1. Git compresses history in two stages: `zlib` on each object, then delta compression, where one object is stored as a small set of instructions for turning another object into it.
2. Delta compression is why a text repository stays tiny. Change one line in a 60,000-line file and the delta is a few dozen bytes.
3. A compressed or random binary file has no useful similarity to the previous version. Change one pixel in a PNG and the compressed bytes change everywhere. The delta is as big as the file, so git stores a whole new copy.
4. That is not a bug and no setting fixes it. It is what content-addressed storage plus general-purpose compression can do.
5. Worse, git never forgets. Delete the 500 MB file today and it is still in every clone forever, because it is still reachable from an old commit.
6. Git LFS works around this by keeping a tiny text pointer in the repository and the real bytes elsewhere. A `clean` filter converts the file to a pointer on `git add`, and a `smudge` filter converts it back on checkout.
7. So the history contains only 132-byte pointers, which delta beautifully, and the big files are transferred by a separate service that fetches only the versions you actually check out.
8. The four scaling techniques attack four different costs, and it is worth being exact about which is which.
9. Shallow clone cuts the number of commits you download. It is the right tool for a build machine that only needs the newest source.
10. Partial clone cuts the number of objects you download, keeping the full commit graph. It is the right tool for a developer who needs history but not every old file.
11. Sparse checkout cuts the number of files written to disk. It does not reduce download size at all, but it makes `git status`, editors and search tools fast again.

12. Git LFS cuts what enters the history in the first place. It is the only one of the four that changes what is committed.
13. And the index is the quiet cost nobody expects. It is one file listing every tracked path with its metadata. For 1,356 files it was 156,135 bytes. Scale that to a million files and the index alone is over one hundred megabytes, read and written by ordinary commands.

■ 40.12.5 TECHNICAL – the engineer’s version

1. Real monorepos, with their published numbers.

Repository	Figure	Source year
Google, all code	86 TB, 2bn lines	2016 paper
Google, source files	~9 million unique	2016 paper
Google, commits	~35 million	2016 paper
Windows in git	~300 GB, 3.5m files	2017 post
Windows pushes	8,421 per day	2017 post

2. The Google figures come from the paper “Why Google Stores Billions of Lines of Code in a Single Repository” by Rachel Potvin and Josh Levenberg, published in Communications of the ACM in July 2016 and describing a January 2015 snapshot. It also reports roughly 25,000 developers, about 16,000 human commits and about 24,000 automated commits on a typical workday.
3. Important honesty point that most retellings omit: Google’s monorepo does not run on git. It runs on Piper, an in-house system, with a virtual filesystem client. So it is evidence that monorepos work at scale, not evidence that git works at that scale.
4. The Windows figures come from Brian Harry’s post of 24 May 2017, “The largest Git repo on the planet”, describing about 4,000 engineers, 1,760 official builds per day across 440 branches, and the Git Virtual File System that Microsoft had to build to make it possible.
5. GVFS was announced in February 2017, later renamed VFS for Git, and the ideas were pushed upstream over the following years as partial clone, sparse checkout in cone mode, the commit-graph file and the built-in filesystem monitor.
6. Version history of the relevant features, so you know what your git can do.

Capability	Git version	Date
Shallow clone, <code>--depth</code>	1.5 era	2007 onward
commit-graph file	2.18	Jun 2018
Partial clone, <code>--filter</code>	2.19 era	Sep 2018
git sparse-checkout	2.25	13 Jan 2020
Built-in fsmonitor	2.37	27 Jun 2022

7. Partial clone filters worth knowing: `--filter=blob:none` omits all blobs; `--filter=blob:limit=1m` omits blobs above a size; `--filter=tree:0` omits trees as well and is meant for tooling, not for humans.
8. A partial clone records the remote as a promisor. Objects arrive lazily, and lazily fetched packs are marked with a `.promisor` file. In the measurement above, 51 such packs appeared during one `git log -p`.
9. The server must permit it. `uploadpack.allowFilter` must be true on the serving side, or `--filter` is silently ignored and you get a full clone.

10. Sparse checkout in cone mode restricts patterns to whole directories, which lets git match paths with prefix comparisons instead of running every pattern against every path. Non-cone mode accepts full gitignore-style patterns and is much slower on large trees.
11. Practical settings for a large repository, all real configuration keys:

```
git config core.fsmonitor true
git config core.untrackedCache true
git config feature.manyFiles true
git maintenance start
```
12. `feature.manyFiles` is an umbrella that sets `index version 4` and `core.untrackedCache`. `git maintenance start` schedules background repacking and commit-graph writing rather than waiting for `git gc` to interrupt you.
13. Git LFS, released by GitHub in April 2015, is not part of git. It is a separate program plus a separate HTTP API. `git lfs track "*.psd"` writes a line to `.gitattributes` naming the clean, smudge and merge filters.
14. Consequences people discover late: anyone cloning your repository needs git-lfs installed or they get pointer files instead of content; LFS storage and bandwidth are billed separately by most hosts; and converting an existing repository to LFS rewrites history, which changes every SHA.
15. Alternatives worth naming: `git-annex`, which predates LFS and is more flexible; and simply keeping large assets out of the repository entirely, in object storage referenced by a versioned manifest file.
16. Removing a large file that is already in history requires rewriting it out. The current recommended tool is `git filter-repo`; the older `git filter-branch` is deprecated for being slow and easy to misuse. Both change every commit hash after the touched point, so every collaborator must re-clone.

■ 40.12.6 WORDS - remember these

1. Monorepo — one repository for many projects — a single version-controlled tree containing multiple deliverables with one commit history.
2. Shallow clone — only the newest commits — `--depth N`, producing a truncated history with grafted boundary commits.
3. Partial clone — download objects on demand — `--filter=blob:none` or similar, with the origin recorded as a promisor remote.
4. Promisor remote — the server that owes you objects — the remote a partial clone will lazily fetch missing objects from.
5. Sparse checkout — only some files on disk — index entries marked `skip-worktree` so git neither writes nor scans them.
6. Cone mode — directory-shaped sparse patterns — the fast form of sparse checkout, matching whole directories by prefix.
7. Delta compression — store the difference, not the file — packfile encoding of one object as instructions against a similar base object.
8. Git LFS — big files kept outside history — a filter that commits a small pointer file and stores real content on a separate service.
9. Pointer file — the 130-odd bytes git actually stores — a three-line text blob giving spec version, a SHA-256 oid and a byte size.
10. `filter-repo` — the supported way to rewrite history — the recommended replacement for `git filter-branch`, which rewrites every affected commit and therefore every hash.

40.13 Backing up a git repository properly

■ 40.13.1 PLAIN – in simple words

1. People say “every clone is a backup”. That is half true, and the missing half is the half that hurts.
2. A clone gives you every commit reachable from the branches you cloned, and the tags. That really is a lot, and it really does survive the server burning down.
3. A clone does not give you other refs, the reflog, stashes, the repository’s own configuration, its hooks, or anybody’s uncommitted work.
4. A mirror gives you every ref, of every kind, under its original name. That is more than a clone.
5. A mirror still does not give you reflogs, hooks or configuration, and it has a specific danger: it copies deletions too.
6. Neither gives you a single thing that lives on the website: issues, pull requests, reviews, build history, releases, secrets or settings.
7. And neither, on its own, protects you from the most common real disaster, which is not hardware failure. It is somebody force-pushing over a branch, or deleting one, and the automatic mirror faithfully copying that within the hour.
8. A real backup therefore has three properties a mirror does not have: it is dated, it is read-only once written, and it is kept for a while.

■ 40.13.2 PLAIN – a picture in your head

1. Imagine three ways of protecting a handwritten manuscript.
2. A friend borrowed a copy last month. That is a clone. It is genuinely useful, it is complete up to when they took it, and it is out of date.
3. A machine in the next room copies your desk every hour, exactly. That is a mirror. It is always current, and if you spill ink on page 40, the machine copies the ink stain within the hour.
4. A sealed, dated envelope goes into a fire safe every night and stays there for ninety days. That is a backup. It cannot be edited, it can be opened at any date you choose, and the ink stain does not reach it.
5. Most teams have the first two and call it done.

Where this comparison breaks:

6. A copy of a manuscript can be a slightly bad copy. A git clone cannot. Every object is verified against its hash, so a corrupted copy is detectable and usually refuses to load rather than lying to you.
7. And the friend with the month-old copy is genuinely enough to save the project, which is not true of a month-old photocopy of an edited book. Git history is append-only in normal use, so old copies stay valid.

■ 40.13.3 PLAIN – a worked example

1. First, what a clone leaves behind. A real source repository was set up with a stash, extra reflog entries, untracked files, a hook and a local setting, then cloned normally:

source repository	clone
stashes: 1	stashes: 0
reflog entries: 3	reflog entries: 1
untracked files: 2	untracked files: 0
custom hooks: 1	custom hooks: 0
local user.signingkey	(absent)
commits: 2	commits: 2

2. The commits came across perfectly. Everything else did not.
3. Second, what a mirror adds. The same source, cloned with `--mirror`:

```
$ git -C mtest.git show-ref
dbcd961d... refs/heads/main
f4caa812... refs/stash
141f4579... refs/tags/backup-2026-08-13

$ ls mtest.git/hooks | grep -v sample | wc -l
0
$ git -C mtest.git reflog | wc -l
0
```

4. Look at the second line of `show-ref`. The mirror picked up `refs/stash`, because its refspec is `+refs/*:refs/*` and a stash is a ref. A plain clone never does that.
5. The hooks did not come. The `reflog` did not come. The source's local configuration did not come.
6. Third, a real backup run, start to finish. This is the whole procedure and every line below is genuine output.

```
$ git -C repo.git remote update --prune

$ git -C repo.git fsck --full
dangling commit de306ffa47620fa7e0d5ef7146...

$ git -C repo.git bundle create vault/proj-2026-08-13.bundle --all

$ ls -l vault/
1045 proj-2026-08-13.bundle

$ git -C repo.git bundle verify vault/proj-2026-08-13.bundle
vault/proj-2026-08-13.bundle is okay
The bundle contains these 4 refs:
a3bfdce1... refs/heads/feature/login
2304fd03... refs/heads/main
fb32611e... refs/tags/v1.0
2304fd03... HEAD
The bundle records a complete history.
The bundle uses this hash algorithm: sha1
```

7. That bundle is one ordinary file. You can copy it anywhere, put it on any storage, and it needs no git server to be useful.
8. `dangling commit` in the `fsck` output is normal, not an error. It means an object exists that no ref points at any more, which happens after a rebase or an amended commit.
9. Fourth, and this is the step almost everyone skips, the restore drill:

```
$ git clone vault/proj-2026-08-13.bundle restore
$ git -C restore log --oneline | head -3
2304fd0 Add app.py
20b8927 First commit: add README
$ git -C restore rev-list --count --all
3
```

10. It restored. Now you know. A backup you have never restored is not a backup; it is a hope.

■ 40.13.4 PLAIN – what is really happening inside

1. Git keeps an object only while something can reach it. Refs are the roots. Anything reachable from a ref is kept; anything not is eventually removed by garbage collection.

2. That single rule explains the whole backup problem.
3. When you clone, git asks for the refs it wants and receives everything reachable from them. Objects reachable only from refs you did not ask for simply do not come.
4. A plain clone asks for refs/heads/* and tags. So refs/stash, refs/notes/* and any custom ref namespace are left behind.
5. A mirror asks for refs/*, so it gets all of them.
6. Neither asks for the reflog, because the reflog is not a ref. It is a local log file under .git/logs, private to one repository, recording where each ref used to point.
7. That matters because the reflog is what saves you from your own mistakes. It is the thing that lets you recover a commit after a bad reset. It is also the thing no backup of the server can give you.
8. Now the deletion problem. Suppose somebody force-pushes over main, discarding fifty commits. On the server the old commits become unreachable.
9. Your hourly mirror runs, sees main moved, moves its own main, and now the mirror is unreachable from those commits too. Run garbage collection on the mirror and they are gone for good.
10. A dated bundle written before the force-push is unaffected, because it is a frozen file, not a live replica. This is the reason bundles exist in a backup plan alongside mirrors.
11. What a bundle actually is: a packfile with a small header listing ref names and, for an incremental bundle, the commits the receiver must already have. `git bundle verify` checks both the pack and those prerequisites.
12. And a bundle is a first-class remote. `git clone file.bundle`, `git fetch file.bundle`, and `git ls-remote file.bundle` all work, which is why the restore drill above is one ordinary clone.

■ 40.13.5 TECHNICAL – the engineer’s version

1. Coverage table. This is the section in one picture.

Item	Clone	Mirror	Bundle –all
Branch commits	yes	yes	yes
Tags	yes	yes	yes
refs/stash	no	yes	yes
refs/notes	no	yes	yes
Custom ref namespaces	no	yes	yes
Reflog	no	no	no
Hooks	no	no	no
Repository config	no	no	no
Uncommitted work	no	no	no
Issues, PRs, CI, releases	no	no	no
Survives a force-push	no	no	yes, if dated

2. Incremental bundles work and are small. A real example: the full bundle was 1,497 bytes and the bundle of everything since a tag was 703 bytes.

```
$ git bundle create incr.bundle main --not backup-2026-08-13
$ git bundle verify incr.bundle
incr.bundle is okay
The bundle contains this ref:
dbcd961d... refs/heads/main
The bundle requires this ref:
141f4579...
```

3. “Requires this ref” is the prerequisite. Applying it to a repository that already has that commit works; applying it to an empty one fails cleanly rather than silently producing a broken repository.

```
$ git fetch /tmp/bk/incr.bundle main:restored
$ git log --oneline restored
dbcd961 Fourth
9cbb377 Third
141f457 Second
69199b0 First
```

4. A backup procedure that actually holds up. Run it from a machine that is not the git server.

```
# once
git clone --mirror git@host:org/proj.git /srv/bk/proj.git

# every hour: refresh the replica
git -C /srv/bk/proj.git remote update --prune

# every night: dated, immutable snapshot
D=$(date +%F)
git -C /srv/bk/proj.git fsck --full --strict
git -C /srv/bk/proj.git bundle create \
  /srv/vault/proj-$D.bundle --all
git -C /srv/bk/proj.git show-ref > /srv/vault/proj-$D.refs
git -C /srv/bk/proj.git bundle verify \
  /srv/vault/proj-$D.bundle
```

5. Then copy /srv/vault off-site, keep snapshots for a stated retention period, and delete older ones on a schedule you wrote down.
6. Why each step is there:

Step	Protects against
Mirror refresh	server loss
fsck --full	silent corruption
Dated bundle	force-push, deletion
show-ref file	knowing what was there
bundle verify	an unreadable backup
Off-site copy	site-wide loss

7. The show-ref file is cheap and disproportionately useful. When somebody asks “what was main pointing at on the ninth?”, it answers in one line without unpacking anything.
8. The 3-2-1 convention is worth applying here: three copies, on two different kinds of storage, one of them off-site. It is a convention from the photography world, not a standard, but it is sound.
9. Verification is not optional and is cheap in git, because every object is named by the hash of its own contents. `git fsck --full --strict` recomputes those hashes and reports any mismatch. No other backup system gets this for free.
10. Restore drills should be scheduled, not improvised. Once a quarter, clone the newest bundle into a scratch directory, compare `git rev-parse main` with the recorded `.refs` file, and delete it.
11. Now the part git cannot help with. Back up the platform metadata separately, because none of it is in any bundle:

```
gh api --paginate repos/OWNER/REPO/issues?state=all \
  > vault/issues-$D.json
gh api --paginate repos/OWNER/REPO/pulls?state=all \
```

```

    > vault/pulls-$D.json
gh api repos/OWNER/REPO/branches/main/protection \
    > vault/protection-$D.json
gh release list --repo OWNER/REPO \
    > vault/releases-$D.txt

```

12. Secrets cannot be exported at all by design. Keep the authoritative copy in a password manager or a secrets service, and treat the platform's copy as a deployment detail, not as storage.
13. Settings are best kept as code. Branch protection, teams and repository options can be declared in a configuration tool and re-applied to a fresh repository in minutes, which is a better recovery story than a JSON dump nobody knows how to replay.
14. Encryption note: a bundle is not encrypted and not signed. If your history is confidential, encrypt the file before it leaves your control, and record the checksum separately so you can prove the file is intact.
15. Retention worth defaulting to, in the absence of a policy: hourly mirror, nightly bundle kept 30 days, weekly bundle kept 12 weeks, monthly bundle kept 12 months. Adjust for how much you would pay to recover a given day.

■ 40.13.6 WORDS - remember these

1. Reachability — an object is kept if a ref can reach it — the rule that decides what a clone transfers and what garbage collection removes.
2. Dangling object — nothing points at it any more — an object with no ref path to it, reported by `git fsck`, normal after rebase or amend.
3. Bundle — a whole repository in one file — a packfile plus a ref header, usable directly as a remote for clone, fetch and `ls-remote`.
4. Prerequisite — what an incremental bundle assumes you have — commit identifiers listed in the bundle header and checked by `bundle verify`.
5. Replica — always current, always obedient — a mirror that reproduces deletions and force-pushes as faithfully as it reproduces work.
6. Snapshot — frozen and dated — an immutable copy taken at a known time and kept for a stated retention period.
7. Restore drill — proving the backup works — a scheduled rehearsal that clones the newest snapshot and compares refs against a recorded list.
8. `fsck` — check every object against its own hash — `git fsck --full --strict`, which detects corruption that ordinary commands might not notice.

40.98 Common wrong ideas

1. Wrong: GitHub stores my code differently from my laptop. Right: it stores the identical objects with the identical hashes. A commit is `2304fd03...` in both places, or one of them is corrupt. GitHub's replication and routing are invisible to the protocol.
2. Wrong: a pull request is a git feature. Right: git has no such concept. `git help -a` lists nothing called pull request. A pull request is a row in a forge's database plus two ref names, exposed to git only as read-only `refs/pull/N/head`.
3. Wrong: forking is a git operation. Right: forking is a forge action. Git's word for taking a copy is `clone`. A fork is a server-side repository plus a recorded parent relationship that git never sees.
4. Wrong: if GitHub goes away my history is lost. Right: every clone holds the complete commit history. What would be lost is the meeting point and the metadata: issues, reviews, build results and releases. Back those up separately, because git cannot.

5. Wrong: a git server needs special server software. Right: it needs a bare repository and a way to reach it. `git init --bare` plus an SSH account with `git-shell` is a complete, secure server.
6. Wrong: a mirror is a backup. Right: a mirror copies deletions and force-pushes too. It protects against the server dying and not against a person making a mistake. Dated bundles protect against the person.
7. Wrong: a clone copies everything in the repository. Right: it copies objects reachable from branches and tags. It leaves behind the reflog, stashes, hooks, local configuration and all uncommitted work.
8. Wrong: `git push` failing means the push did not happen. Right: a failure while reading the reply, such as `send-pack: unexpected disconnect while reading sideband packet`, tells you the answer was lost, not what the server did. Re-query with `git ls-remote` to find out.
9. Wrong: LFS makes big binary files cheap in git. Right: it moves them out of git. The repository holds a 132-byte pointer, and the bytes live on a separate service with separate storage, separate billing and a separate program that everyone must install.
10. Wrong: a partial or shallow clone is strictly better because it is smaller. Right: it moves cost, it does not remove it. The same `git log -p -300` took 0.197 seconds in a full clone and 106 seconds in a blobless clone, because every missing blob became a network round trip.

40.99 Chapter summary in 20 lines

1. A git server is just another git repository that other machines can reach; there is no special server format and no central authority.
2. The meeting-point copy is normally bare, meaning it has the contents of `.git` at its top level and no working files.
3. `git init --bare proj.git` builds one in about ten milliseconds, and pushing into a non-bare repository's checked-out branch is refused by default.
4. Running the whole loop by hand proves the model: create the bare repository, push, clone elsewhere, commit there, push back, pull into the first copy.
5. A remote is a name for a URL plus a refspec, and a URL is only a path plus a way of reaching it, so `/tmp/lab/srv/proj.git` and `git@host:proj.git` are the same idea.
6. The refspec `+refs/heads/*:refs/remotes/origin/*` says: take every branch, store it under a separate prefix, and allow non-fast-forward updates.
7. Server hooks are real enforcement: `pre-receive` gates the whole push, `update` gates one ref, `post-receive` acts afterwards and cannot refuse.
8. Client hooks are advice, because `--no-verify` skips them, they are not versioned, and a non-executable hook file is silently ignored.
9. GitHub is four layers: hosting for bare repositories, a web interface, identity and permissions, and automation. Founded 2008, bought by Microsoft in 2018 for 7.5 billion United States dollars.
10. The git layer of GitHub is ordinary git; `git ls-remote` against it prints exactly the same shape of output as against a folder in `/tmp`.
11. Pull requests, reviews, branch protection, required checks, CODEOWNERS behaviour, issues, projects, releases, packages, Actions, both APIs and the permission model are all GitHub, not git.
12. The reader's outage proves the boundary: local git kept working, remote git and the whole GitHub API did not, exactly as the local/remote split predicts.
13. `origin/main` reading `0a95cc8` during the outage was a cached photograph, not a live fact, and a failure while reading a reply says nothing about whether the write landed.
14. Self-hosting is real and cheap: SSH plus `git-shell` costs tens of megabytes, Gitea or Forgejo runs in 1 GB, GitLab CE wants 8 to 16 GB.

15. Self-hosting buys control, privacy and no lock-in, and it makes you the operator, responsible for backups, uptime and patches at three in the morning.
16. Migration moves commits perfectly and almost nothing else; issue numbers, cross-references, timestamps, attachments and build history do not survive.
17. Choose the collaboration model by trust: shared repository for a team you trust, forks for strangers; then protect main, or every rule is a suggestion.
18. Git flow, GitHub flow and trunk-based development disagree about exactly one thing: how long a change may live away from the mainline.
19. Large repositories are managed with shallow clones, partial clones, sparse checkout and LFS, and binaries remain git's weak point because they do not delta-compress.
20. A clone is not a backup, a mirror is not a backup, and a backup you have never restored is not a backup either.

CI/CD and What a “Run” Really Is

41.0 What this chapter gives you

1. You will be able to explain what continuous integration is as a practice, and say clearly why it is not the same thing as a tool that runs tests.
2. You will be able to state the difference between continuous delivery and continuous deployment in one sentence each, without muddling them.
3. You will be able to describe what a runner is, what it has installed when it starts, and why a command that works on your laptop fails there.
4. You will be able to read a complete GitHub Actions workflow file line by line, and translate the same pipeline into GitLab CI.
5. You will be able to name every common trigger, and explain why `pull_request_target` is a security trap while `pull_request` is not.
6. You will be able to explain the single most important idea here: a run is attached to one commit hash, never to a branch name.
7. You will be able to verify continuous integration by run ID against an exact head hash, using real commands, and list six ways a branch-level green tick can lie to you.
8. You will be able to explain what a merge queue is, what problem it solves, and what every `mergeStatus` value means and implies.
9. You will be able to lay out a sensible pipeline in order, choose a deployment strategy, and handle secrets without leaking them.
10. You will be able to read a failed run methodically instead of guessing.

41.1 What continuous integration means and the problem it solves

■ 41.1.1 PLAIN – in simple words

1. Several people work on the same program at the same time.
2. Each person has their own copy, and each changes different files.
3. Sooner or later all those changes must be joined into one program.
4. Joining them is called **integration**. It is the moment of truth.
5. If everyone waits weeks before joining, the changes have drifted far apart and joining them is slow, painful and full of surprises.
6. Old teams had a word for this: integration hell. It could take days.
7. **Continuous integration** is the opposite habit. Everyone joins their work into the shared copy very often, at least once a day.
8. Small joins are easy. Big joins are hard. So you make the joins small.
9. But joining often is only safe if you also check often.

10. So every time anyone joins, a machine automatically builds the program and runs the tests, and tells you within minutes if it broke.
11. That habit, plus that automatic check, is continuous integration.
12. Notice that the habit comes first. The machine only enforces the habit.

■ 41.1.2 PLAIN – a picture in your head

1. Five students must write one report together, one chapter each.
2. Plan A: everyone writes alone for three weeks, then meets the night before to glue the chapters together.
3. That night is chaos. Two people defined the same term differently. Three people numbered their figures from one. The introduction promises a section that nobody wrote.
4. Plan B: every evening, each student pastes what they have into the one shared document, and one person reads the whole thing top to bottom.
5. Under plan B a clash is found the same evening it is created, while both students still remember what they meant.
6. Now replace “one person reads it top to bottom” with a machine that reads it every single time anyone pastes anything, in two minutes.
7. That machine is the continuous integration server. The evening paste is the practice.

Where this comparison breaks: a report can be a bit inconsistent and still be readable. A program cannot. One mismatched function name and nothing runs at all. Also, a human reader gets bored and misses things on the tenth read. A test suite does not get bored, but it only checks what somebody wrote a test for, which is always less than everything.

■ 41.1.3 PLAIN – a worked example

1. Take a team of five people. Each writes about 200 changed lines a day.
2. Under plan A they integrate once every three weeks, so 15 working days.
3. Lines waiting to be joined: 5 people $\times$ 200 lines $\times$ 15 days = 15,000 lines.
4. Under plan B they integrate once a day: 5 $\times$ 200 $\times$ 1 = 1,000 lines.
5. The pain of a merge does not grow in a straight line with size. Two changes can clash, and the number of possible clashing pairs grows roughly with the square of the number of changes.
6. So a batch fifteen times bigger can feel far worse than fifteen times worse.

Integration gap	Lines in flight	Typical feel
Every 3 weeks	15,000	Days of merge work
Every week	5,000	Hours of merge work
Every day	1,000	Minutes, usually clean
Every commit	~200	Almost always clean

7. The numbers in that table are illustrative, not measured. The shape is what matters: smaller batches, cheaper joins.

■ 41.1.4 PLAIN – what is really happening inside

1. You finish a small piece of work and commit it locally.
2. You push it to the shared server. The push is just data transfer.
3. The server notices that a branch moved and fires an event.

4. That event is delivered to whatever is listening. On a hosted service it goes to an internal queue. For an external tool it goes out as a **webhook**, which is a small message posted to a web address you registered.
5. The listener picks a free machine, or starts a fresh one.
6. That machine downloads the exact commit that was pushed. Not the branch. The commit.
7. It installs the tools the project needs, builds the program, and runs the tests.
8. It records success or failure, and posts that result back, attached to the same commit hash it downloaded.
9. The web page you look at then draws a tick or a cross next to that commit.
10. The whole loop is usually two to twenty minutes. Under ten minutes is the target most teams aim at, because longer than that and people stop waiting for the answer and start guessing.

■ 41.1.5 TECHNICAL – the engineer’s version

1. The phrase “continuous integration” was coined by Grady Booch in his 1991 book Object-Oriented Design With Applications, where it described the habit of integrating incrementally rather than in a big bang.
2. Extreme Programming, developed by Kent Beck on the Chrysler C3 project from 1996 and set out in Extreme Programming Explained in 1999, made it one of its named practices, with the rule that the team integrates and builds many times a day.
3. Martin Fowler and Matthew Foemmel published the article Continuous Integration in 2000, revised by Fowler in 2006 and again in 2024. That article is where most of the working definition comes from.
4. CruiseControl, written at ThoughtWorks and first released on 30 March 2001, was the first widely used continuous integration server. It polled the version control system on a timer, because webhooks did not exist yet.
5. Hudson was started by Kohsuke Kawaguchi at Sun Microsystems in 2004 and first released in 2005. After a dispute with Oracle, a rename vote was called on 11 January 2011 and approved on 29 January 2011. The renamed project is Jenkins.

Year	Thing	Who
1991	Term coined	Grady Booch
1999	XP names the practice	Kent Beck
2000	The defining article	Fowler and Foemmel
2001	CruiseControl released	ThoughtWorks
2011	Hudson renamed Jenkins	Community vote
2019	GitHub Actions CI GA	GitHub

6. Travis CI launched in 2011 and popularized the idea of a build configuration file living inside the repository. CircleCI launched the same year. GitLab CI began as a separate application in 2012 and was folded into GitLab itself in version 8.0 in September 2015.
7. GitHub Actions was announced as a general automation product in October 2018. Its continuous integration capability was announced in beta on 8 August 2019 and became generally available on 13 November 2019.
8. The practice, in its strict form, has three testable properties: everyone merges to the mainline at least daily, every merge triggers an automated build and test, and a broken mainline is fixed immediately and takes priority over new work.

9. Say this plainly: a team running Jenkins on a branch that merges to main once a quarter is not doing continuous integration. It owns a continuous integration tool. The practice and the tool are different things.
10. Observing tools: `gh run list`, `gh run view`, `git log --oneline --since='1 day ago' origin/main` to see integration frequency, and any dashboard that plots merges to trunk per day.

■ 41.1.6 WORDS - remember these

1. Integration — joining everyone’s work into one copy — merging feature branches into the mainline and producing a buildable tree.
2. Integration hell — the painful big join at the end — the superlinear cost of merging long-lived divergent branches.
3. Continuous integration — join often, check automatically every time — the practice of at-least-daily mainline merges verified by an automated build.
4. Webhook — a message the server sends when something happens — an HTTP POST to a registered endpoint carrying a JSON event payload.
5. Mainline or trunk — the one branch everybody joins into — usually main, the integration target for all short-lived branches.
6. Build — turning source into a runnable thing — compile, link, package, including dependency resolution.

41.2 Continuous delivery and continuous deployment

■ 41.2.1 PLAIN - in simple words

1. Continuous integration answers one question: does the joined code work.
2. There is a second question: could we give it to users right now.
3. **Continuous delivery** means the answer is always yes. Every change that passes the checks is packaged, tested in a realistic place, and left in a state where one button press would put it in front of users.
4. A human still decides when to press the button.
5. **Continuous deployment** goes one step further. There is no button. If the checks pass, the change goes live automatically.
6. So the difference is exactly one thing: whether a human approves the last step.
7. Continuous delivery is a capability. Continuous deployment is a policy you can only adopt once you have that capability.
8. Both are abbreviated CD, which is why people confuse them constantly.
9. If somebody says “we do CI/CD”, you have learned almost nothing. Ask which D they mean, and ask what the last manual step is.

■ 41.2.2 PLAIN - a picture in your head

1. Think of a bakery that supplies a shop.
2. Continuous integration is the taste test after mixing. Is the dough right.
3. Continuous delivery is: the bread is baked, wrapped, labelled, loaded onto the van, and the van is parked outside with the engine running.
4. Any moment the manager says go, it leaves. Nothing more to prepare.
5. Continuous deployment is: the van leaves the moment the loading is finished. No manager, no decision.
6. Notice that a bakery can be excellent at delivery and still choose to send the van only twice a day, for business reasons.

7. That is a real and respectable choice. The point of delivery is that the delay is a decision, not a limitation.

Where this comparison breaks: bread cannot be un-delivered. Software can be rolled back, sometimes. Also the van either goes or does not, whereas software can go to one percent of users first, which has no bakery equivalent.

■ 41.2.3 PLAIN – a worked example

1. Here is one change moving through a delivery pipeline, with times.

Stage	What happens	Time
Commit stage	Lint, build, unit tests	4 min
Package	Build image, push it	2 min
Staging deploy	Install to staging	1 min
Acceptance tests	End-to-end suite	9 min
Ready to release	Waiting for approval	0 min
Production deploy	Rolling update	3 min

2. Total machine time is 19 minutes. Under continuous delivery the change sits at “ready to release” until a person approves it.
3. Under continuous deployment, the row “Ready to release” is deleted and the change is live 19 minutes after the commit.
4. The test suites did not change. The pipeline did not change. Only the gate changed.

■ 41.2.4 PLAIN – what is really happening inside

1. The pipeline is a chain of stages. Each stage takes the output of the one before, not a fresh copy of the source.
2. That is the key rule: you build the artifact once, and the same bytes are what gets tested and what gets deployed.
3. If you rebuild before deploying, you have tested something other than what you shipped, and the test result no longer applies.
4. Early stages are fast and cheap and run on everything.
5. Later stages are slow and expensive and only run on things that passed.
6. Each stage either passes the artifact forward or stops it dead.
7. The pipeline itself records which commit each artifact came from, so you can always answer “what is running in production, exactly”.
8. Continuous deployment simply removes the human gate from the last hop, and compensates with automatic checks after the deploy: health checks, error rate alarms, and automatic rollback.

■ 41.2.5 TECHNICAL – the engineer’s version

1. The deployment pipeline as a named pattern comes from Continuous Delivery: Reliable Software Releases through Build, Test, and Deployment Automation by Jez Humble and David Farley, published in 2010.
2. Its core rules are: build binaries once, deploy the same way to every environment, smoke-test every deployment, and stop the line if any stage fails.
3. Continuous delivery: every change that passes automated checks is a release candidate that could be deployed on demand. Continuous deployment: every such change is deployed without human intervention.

4. The DORA research programme, published in the State of DevOps reports from 2014 and in the 2018 book *Accelerate* by Nicole Forsgren, Jez Humble and Gene Kim, measures four things.

DORA metric	What it measures
Deployment frequency	How often you ship
Lead time for changes	Commit to production time
Change failure rate	Percent of deploys causing harm
Failed deployment recovery	Time to restore service

5. The consistent finding across those reports is that speed and stability move together rather than trading off. That is a statistical association in survey data, not a controlled experiment. Treat it as strong evidence, not proof.
6. There is genuine expert disagreement about whether continuous deployment is right for every domain. Web services with cheap rollback lean yes. Firmware, medical devices and payment cores lean no, because the cost of a bad release is not symmetric with the cost of a slow one.
7. The honest version: most organizations that say “we do CD” mean continuous delivery to a staging environment and manual promotion to production. That is a fine place to be. It is just not continuous deployment.

■ 41.2.6 WORDS - remember these

1. Continuous delivery — always ready to ship — every passing change is a deployable release candidate, promoted on demand.
2. Continuous deployment — ships by itself — every passing change is deployed to production without manual approval.
3. Deployment pipeline — the chain of stages a change walks — an automated implementation of the path from commit to release, with binary reuse.
4. Release candidate — a version that could go live — an immutable artifact that has passed all preceding pipeline stages.
5. Promotion — moving an artifact to the next environment — deploying the same artifact to a higher environment without rebuilding.
6. Lead time for changes — how long from writing to live — the DORA metric measuring commit timestamp to production deploy timestamp.

41.3 What a runner actually is

■ 41.3.1 PLAIN - in simple words

1. Something has to actually execute your build. That something is a computer.
2. In continuous integration that computer is called a **runner**, or an agent, or an executor, depending on the product.
3. It can be a whole machine, a virtual machine, or a container. From your side it does not matter much: it is a place with a filesystem and a shell.
4. When work arrives, the runner downloads your code at one exact commit and runs your steps one after another, in order, in a shell.
5. It reports the exit code of each step. Zero means success. Anything else means failure, and by default the job stops there.

- Two kinds exist. **Hosted** runners are supplied by the service, created fresh for your job, and destroyed afterwards. **Self-hosted** runners are machines you own, running an agent program that asks for work.
- The most important fact about a fresh hosted runner: it contains only what the image ships with. Nothing of yours. No files, no settings, no tools you installed last year and forgot about.
- That is exactly why builds fail on the runner and pass on your laptop.

■ 41.3.2 PLAIN – a picture in your head

- Imagine a hotel kitchen you can rent by the minute.
- It is spotless. Every surface wiped. Standard ovens, standard knives.
- Whatever you want to cook, you must bring the recipe and the ingredients, or ask the hotel for them at the door.
- Your own kitchen at home has a jar of your grandmother’s spice mix on the top shelf. You use it without thinking. It is not in your recipe.
- In the hotel kitchen, the dish comes out wrong, and you cannot see why, because the missing thing was never written down anywhere.
- When your work is finished, the hotel demolishes the kitchen and builds a new one for the next customer. Nothing you left behind survives.

Where this comparison breaks: a real kitchen is never truly identical twice. Runner images are updated every week or two, so tool versions drift under you. And a self-hosted runner is more like your own kitchen: it does keep the spice jar, which is convenient right up until it becomes the bug.

■ 41.3.3 PLAIN – a worked example

- This step works perfectly on the reader’s macOS laptop and fails on a Linux runner.

```
| python script.py --config Config.json
```
- On macOS the default filesystem is APFS, set up case-insensitive. The file on disk is `config.json`, and `Config.json` finds it anyway.
- On the Linux runner the filesystem is case-sensitive. `Config.json` does not exist. The script exits non-zero. The job fails.
- The error message is `FileNotFoundError`, which sounds like the file was not committed, so the first hour is spent looking in the wrong place.
- Here are the usual suspects, all of the same shape.

Works locally because	Runner reality
Case-insensitive filesystem	Case-sensitive filesystem
Tool installed years ago	Only image defaults present
<code>.env</code> file on disk	Untracked files do not exist
Local time zone	Runner is UTC
Logged in to a registry	No credentials at all
Dependencies already cached	Cold download every time

■ 41.3.4 PLAIN – what is really happening inside

- A job goes through the same seven phases every time. Learn them and you can place any failure.

```
| 1 QUEUE    job waits for a free runner
| 2 ALLOCATE a runner is chosen or a VM is created
```

```

3 PROVISION boot image, start agent, set environment
4 CHECKOUT  fetch the repository at one exact commit
5 RESTORE   pull caches: packages, compiler output
6 STEPS     run each step in order, stop on failure
7 UPLOAD    save artifacts and logs
8 CLEAN     destroy the machine or wipe the workspace

```

2. Phase 1 costs nothing but wall-clock time. If jobs sit here, you have hit a concurrency limit, not a bug.
3. Phase 3 is where the operating system image is decided. That image is a product of the service and it changes.
4. Phase 4 usually does a shallow fetch of depth one: only the one commit, not the whole history, because history is large and rarely needed.
5. Phase 5 restores a cache keyed on something like the hash of your lock file. A cache miss is slow but correct. A wrong cache hit is fast and wrong, which is worse.
6. Phase 6 runs each step as a separate shell invocation. Variables set with plain `export` in one step do not survive to the next step, because the shell exited.
7. Phase 8 is why “it left a file behind last time” is never an explanation on a hosted runner. There is no last time.

■ 41.3.5 TECHNICAL - the engineer’s version

1. GitHub-hosted runners are ephemeral virtual machines in Microsoft Azure, with a fresh instance per job, running the open-source actions/runner agent. Figures below were taken from GitHub documentation in August 2026 and change over time.

Label	vCPU	RAM	Disk
ubuntu-latest public	4	16 GB	14 GB
ubuntu-slim public	1	5 GB	14 GB
windows-latest public	4	16 GB	14 GB
macos-latest (M1)	3	7 GB	14 GB

2. For private repositories the standard Linux and Windows runners are smaller, at 2 vCPU and 8 GB RAM as of August 2026. Larger runners are a paid option.
3. Hard limits for GitHub Actions, as documented in August 2026: a job may run up to 6 hours on a hosted runner and up to 5 days on a self-hosted runner; a workflow run is cancelled after 35 days; a matrix can generate at most 256 jobs per run; a self-hosted job may sit queued for 24 hours.
4. Concurrent job limits by plan: 20 on Free, 40 on Pro, 60 on Team and 500 on Enterprise. The `GITHUB_TOKEN` is rate limited to 1,000 API requests per hour per repository.
5. GitLab uses a separate `gitlab-runner` binary with pluggable executors: `docker`, `shell`, `kubernetes`, `docker-machine` and others. Jenkins calls the same idea an agent, historically a “slave”, connected by JNLP or SSH.
6. Self-hosted runners on a public repository are a documented security hazard: a fork can propose a workflow change that executes on your hardware. GitHub documents this and recommends self-hosted runners only for private repositories, or with ephemeral, isolated, single-use runners.
7. Runner images are built in the open. The `actions/runner-images` repository publishes the exact contents of each image and a changelog per release, which is the correct place to check whether a tool version moved under you.

8. Observing tools: runs -on in the workflow file, the “Set up job” log group which prints the image version and the resolved runner name, `uname -a, df -h, nproc and env | sort` as diagnostic steps.

■ 41.3.6 WORDS - remember these

1. Runner — the machine that executes your build — an ephemeral or persistent host running an agent that claims and executes jobs.
2. Hosted runner — supplied and destroyed by the service — a per-job ephemeral VM from a published image, with no state between jobs.
3. Self-hosted runner — your own machine doing the work — a long-lived or ephemeral host running the agent, with persistent state unless wiped.
4. Job — one unit of work on one runner — a named collection of steps sharing a workspace, filesystem and environment.
5. Step — one command or one action inside a job — a separate shell invocation or a container/JavaScript action execution.
6. Workspace — the folder your code is checked out into — the working directory, exposed as `GITHUB_WORKSPACE` or `CI_PROJECT_DIR`.
7. Exit code — the number a command returns — 0 for success, non-zero for failure; the runner uses it to decide whether to continue.

41.4 The workflow file

■ 41.4.1 PLAIN - in simple words

1. Somewhere you must write down what the machine should do. That written description is the **workflow file**.
2. It is a plain text file in YAML, a format that uses indentation instead of brackets to show what belongs to what.
3. On GitHub it lives in the folder `.github/workflows/` inside your repository, and any file there ending in `.yml` or `.yaml` is picked up.
4. On GitLab it is a single file called `.gitlab-ci.yml` at the top of the repository.
5. It sits inside the repository, next to the code, in the same history. That is the important part.
6. Because it is in the history, the workflow that ran for an old commit is the workflow as it existed at that commit. Not today’s version.
7. So changing your tests and changing how they run is one change, one review, one commit. They can never drift apart.

■ 41.4.2 PLAIN – a picture in your head

1. Think of a recipe card taped inside the lid of the box that holds the ingredients.
2. If you change the ingredients, you open the box, so you see the recipe and change it too.
3. Compare with a recipe pinned on a noticeboard in another room. It slowly becomes a description of a dish nobody makes any more.
4. A configuration stored in a web interface on the build server is the noticeboard. A workflow file in the repository is the card inside the lid.
5. And if you open a box from three years ago, the card inside tells you exactly how that batch was made.

Where this comparison breaks: the recipe card is not fully self-contained. It says “use action X at version 4”, and version 4 is fetched fresh at run time from somewhere else. So an old commit can still build differently today. Section 41.13 explains how pinning fixes that.

■ 41.4.3 PLAIN – a worked example

1. Here is a complete, working GitHub Actions workflow. Every line is explained underneath.

```
name: CI

on:
  push:
    branches: [main]
  pull_request:
    branches: [main]

permissions:
  contents: read

concurrency:
  group: ci-${{ github.ref }}
  cancel-in-progress: true

env:
  CI: "true"

jobs:
  lint:
    runs-on: ubuntu-latest
    timeout-minutes: 10
    steps:
      - uses: actions/checkout@v4
      - uses: actions/setup-node@v4
        with:
          node-version: "22"
          cache: npm
      - run: npm ci
      - name: Static checks
        run: npm run lint

  test:
    needs: [lint]
    runs-on: ${{ matrix.os }}
    timeout-minutes: 20
    strategy:
      fail-fast: false
    matrix:
```

```

    os: [ubuntu-latest, macos-latest]
    node: ["20", "22"]
  steps:
    - uses: actions/checkout@v4
    - uses: actions/setup-node@v4
      with:
        node-version: ${ matrix.node }
        cache: npm
    - run: npm ci
    - name: Unit tests
      run: npm test
    - env:
        TZ: UTC
    - name: Save the report
      if: always()
      uses: actions/upload-artifact@v4
      with:
        name: junit-${ matrix.os }-${ matrix.node }
        path: reports/junit.xml

```

2. name is the label shown in the user interface. Cosmetic only.
3. on lists the events that start a run. Here: a push to main, and any pull request whose target is main.
4. permissions sets what the automatic token may do. contents: read means the job can read the repository and nothing else.
5. concurrency groups runs. Two runs in the same group cannot overlap, and cancel-in-progress: true kills the older one. This stops five pushes in a minute from starting five full pipelines.
6. env at the top sets environment variables for every job.
7. jobs holds one or more jobs. lint and test are job IDs, chosen by you.
8. runs-on picks the runner label. ubuntu-latest means a hosted Linux VM.
9. timeout-minutes kills a job that hangs. Without it a stuck job burns until the six-hour limit.
10. steps is an ordered list. Each item is either uses or run.
11. uses runs a prepackaged **action**, here actions/checkout at major version 4, which clones the repository at the right commit.
12. with passes named inputs to that action.
13. run executes a shell command on the runner.
14. name on a step is the label in the log. Give every non-obvious step one, because that label is what you will search for when it fails.
15. needs: [lint] makes test wait for lint to succeed. Without needs, jobs run in parallel.
16. strategy.matrix expands one job into several. Two operating systems by two Node versions gives four jobs.
17. fail-fast: false says: if one matrix cell fails, let the others finish. The default, true, cancels the siblings, which is faster but tells you less.
18. if: always() on the upload step means “run this even if a previous step failed”, which is how you get the test report from a failing build.
19. \${ ... } is an expression. It is evaluated by the service before the step runs, and substituted as text.

■ 41.4.4 PLAIN – what is really happening inside

1. Here is the same pipeline written for GitLab CI, in .gitlab-ci.yml.

```

stages: [lint, test]

```

```

default:
  image: node:22-bookworm
  cache:
    key:
      files: [package-lock.json]
    paths: [.npm/]

variables:
  CI: "true"

lint:
  stage: lint
  script:
    - npm ci --cache .npm --prefer-offline
    - npm run lint

unit-test:
  stage: test
  needs: [lint]
  parallel:
    matrix:
      - NODE_TAG: ["20", "22"]
  image: node:${NODE_TAG}-bookworm
  script:
    - npm ci --cache .npm --prefer-offline
    - npm test
  artifacts:
    when: always
    reports:
      junit: reports/junit.xml
  rules:
    - if: $CI_PIPELINE_SOURCE == "merge_request_event"
    - if: $CI_COMMIT_BRANCH == $CI_DEFAULT_BRANCH

```

2. The differences are worth naming, because they are differences of model, not of syntax.
3. GitLab has a first-class concept of **stages**: named phases that run in order, with all jobs in a stage running together. GitHub has no stages, only needs edges between jobs, which form a graph.
4. GitLab jobs run inside a container image by default, set with `image`. GitHub jobs run directly on the runner VM, and containers are opt-in.
5. GitLab has no uses. Reuse comes from `include`, `extends` and YAML anchors, plus CI/CD components. GitHub’s marketplace of actions has no direct GitLab equivalent.
6. GitLab checks out the code for you automatically. GitHub requires an explicit `actions/checkout` step, and forgetting it is a classic first-day mistake.
7. GitLab’s `rules` replaces GitHub’s `on` plus `if`, combining trigger and condition into one list evaluated top to bottom.
8. Both put the file in the repository, and both therefore get the same benefit: the pipeline definition is versioned, reviewable and bisectable.

■ 41.4.5 TECHNICAL – the engineer’s version

1. GitHub reads every file matching `.github/workflows/*.yml` and `.github/workflows/*.yaml` on the branch that the event applies to. This is a documented behaviour, not a convention.
2. For push events the workflow file used is the one at the pushed commit. For `pull_request` events it is the one at the pull request’s head. For `pull_request_target` and `schedule` it is the one on the base or default branch. That asymmetry is the root of section 41.5’s security discussion.

3. Available contexts inside `${{ }}` include `github`, `env`, `vars`, `secrets`, `job`, `steps`, `runner`, `strategy`, `matrix`, `needs` and `inputs`. Context values are substituted before the shell sees them, which is why interpolating untrusted text directly into a run block is a script injection hole. Pass it through `env` instead.
4. Each run block is written to a temporary script and executed with the default shell: `bash -e` on Linux and macOS, `pwsh` on Windows. Because `-e` is set, the first failing command ends the step. Add `set -o pipefail` if you use pipes, since a pipeline’s exit code is the last command’s.
5. YAML has a real trap here. In YAML 1.1, the bare word `on` is a boolean `true`, so strict linters flag `on:` as the key `true`. GitHub’s parser special-cases it. Quoting as `"on"`: also works. This is an implementation detail worth knowing when a linter shouts at a file that runs fine.
6. Reuse mechanisms: composite actions (steps bundled in an `action.yml`), reusable workflows called with `uses` at job level and triggered by `workflow_call`, and Docker container actions. Reusable workflows can be nested up to four levels deep.
7. GitLab equivalents: `include:local`, `include:project`, `include:remote`, `extends`, and CI/CD components introduced in GitLab 16.6 in late 2023.
8. Because the file is versioned, `git log -p .github/workflows/` answers “when did this check start being required” and `git bisect` can walk a pipeline regression the same way it walks a code regression.
9. A practical consequence the reader met directly: a GitHub personal access token needs the `workflow` scope to push a commit that adds or edits a file under `.github/workflows/`. Without it the push is refused, even though the same token can push ordinary code. The workflow file is treated as more dangerous than code, because it is.

■ 41.4.6 WORDS – remember these

1. Workflow file — the written plan for the machine — a YAML document defining triggers, jobs and steps, stored in the repository.
2. YAML — a text format that uses indentation — a data serialization language; GitHub Actions and GitLab CI both use it for pipeline definitions.
3. Action — a reusable prepackaged step — a JavaScript, Docker or composite unit referenced by `uses: owner/repo@ref`.
4. Matrix — one job definition expanded into many — a cross product of variable values generating up to 256 jobs per run.
5. Stage — a named phase in GitLab — an ordered grouping of jobs; GitHub models the same idea as `needs` dependencies instead.
6. Context — the data available to expressions — named objects such as `github`, `matrix` and `secrets` resolved before the step runs.
7. Script injection — untrusted text becoming code — interpolating attacker controlled values into a run block, mitigated by passing through `env`.

41.5 Triggers: what starts a run

■ 41.5.1 PLAIN – in simple words

1. A run never starts on its own. Something has to ask for it.
2. The thing that happens is called an **event**. The rule in your file that listens for it is called a **trigger**.
3. The commonest event is a **push**: you send new commits to the shared server.
4. The next commonest is a **pull request**: you propose joining one branch into another.
5. A clock can be the event: run every night at two in the morning.

6. A person can be the event: somebody clicks a “Run workflow” button.
7. Another program can be the event: an outside system sends a message asking for a run.
8. Creating a **tag**, which is a permanent name pinned to one commit, can be the event.
9. Publishing a **release**, which is a tag plus notes and downloadable files, can be the event.
10. Every event carries facts with it: which repository, which branch, which commit, and who caused it.
11. Your workflow file lists the events it cares about. Every other event is ignored by that file.
12. You can narrow an event further: only on this branch, only when these files changed.
13. Narrowing matters because every run costs minutes and money, and most runs on most changes are wasted work.

■ 41.5.2 PLAIN – a picture in your head

1. Picture a workshop with a row of bells along one wall.
2. Bell one rings when a delivery van drops parts at the door. That is push.
3. Bell two rings when somebody posts a proposed change to the plans. That is pull_request.
4. Bell three is wired to a timer and rings itself at 2 a.m. every night. That is schedule.
5. Bell four has a rope hanging down, and any worker may pull it whenever they like. That is workflow_dispatch.
6. Bell five is a phone line from the factory next door, so they can call you. That is repository_dispatch.
7. Beside each bell hangs a small card saying which deliveries are worth getting up for.
8. One card says “steel only, ignore paint”. That is a path filter.
9. Another says “only deliveries addressed to the main workshop”. That is a branch filter.

Where this comparison breaks: bells in a workshop ring one at a time. Real events overlap. A single push to a branch that already has an open pull request rings two bells and can start two nearly identical runs on nearly the same code. Also a bell carries no information, while an event carries a whole document describing exactly what happened, which your job can read.

■ 41.5.3 PLAIN – a worked example

1. Here is one on: block using most of the common triggers at once.

```
on:
  push:
    branches:
      - main
      - 'release/**'
  tags:
    - 'v*.*.*'
  paths:
    - 'src/**'
    - 'package-lock.json'
  pull_request:
    types: [opened, synchronize, reopened, ready_for_review]
    branches: [main]
  schedule:
    - cron: '17 2 * * *'
  workflow_dispatch:
    inputs:
      environment:
        description: 'Where to deploy'
        type: choice
        options: [staging, production]
```

```

    default: staging
  dry_run:
    type: boolean
    default: true
  repository_dispatch:
    types: [deploy-request]
  release:
    types: [published]

```

2. `push.branches` lists branch name patterns. `release/**` matches `release/2026-08` and `release/hotfix/db`.
3. `push.tags` lists tag patterns. `v*.*.*` matches `v2.4.1`. If both branches and tags are present, a match on either one starts a run.
4. `push.paths` says: only start if at least one changed file matches. A commit that only edits `README.md` starts nothing.
5. `pull_request.types` lists the sub-kinds of the event. `synchronize` means “the pull request branch got a new push”, which is the one people forget.
6. `ready_for_review` fires when a draft pull request stops being a draft. It is not in the default list, so you must ask for it.
7. `schedule.cron` is five fields: minute, hour, day of month, month, day of week. `17 2 * * *` is 02:17 every day, in UTC always.
8. The 17 is deliberate. Everyone writes `0 * * * *`, so the top of the hour is the busiest queue on the service. Pick an odd minute.
9. `workflow_dispatch.inputs` builds a small form in the web page and also accepts the same values from the command line.
10. `repository_dispatch.types` filters on a label chosen by the outside caller, so one repository can serve several kinds of external request.
11. `release.types: [published]` fires when a release is published, which is the usual moment to build and upload artifacts.

Trigger	Typical use
<code>push</code>	Test the mainline
<code>pull_request</code>	Test a proposal
<code>schedule</code>	Nightly, slow scans
<code>workflow_dispatch</code>	Manual deploy
<code>repository_dispatch</code>	Called by another system
<code>release</code>	Publish artifacts

■ 41.5.4 PLAIN - what is really happening inside

1. Now the confusing pair. `pull_request` and `pull_request_target` look almost the same and behave very differently.
2. When somebody outside your team proposes a change from their own copy, that code is a stranger’s code. You have not read it yet.
3. A run started by `pull_request` does check out the stranger’s code, but it runs with almost no power.
4. It gets a read-only token, and it gets none of your secrets.
5. So even if the stranger’s code is hostile, it can make a mess inside its own throwaway machine and steal nothing.

6. That is the safe default. It is also why a first-time contributor often sees “waiting for a maintainer to approve running workflows”.
7. But it is inconvenient. A run with no secrets cannot post a comment, cannot upload to your storage, and cannot add a label.
8. So a second trigger exists: `pull_request_target`.
9. `pull_request_target` reads the workflow file from your own base branch, not from the stranger’s branch.
10. Because the file is yours and was reviewed by you, the service trusts it and hands it a write token and your secrets.
11. Here is the trap, and it is a sharp one. The workflow file is yours. The code being proposed is still theirs.
12. If your trusted workflow checks out the pull request’s head and then executes anything from it, you have just handed a stranger your keys.
13. “Executes anything” is wider than it sounds. It includes `npm test`. It also includes `npm install`, because a dependency can run an install script.
14. It includes a build tool that reads a config file naming a plugin, a Makefile, a test fixture, or a linter with a custom rule.
15. GitHub’s own security team named this family of bug **pwn requests** in an article published in August 2020.
16. The rule is one sentence. With `pull_request_target`, do not check out the head; and if you truly must, do not execute one byte of it.

	<code>pull_request</code>	<code>pull_request_target</code>
	-----	-----
workflow file	PR head branch	base branch
checked out	PR merge result	base branch by default
token	read-only (fork)	read and write
secrets	none (fork)	all of them
safe by	having no power	you not running their code

■ 41.5.5 TECHNICAL - the engineer’s version

1. GitHub Actions documents more than thirty webhook-backed events plus the non-webhook triggers `schedule`, `workflow_dispatch` and `workflow_call`.

Trigger	Fires when	Note
<code>push</code>	commits or tags land	branch, tag, path filters
<code>pull_request</code>	PR opened, updated	forks get no secrets
<code>pull_request_target</code>	same, base context	write token, dangerous
<code>schedule</code>	cron time in UTC	5 minute minimum
<code>workflow_dispatch</code>	manual or API call	up to 10 inputs
<code>repository_dispatch</code>	external POST	default branch only
<code>release</code>	release published	types include published
<code>merge_group</code>	merge queue asks	<code>checks_requested</code>
<code>workflow_run</code>	another run ends	base branch file

2. The default activity types for `pull_request` are `opened`, `synchronize` and `reopened`. `synchronize` fires on every new push to the head branch.
3. `schedule` uses five-field POSIX cron, always evaluated in UTC, never in local time. The shortest documented interval is every 5 minutes.

4. Scheduled runs are queued, not guaranteed punctual. Delays of many minutes at the top of the hour are normal and documented.
5. In a public repository, a scheduled workflow is disabled automatically after 60 days with no repository activity. This is documented behaviour and a very common cause of “our nightly build silently stopped”.
6. `workflow_dispatch` accepts at most 10 top-level inputs, of types string, choice, boolean and environment, with a total payload limit of 65,535 characters. Start it with `gh workflow run` or `POST /repos/{owner}/{repo}/actions/workflows/{id}/dispatches`.
7. `repository_dispatch` is `POST /repos/{owner}/{repo}/dispatches` carrying `event_type` and an optional `client_payload` JSON object, readable as `github.event.client_payload`. It only starts workflows whose file lives on the default branch, which surprises people testing it from a branch.
8. Filter keys are branches, branches-ignore, tags, tags-ignore, paths and paths-ignore. You cannot use a key and its -ignore partner for the same event in the same workflow.
9. Glob syntax in these filters: `*` matches any characters except `/`, `**` matches any characters including `/`, `?` matches one character, `+` and `*` act as repeaters, `[]` is a character class, and a leading `!` negates.
10. A documented caveat with real consequences: if a push contains more than 1,000 commits, or GitHub cannot compute the diff because it timed out, path filters are ignored and the workflow runs anyway.
11. The opposite caveat matters more. A path-filtered workflow that does not run produces no check at all, and a required status check that never arrives blocks the pull request forever. Section 41.8 covers the fix.
12. The precise difference between the two pull request triggers:

Aspect	<code>pull_request</code>	<code>pull_request_target</code>
Workflow file from	PR head	base branch
<code>GITHUB_REF</code>	<code>refs/pull/N/merge</code>	base branch ref
Fork secrets	none	all
Fork token	read-only	read and write

13. For a fork-originated `pull_request`, the `GITHUB_TOKEN` is issued with read permissions only, and no repository, environment or organization secret is exposed. Public repositories can additionally require maintainer approval before a first-time contributor’s workflow runs at all.
14. The dangerous pattern, written out so you can recognize it in review:

```
# DANGEROUS when combined with pull_request_target
- uses: actions/checkout@v4
  with:
    ref: ${github.event.pull_request.head.sha}
- run: npm ci && npm test    # their code, your secrets
```

15. The safe pattern when you genuinely need write access on a fork pull request: split into two workflows. The `pull_request` workflow does the untrusted work with no secrets and uploads an artifact. A second workflow on `workflow_run` has permissions, downloads that artifact, and treats its contents as data, never as code.
16. `workflow_run` carries the same hazard in a different coat: it also runs the file from the default branch with a full token, so an artifact produced by an untrusted run must never be executed or expanded into a path you trust.
17. GitLab expresses all of this through rules and the `CI_PIPELINE_SOURCE` variable, whose values include `push`, `merge_request_event`, `schedule`, `web`, `api`, `trigger` and `pipeline`. GitLab further

distinguishes merge request pipelines from merged results pipelines, which test the combined result rather than the source branch.

18. Observing tools: `gh run list --json event,headBranch,headSha`, the event name shown at the top of any run page, and `gh api repos/OWNER/REPO/hooks` to see which webhooks a repository sends to outside systems.

■ 41.5.6 WORDS - remember these

1. Event — the thing that happened — a webhook payload describing a repository or platform change.
2. Trigger — the rule that listens — the on: key naming events, activity types and filters.
3. Activity type — the sub-kind of an event — such as opened or synchronize for `pull_request`.
4. Path filter — only run when these files changed — paths or paths-ignore globs matched against the push diff.
5. `workflow_dispatch` — the manual run button — a non-webhook trigger with up to 10 typed inputs, also callable by API.
6. `repository_dispatch` — an outside system asking for a run — a POST to the repository’s dispatches endpoint with an `event_type`.
7. Pwn request — a stranger’s code running with your keys — arbitrary code execution obtained by checking out untrusted head under `pull_request_target`.

41.6 The most important idea: a run belongs to a commit, not a branch

■ 41.6.1 PLAIN - in simple words

1. This is the idea the whole chapter is built around. Read it twice.
2. A branch name is not a box holding commits. It is a label stuck on exactly one commit.
3. Chapter 38 put it this way: a branch is a moving pointer. Add a commit and the label moves forward to the new one.
4. A test run is not stuck to a label. It is stuck to one exact commit.
5. The machine downloaded one commit, tested those exact bytes, and wrote the answer against that commit’s fingerprint.
6. That fingerprint is the commit hash, a long string of hexadecimal digits computed from the contents.
7. So the sentence “CI passed on main” is short for something much longer.
8. In full it means: “CI passed on whichever commit main happened to point at when that run started”.
9. If main has moved since, the sentence stays true and becomes useless. It is a fact about a commit nobody is looking at any more.
10. The tick you see beside a branch name on a web page is a summary drawn at the moment the page loaded. It is not a promise about now.
11. So never accept a tick beside a branch name as evidence that anything in particular was tested.
12. Get the exact commit hash first. Then ask whether that hash passed.

■ 41.6.2 PLAIN - a picture in your head

1. Think of a hotel with a brass plate on one door reading MANAGER.
2. A health inspector visits, inspects the room behind that plate, and issues a certificate.
3. The certificate does not say MANAGER. It says room 412, and it lists what was in room 412 on that day.

4. Months later the manager moves office. Somebody unscrews the brass plate and screws it onto room 509.
5. Now walk up to the door marked MANAGER and ask: is this room certified?
6. The plate is not the room. The certificate belongs to 412. The door in front of you is 509, and nobody has inspected it.
7. The plate is the branch name. The room number is the commit hash. The certificate is the run.

Where this comparison breaks: a hotel room keeps its contents when the plate moves, so you could at least argue about it. A commit is defined by its contents, so it cannot change at all. Alter one byte and it becomes a different commit with a different hash and no certificate whatsoever. Git is stricter than the hotel, not looser.

■ 41.6.3 PLAIN – a worked example

1. During the reader’s outage, the machine reported origin/main as 0a95cc8.
2. That was a cached remote-tracking value written by the last successful fetch, not a live fact about the server.
3. Now watch the sequence that makes a green tick lie. The clock times are invented; the shape is exactly real.

```
09:00 main -> 0a95cc8
09:01 run 1187 starts, head_sha = 0a95cc8
09:07 run 1187 finishes, conclusion = success
09:07 branch page shows: main [tick]

09:40 a pull request is merged
09:40 main -> 3f1d02c          (the label moved)
09:40 branch page still shows: main [tick]  <- nothing
                                           tested 3f1d02c

09:41 run 1194 starts, head_sha = 3f1d02c
09:53 run 1194 finishes, conclusion = failure
```

4. Between 09:40 and 09:41 the page showed a tick beside main while nothing at all had tested 3f1d02c.
5. At 09:53 the honest summary is: 0a95cc8 passed, 3f1d02c failed, and main is 3f1d02c.
6. If at 09:40 somebody asked “did main pass?”, the correct answer is that the question is badly formed.
7. The well-formed question is “did 3f1d02c pass?”, and at 09:40 the answer was “no run for that commit exists yet”.
8. There is a second way to get burned where nobody does anything wrong.
9. The reader rebased a local branch onto a moved main, and the branch’s hash changed.
10. Rebase does not carry commits across. It builds new commit objects with new parents, and new parents mean new hashes.
11. Every run recorded against the old hashes is still there, still correct, and now attached to commits that no branch points at.
12. The branch label now sits on brand new commits with zero runs. The tick you remember belonged to commits that are effectively gone.

■ 41.6.4 PLAIN – what is really happening inside

1. A run record on the server stores many fields. Two of them matter here.
2. head_sha is the exact commit the run checked out. This field is the truth.
3. head_branch is the branch name as it read at trigger time. This field is a label, and labels move.

4. When you open a branch page, the service does roughly this: find the commit the branch points at right now, then look up the statuses and check runs attached to that commit.
5. That is correct behaviour, and it gives a right answer for the instant the page was rendered.
6. So where does the lie come from? Three places, none of them a bug.
7. Caching in your own tools. The reader’s machine reported 0a95cc8 from a file on disk, either .git/refs/remotes/origin/main or an entry in .git/packed-refs, written by the last fetch.
8. Human memory. You looked at the tick five minutes ago, then merged three pull requests, and then trusted the memory.
9. Frozen evidence. A screenshot or a chat message saying “CI is green, see attached” is a statement about a moment, not about now.
10. The fix is mechanical and takes one extra command.
11. Never carry a branch name into the verification step. Resolve it to a hash once, from the server, and carry the hash.
12. If somebody pushes between your resolve and your check, your conclusion is still exactly true, because it was a statement about the hash you named.
13. That is the whole difference between a claim you can defend and a claim you merely believe.

■ 41.6.5 TECHNICAL – the engineer’s version

1. Step one: get the head SHA from the server, not from your local cache.

```
# live from the remote, no local cache involved
git ls-remote origin refs/heads/main
# 3f1d02c9d5f0a1b2c3d4e5f60718293a4b5c6d7e refs/heads/main

# or through the API
export SHA=$(gh api repos/OWNER/REPO/commits/main --jq .sha)
echo "$SHA"
```

2. git rev-parse origin/main does not do this. It reads the remote-tracking ref from disk and answers from cache. That is what produced 0a95cc8 during the reader’s outage while the real server value was unknown.
3. Step two: list the runs filtered by that exact SHA, never by branch.

```
gh run list --commit "$SHA" \
  --json databaseId,workflowName,event,status,conclusion,headSha
```

4. The same query in raw REST, which is what gh calls underneath:

```
gh api "repos/OWNER/REPO/actions/runs?head_sha=$SHA" \
  --jq '.workflow_runs[]
    | {id, name, event, status, conclusion, head_sha}'
```

5. Step three: look at the one run you care about, by its numeric ID, and read both its conclusion and its head SHA.

```
gh run view 11947722301 \
  --json status,conclusion,headSha,headBranch,event,url
```

6. Step four: assert rather than eyeball. A human reading two long hex strings side by side will miss a mismatch.

```
gh run view "$RUN_ID" --json headSha,conclusion \
  --jq 'if .headSha == env.SHA and .conclusion == "success"
    then "VERIFIED" else "NOT VERIFIED" end'
```

7. Two commit-level views give the rolled-up answer for that SHA, one per API:

```
# newer checks API, one entry per check run
gh api "repos/OWNER/REPO/commits/$SHA/check-runs" \
  --jq '.check_runs[] | {name, status, conclusion}'

# older commit status API, already rolled up
gh api "repos/OWNER/REPO/commits/$SHA/status" \
  --jq '{state, total_count}'
```

8. For a pull request, ask for the head object ID directly rather than deriving it, and pull the rollout in the same call:

```
gh pr view 42 --json headRef0id,statusCheckRollup \
  --jq '{sha: .headRef0id,
        checks: [.statusCheckRollup[]
                  | {name, conclusion}]}'
```

9. Field naming differs between the two interfaces and it trips people up. The `gh --json` output uses camelCase such as `headSha` and `databaseId`. REST uses snake_case such as `head_sha` and `id`. Same values, two spellings.
10. GET `/repos/{owner}/{repo}/actions/runs` accepts `head_sha`, `branch`, `event`, `status`, `actor`, `created`, `check_suite_id` and `exclude_pull_requests` as query parameters.
11. One commit can carry many runs: one per workflow file, plus every re-run, plus a separate run for the push event and the pull_request event. So “did this SHA pass” is incomplete without “in which workflow”.
12. A subtlety worth memorizing. For a pull_request event the run’s `head_sha` is the pull request branch head, but the code checked out is the ephemeral merge of that head into the base, which is what `GITHUB_SHA` holds. The run is filed under one hash and tested another.
13. The hash itself is a SHA-1 digest over the commit object in classic repositories, and SHA-256 in repositories created with the newer object format, which Git has supported experimentally since version 2.29 in October 2020. The commit object names its tree and its parents, so the hash transitively covers the entire content and history.
14. Because of that, verifying against a hash is verifying against exact bytes. There is no room left for “roughly the same code”.
15. Rebase consequence, stated precisely: rebasing writes new commit objects, so check runs and statuses remain attached to the abandoned hashes. They are not migrated, and there is no mechanism that would migrate them. `git reflog` still finds the old commits locally until garbage collection.
16. The sentence to memorize: a run R proves a property about commit R.`head_sha`, and proves nothing whatsoever about any ref.

■ 41.6.6 WORDS – remember these

1. Commit SHA — the fingerprint of one exact snapshot — a 40-hex SHA-1, or 64-hex SHA-256, digest over the commit object.
2. Ref — a name pointing at a commit — a file under `.git/refs` or a line in `.git/packed-refs`.
3. `head_sha` — the commit the run really tested — the field on a workflow run record, spelled `head-Sha` in `gh --json` output.
4. Remote-tracking ref — your last known copy of the server’s branch — `refs/remotes/origin/main`, updated only by fetch, never live.

5. `git ls-remote` — ask the server what it has right now — a live ref advertisement over the transport, bypassing every local cache.
6. Stale tick — a pass mark for a commit that is no longer the head — a status attached to a superseded SHA and displayed next to a moved branch name.

41.7 Why verifying by run ID against a head SHA is the stronger claim

■ 41.7.1 PLAIN – in simple words

1. In the reader’s session, continuous integration was verified by run ID against the exact head hash.
2. It was not verified by glancing at a tick beside a branch name. That is the difference between proof and belief.
3. Here is the procedure in words, four steps.
4. Ask the server what the branch points at right now. Write that hash down.
5. List the runs whose tested commit is that hash.
6. Pick the run you care about and note its number.
7. Read that run’s result, and read the commit that run tested, and confirm it equals the hash you wrote down.
8. Only then say “this commit passed”.
9. That claim survives questioning, because every step names something that cannot move.
10. A hash cannot move. A run number cannot move. A branch name moves all day.
11. The extra cost is about ten seconds and three commands.
12. The cost it avoids is a bad deploy at six o’clock on a Friday.
13. There is a second reason this method is stronger, and it is the reason engineers care most about.
14. It fails loudly. If nothing tested your commit, the list comes back empty and you cannot mistake an empty list for a pass.
15. A tick beside a branch name never comes back empty. It always shows something, and that is exactly the problem.

■ 41.7.2 PLAIN – a picture in your head

1. A school posts a notice on the board: “Class 10B: PASS”.
2. You are in class 10B. Are you finished?
3. Not yet. The board is a summary about a group, at a moment, written by somebody in a hurry.
4. Your own certificate carries your roll number. That number was never reassigned to anybody else.
5. Ask for the certificate bearing your roll number, and read the result printed on it.
6. Then compare the roll number on the certificate with the roll number on your identity card.
7. Two documents, one shared identifier, one comparison. That is the entire method, in school and in continuous integration.

Where this comparison breaks: a class notice can only be wrong in one way, by summarizing. A branch tick can be wrong in at least six different ways, and several of them look identical on the screen. Worse, a school certificate is issued by one office, while a commit status can be posted by anything holding a token, including a person typing an API call by hand.

■ 41.7.3 PLAIN – a worked example

1. Start from the branch name and refuse to trust it.

```
$ export SHA=$(gh api repos/OWNER/REPO/commits/main --jq .sha)
$ echo "$SHA"
3f1d02c9d5f0a1b2c3d4e5f60718293a4b5c6d7e
```

```
$ gh run list --commit "$SHA" \
  --json databaseId,workflowName,conclusion,headSha
[]
```

2. An empty list. Nothing has ever tested this commit, even though the branch page a moment ago showed a green tick.
3. That tick belonged to 0a95cc8, the previous head. The claim “main is green” was true about a commit nobody is deploying.
4. Now the good case, after the run has actually happened.

```
$ gh run list --commit "$SHA" \
  --json databaseId,workflowName,conclusion,headSha
[
  {
    "databaseId": 11947722301,
    "workflowName": "ci",
    "conclusion": "success",
    "headSha": "3f1d02c9d5f0a1b2c3d4e5f60718293a4b5c6d7e"
  }
]
```

5. Now name the run and read it back on its own, so the answer does not depend on the filter having worked.

```
$ gh run view 11947722301 \
  --json conclusion,headSha,status,event,runAttempt
{
  "conclusion": "success",
  "headSha": "3f1d02c9d5f0a1b2c3d4e5f60718293a4b5c6d7e",
  "status": "completed",
  "event": "push",
  "runAttempt": 1
}
```

6. Four things were checked and all four matter.
7. status is completed, so the run finished rather than still running.
8. conclusion is success, so it finished well.
9. headSha equals the hash you resolved, so it tested the right commit.
10. runAttempt is 1, so nobody re-ran it until it went green.
11. Now the sentence you may say out loud: commit 3f1d02c passed workflow ci in run 11947722301 on the first attempt.

■ 41.7.4 PLAIN - what is really happening inside

1. Six ways a branch-level tick can lie. Each is a real, ordinary situation, not a bug and not sabotage.
2. **The run was for an older commit.** The branch moved after the run. The page shows the newest result it can find, and briefly that is the old one.
3. **The run tested the merge result, not your head.** For a pull request the service builds a temporary merge of your branch into the target and tests that. Your head commit was never tested alone.
4. **A required check was skipped, not passed.** A job that never ran can report in a way that satisfies a rule, and a workflow that never started reports nothing at all.
5. **The status came from something other than the run you have in mind.** The name “build” on the screen is just a text label. Anything with a token can post that label.

6. **A re-run replaced the result.** Somebody pressed re-run until it went green. The run ID is the same, the number of attempts is not.
7. **The check belongs to a merge commit that no longer exists.** After a squash or rebase merge, the commit that was tested is not the commit that landed on the target branch.
8. Notice what all six have in common. In every case the tick is truthful about something, and that something is not the thing you are about to deploy.
9. The method in 41.7.1 defeats all six because it never asks a question whose subject can move.

■ 41.7.5 TECHNICAL – the engineer’s version

1. The failure modes and the exact field to inspect for each.

Failure mode	Detect by
Run is for an older commit	compare headSha to head
Run tested the merge result	read the event field
Check skipped, not passed	read conclusion
Status posted by another app	list app.slug per check
Re-run replaced the result	read runAttempt
Merge commit gone after merge	resolve the new head SHA

2. Older commit. `gh run list --commit "$SHA"` returns an empty array when nothing tested that hash. Treat an empty array as a hard failure of verification, never as an absence of bad news.
3. Merge result. If event is `pull_request`, the run’s `head_sha` is the pull request branch head, but the job checked out `refs/pull/N/merge`, and `GITHUB_SHA` inside the job was that ephemeral merge commit. GitHub’s own troubleshooting page states that when the test merge commit has a status, it is the test merge commit that must pass, not the head commit.
4. Skipped versus passed. This is the sharpest edge in the whole area, and GitHub documents three different outcomes:

Situation	Reported as
Workflow skipped by path filter	stays Pending, blocks
Workflow skipped by <code>[skip ci]</code>	stays Pending, blocks
Job skipped by an <code>if: condition</code>	Success
Job skipped after a failed needs	skipped, may not block

5. Read that table again. A job you skipped on purpose reports success and satisfies a required check. A workflow that never started reports nothing, stays pending, and blocks forever. Same English word, opposite consequences.
6. The documented mitigation for the fourth row is to add `if: always()` to a final summary job that depends on the others and explicitly fails if any dependency did not succeed.
7. Wrong poster. Any token with write access can create a commit status with any context and state, including success:

```
gh api -X POST repos/OWNER/REPO/statuses/$SHA \
  -f state=success -f context=build \
  -f description='looks fine to me'
```

8. That call is legitimate API use and is indistinguishable on the branch page from a real build result. Inspect the poster:

```
gh api "repos/OWNER/REPO/commits/$SHA/check-runs" \
  --jq '.check_runs[] | {name, conclusion, app: .app.slug}'

gh api "repos/OWNER/REPO/commits/$SHA/status" \
  --jq '.statuses[] | {context, state, creator: .creator.login}'
```

9. Re-runs. A re-run does not create a new run ID. It increments `run_attempt` on the same run, and the interface shows the latest attempt. Fetch an earlier attempt explicitly:

```
gh api repos/OWNER/REPO/actions/runs/11947722301/attempts/1 \
  --jq '{attempt: .run_attempt, conclusion, head_sha}'
```

10. "Re-run failed jobs" is more subtle still: it produces a new attempt in which the previously successful jobs are not executed again. The green you see is assembled from two different points in time.
11. Vanished merge commit. A squash merge creates one brand new commit on the target with a new hash and no checks. A rebase merge creates new commits for the same reason. Only a true merge commit preserves the tested parent.
12. So after any squash or rebase merge, the correct next step is to resolve the new head of the target branch and verify that hash on its own. What passed before the merge is evidence about a commit that is no longer in the first parent line of your branch.
13. Two further modes worth knowing, beyond the six:
14. `continue-on-error: true` on a step or job makes a real failure report as success at the job or run level. Read the step conclusions, not only the run conclusion.
15. A `strategy.matrix` job cancelled by `fail-fast: true` reports cancelled, which is not failure, and people read the absence of red as green.
16. A script for the whole verification, safe to put in a release checklist:

```
set -euo pipefail
REPO=OWNER/REPO
SHA=$(gh api "repos/$REPO/commits/main" --jq .sha)
RUN=$(gh run list --repo "$REPO" --commit "$SHA" \
  --workflow ci --limit 1 --json databaseId \
  --jq '.[0].databaseId')
test -n "$RUN" || { echo "no run for $SHA"; exit 1; }
gh run view "$RUN" --repo "$REPO" \
  --json conclusion,headSha,status,runAttempt \
  --jq --arg sha "$SHA" '
    if .status=="completed" and .conclusion=="success"
      and .headSha==$sha
    then "VERIFIED \($sha) run \(.runAttempt) attempt(s)"
    else error("NOT VERIFIED") end'
```

17. GitLab equivalent concepts: a pipeline has a sha, a status, and an id. `glab ci status` and the pipelines API filtered by sha do the same job. Jenkins records the built revision in the build metadata, reachable through the `api/json` endpoint of a build.

■ 41.7.6 WORDS – remember these

1. Verification by run ID — naming the run rather than the branch — asserting `run.head_sha == resolved_head` and `conclusion == success`.
2. Test merge commit — the temporary join of your branch into the target — the `refs/pull/N/merge` ref that pull request runs actually check out.
3. Run attempt — which try you are looking at — the `run_attempt` counter, incremented by a re-run, with the latest shown by default.
4. Commit status — a small note pinned to a commit — a state plus a context, creatable by any token with write access.
5. `continue-on-error` — keep going after a failure — a step or job setting that turns a real failure into a reported success upstream.
6. Squash merge — many commits collapsed into one new commit — a merge strategy producing a target-branch commit that no check has ever seen.

41.8 Statuses, checks, and the two APIs behind them

■ 41.8.1 PLAIN – in simple words

1. There are two separate systems for pinning a result onto a commit. They were built years apart and both are still alive.
2. The older one is the **commit status**. It is a small note with four parts: a state, a short description, a link, and a name called the context.
3. Its states are `pending`, `success`, `failure` and `error`. That is all it can say.
4. The newer one is the **check run**, part of the checks system.
5. A check run says much more: whether it is `queued`, `running` or `finished`; what the outcome was; when it started and ended; a block of output text; and notes pinned to particular lines of particular files.
6. Check runs are collected into a **check suite**, which is roughly “everything one tool reported about one commit”.
7. Both systems attach their results to a commit hash. Both draw ticks and crosses in the same place on the page. That is why they get confused.
8. Branch protection lets you name some of these results as **required**.
9. A required result means: this pull request may not merge until a result with exactly that name reports success.
10. And here is the sharp edge. A required check that never arrives blocks the merge forever.
11. It blocks because “has not arrived” is not the same as “failed”. It sits in a third state that means “we are still waiting for this”.
12. Nothing times it out. Nothing gives up. It waits, and the merge button stays grey.

■ 41.8.2 PLAIN – a picture in your head

1. Imagine a building site where a flat cannot be handed over until three inspection slips are pinned to the door.
2. Slip one is from the electrician, slip two from the plumber, slip three from the fire officer.
3. The old slips were postcards: a tick or a cross, a line of writing, nothing else.
4. The new slips are full forms: who inspected, when they started, when they finished, and photographs with arrows pointing at specific pipes.
5. The handover clerk does not judge quality. The clerk only checks that all three named slips are present and say “pass”.

6. Now suppose the fire officer was never told this flat exists.
7. There is no cross on the door. There is simply no third slip.
8. The clerk waits. Nobody is at fault, no alarm rings, and the flat is never handed over.

Where this comparison breaks: real inspectors eventually notice and telephone somebody. A required check has nobody to telephone. The rule is purely mechanical, and the only cure is a human editing the rule or arranging for the missing slip to appear.

■ 41.8.3 PLAIN – a worked example

1. A commit status, created by hand, exactly as an old-style build tool would:

```
gh api -X POST repos/OWNER/REPO/statuses/$SHA \
  -f state=success \
  -f context='ci/unit-tests' \
  -f target_url="$BUILD_PAGE_URL" \
  -f description='412 tests, 0 failures'
```

2. A check run, as posted by an app, has far more structure:

```
{
  "name": "unit-tests",
  "head_sha": "3f1d02c9d5f0a1b2c3d4e5f6...",
  "status": "completed",
  "conclusion": "failure",
  "started_at": "2026-08-13T09:41:02Z",
  "completed_at": "2026-08-13T09:53:11Z",
  "output": {
    "title": "3 failing",
    "summary": "412 tests, 3 failures, 0 skipped",
    "annotations": [
      {
        "path": "src/cart/total.ts",
        "start_line": 44,
        "annotation_level": "failure",
        "message": "expected 1200, received 1199"
      }
    ]
  }
}
```

3. The annotation is the visible difference. It is what draws a red marker on line 44 of that file inside the pull request diff.
4. Reading both systems for one commit:

```
# newer: individual check runs
gh api "repos/OWNER/REPO/commits/$SHA/check-runs" \
  --jq '.check_runs[] | {name, status, conclusion}'

# older: the rolled-up commit status
gh api "repos/OWNER/REPO/commits/$SHA/status" \
  --jq '{state, statuses: [.statuses[]].context[]}'
```

5. The rollup rule for the older API is documented and simple: the combined state is failure if any context is error or failure; pending if there are no statuses at all or any context is pending; success only if every context's latest status is success.
6. Read that middle clause again. Zero statuses rolls up to pending, not to success. Silence is treated as “not yet”, which is exactly the behaviour that makes a missing required check block forever.

■ 41.8.4 PLAIN – what is really happening inside

1. When a run starts, the service creates a check suite for that commit and one check run per job.
2. Each check run begins as queued, becomes in progress, and finally becomes completed with a conclusion.
3. The conclusion is written once, when the job ends. Until then there is no conclusion at all, only a status.
4. That two-field design is the whole reason “pending” and “failed” are different things: status says whether it is over, conclusion says how it went, and the second is empty until the first says completed.
5. Branch protection compares a list of required names against the results present on the head commit of the pull request.
6. The comparison is by name, as text. It has no idea which tool produced the result and no idea what the tool did.
7. So renaming a job in your workflow file silently breaks a required check. The old name never arrives again, and every pull request blocks.
8. This is the single commonest cause of “the repository is stuck and nobody changed the rules”. Somebody did change something: the job’s name.
9. Path filters cause the same shape of failure from the other direction. If the workflow does not start, the check does not exist, and the required name never arrives.
10. The cure is a small job that always runs and always reports the required name, whose only work is to look at the other jobs and decide.

■ 41.8.5 TECHNICAL – the engineer’s version

1. The commit status API is the older of the two and dates from the early years of the GitHub API. Create with `POST /repos/{owner}/{repo}/statuses/{sha}`. Fields: state (one of error, failure, pending, success), target_url, description, and context which defaults to the literal string default.
2. Documented limit: 1,000 statuses per SHA and context pair in a repository. Read them with `GET /repos/{owner}/{repo}/commits/{ref}/statuses` for the list, or `.../status` for the rollout.
3. In GraphQL the type is `StatusState`, with exactly five values: `ERROR`, `EXPECTED`, `FAILURE`, `PENDING`, `SUCCESS`. `EXPECTED` is the one you cannot post yourself; it is what a required-but-absent check looks like.
4. The checks API arrived with GitHub Apps in 2018 and is richer. A **check suite** is a collection of check runs created by one app for one commit. A **check run** is one individual test of that commit.
5. Only a GitHub App can create check runs. `GITHUB_TOKEN` inside Actions acts as an app installation token, which is why Actions can create them and your personal token generally cannot.
6. In GraphQL, `CheckStatusState` has six values: `QUEUED`, `REQUESTED`, `WAITING`, `PENDING`, `IN_PROGRESS`, `COMPLETED`. The REST spelling is lowercase.
7. `CheckConclusionState` has nine values. This table is the one to keep.

Conclusion	Means	Required check
success	it passed	satisfied
failure	it failed	blocks
neutral	ran, no judgement	satisfied
cancelled	stopped early	blocks
skipped	did not execute	see 41.7.5
timed_out	exceeded its limit	blocks

Conclusion	Means	Required check
action_required	needs a human	blocks
stale	superseded by GitHub	blocks
startup_failure	never got going	blocks

8. Notes on the awkward ones. `neutral` exists so a linter can report advice without blocking; it counts as not-failing. `action_required` is what an app returns when it needs you to authorize something, such as granting access.
9. `stale` can only be set by GitHub itself, and marks a result the platform has decided is no longer meaningful. `startup_failure` means the run could not begin, most often an invalid workflow file or an unavailable runner label.
10. `timed_out` on GitHub Actions arrives at `timeout - minutes` if you set one, and at the platform limit of 6 hours for a hosted job if you did not.
11. Branch protection matches required checks by name string against results on the head commit. Configure with `PATCH /repos/{owner}/{repo}/branches/{branch}/protection` or, in the newer model, with repository rulesets.
12. The permanent-block conditions, all documented, all real:

Cause	Effect
Workflow skipped by filter	check absent, stays Expected
Job name renamed	old name never arrives
App uninstalled	its checks never post
Required name never existed	typo blocks every PR

13. `[skip ci]`, `[ci skip]`, `[no ci]`, `[skip actions]` and `[actions skip]` in a commit message, or a `skip-checks: true` trailer, suppress the run entirely. On a repository with required checks that is a self-inflicted permanent block.
14. The standard workaround is a gate job that always runs:

```

ci-gate:
  if: always()
  needs: [lint, test, build]
  runs-on: ubuntu-latest
  steps:
    - name: Fail if any dependency did not succeed
      if: contains(needs.*.result, 'failure')
        || contains(needs.*.result, 'cancelled')
      run: exit 1

```

15. Require `ci-gate` and nothing else. It runs on every event that the workflow runs on, and its name is stable even when the jobs beneath it are renamed.
16. GitLab models the same idea differently: a job has `allow_failure`, a pipeline has a single status, and merge request approval rules reference the pipeline rather than individual named checks. There is no direct equivalent of a required check name, which removes this class of bug and removes the fine-grained control with it.
17. Observing tools: `gh pr checks 42`, `gh pr checks 42 --watch`, `gh api repos/OWNER/REPO/commits/$SHA/check-runs`, `gh api repos/OWNER/REPO/branches/main/protection --jq .required_status_checks`.

■ 41.8.6 WORDS – remember these

1. Commit status — the old-style note on a commit — a state, context, description and target_url posted to the statuses endpoint.
2. Context — the name of an old-style status — the string branch protection matches against, defaulting to default.
3. Check run — the new-style detailed result — an app-created record with status, conclusion, timings, output and line annotations.
4. Check suite — all check runs from one app for one commit — the grouping the interface shows as a single reporting tool.
5. Annotation — a note pinned to a line of a file — a check run output entry with path, start_line and annotation_level.
6. Required status check — a name that must report success — a branch protection rule compared by text against results on the head commit.
7. Expected — waiting for a result that never came — StatusState.EXPECTED, the state that blocks a merge indefinitely.

41.9 Merge queues

■ 41.9.1 PLAIN – in simple words

1. Here is a problem that green ticks cannot solve on their own.
2. Two people each propose a change. Each change is tested alone, and each passes.
3. Both are merged within a minute of each other. The result is broken.
4. Nothing went wrong with either test. The tests answered the questions they were asked.
5. Neither test was ever asked the only question that matters: what happens when both of these land together?
6. Chapter 39 called this a semantic conflict: two changes that do not touch the same lines, and still contradict each other.
7. One person renames a function. The other person adds a new call to the old name. No line overlaps. The program does not build.
8. A **merge queue** exists to ask the missing question before the merge, not after.
9. It works like a queue at a counter. Changes wait in a line, and only one thing is joined at a time.
10. For each change in the line, the machine builds the result you would get if that change landed on top of everything ahead of it.
11. It tests that combined result.
12. Only if that passes does the change actually land.
13. So the thing that is tested is the thing that lands, in the order it lands.
14. That is the whole idea, and it is the only mechanical way to keep a mainline that always builds.

■ 41.9.2 PLAIN – a picture in your head

1. Think of an aeroplane runway with one strip and a queue of aircraft.
2. Each pilot has already done a check on their own aircraft in the hangar. All passed.
3. But the tower does not clear them by hangar checks. The tower clears one aircraft at a time, in a known order, and re-checks the runway state each time.
4. Now add impatience. Waiting for each aircraft to finish before starting the next check is slow.
5. So the tower guesses. It assumes number one will be fine, and starts checking number two against a runway that already has number one on it.
6. It does the same for three and four. Four checks run at once, each assuming everything ahead of it succeeded.
7. If all guesses hold, everything lands in one runway’s worth of time instead of four.
8. If number two turns out to be faulty, the guesses made for three and four were built on a false assumption and must be thrown away and redone.
9. That guessing is called speculative execution, and it is the trick that makes queues fast enough to use.

Where this comparison breaks: aircraft are physical and independent; software changes interact. A faulty aircraft does not make the next one faulty, but a bad merge genuinely can invalidate every speculation behind it. Also, a runway handles one landing at a time by physics. A merge queue chooses to serialize, and could choose not to, at the cost of correctness.

■ 41.9.3 PLAIN – a worked example

1. Three pull requests are ready. The test suite takes 12 minutes.
2. The old discipline, “rebase onto the latest mainline and re-run before merging”, plays out like this.

```

0 min  A rebases onto main, starts CI
12 min  A green, A merges. main moves.
12 min  B rebases onto new main, starts CI
24 min  B green, B merges. main moves.
24 min  C rebases onto new main, starts CI
36 min  C green, C merges.
```

3. Total elapsed: 36 minutes, and three humans had to sit and watch.
4. The same three in a merge queue with speculation.

```

0 min  A, B, C enter the queue in that order
0 min  build main+A          (entry 1)
0 min  build main+A+B        (entry 2, speculative)
0 min  build main+A+B+C      (entry 3, speculative)
12 min  all three green
12 min  A, B, C merge in order. main moves once.
```

5. Total elapsed: about 12 minutes, and nobody watched anything.
6. Now the interesting case. Entry 2 fails, because B contradicts A.

```

12 min  entry 1 green, entry 3 green, entry 2 FAILED
12 min  A merges
12 min  B is removed from the queue and its author told
12 min  entry 3 is discarded: it assumed B would land
12 min  rebuild main+A+C
24 min  green, C merges
```

7. Entry 3’s result was correct about a world that never happened, so it is thrown away. That is the cost of speculation.
8. Costs compared, using 12-minute runs and a 5 percent chance that any given change fails when combined:

Approach	3 changes, all pass	Human effort
Merge and hope	12 min	none, breaks main
Rebase and re-run	36 min	three people wait
Queue, no speculation	36 min	none
Queue, speculative	12 min	none

9. The wasted machine time under speculation is real: a failure at position two discards every build behind it. Teams accept that because machine minutes are cheaper than a broken mainline and cheaper than engineers waiting.

■ 41.9.4 PLAIN – what is really happening inside

1. When a pull request is added to the queue, the service does not merge it. It creates a temporary branch.
2. That temporary branch contains the target branch, plus every queued change ahead of this one, plus this one.
3. That temporary branch is the thing your workflows run against. It is a real commit, with a real hash, and the run is filed against that hash.
4. This is why a merge queue needs its own trigger. A workflow that only listens for `pull_request` will never run for a queue entry.
5. When the run for an entry finishes green and everything ahead of it has merged, the entry is merged into the target branch.
6. If the run fails, that entry is removed from the queue, the author is told why, and the temporary branches for everything behind it are rebuilt without it.
7. Batching is the other lever. Instead of one entry per build, group five entries into one temporary branch and test the group.
8. A green batch merges five changes for the price of one build. A red batch tells you only that one of five is bad, and you must split it to find out which.
9. Splitting a failed batch in half repeatedly finds the culprit in about $\log_2(n)$ further builds. That is the same bisection idea as `git bisect` from Chapter 40.
10. Every serious queue has the same three knobs: how many entries to build at once, how many to merge at once, and how long to wait before giving up on filling a batch.

■ 41.9.5 TECHNICAL – the engineer’s version

1. The property a merge queue enforces has a name in the Rust community: the “not rocket science rule of software engineering”, a phrase attributed to Graydon Hoare, Rust’s original author. Stated plainly: automatically maintain a repository of code that always passes all the tests.
2. History. The Rust project’s `bors` bot implemented this from the early 2010s, later reimplemented as `homu` and `bors-ng`. OpenStack’s `Zuul`, in use from 2012, added speculative execution across multiple projects and called the mechanism a gate pipeline. `Zuul` v3 arrived in 2017.
3. Commercial and hosted implementations followed: `Mergify`, `Aviator`, `Graphite`, and `GitLab’s` merge trains, which appeared in `GitLab` 11.2 in 2018.
4. `GitHub’s` own merge queue entered public beta on 8 February 2023 and became generally available on 12 July 2023.

5. Mechanically, on GitHub: entries create temporary branches under a reserved prefix, `gh-readonly-queue/`, one per entry, named after the base branch and the pull request. You cannot push to them.
6. Workflows must listen for the `merge_group` event with activity type `checks_requested`, or they will not run for queue entries at all:

```
on:
  pull_request:
    branches: [main]
  merge_group:
    types: [checks_requested]
```

7. Forgetting `merge_group` is the classic first-day merge queue failure. The entry sits waiting for a required check that no workflow will ever produce, which is exactly the permanent-block condition from 41.8.
8. Documented settings, with their ranges as of August 2026:

Setting	Range	Meaning
Build concurrency	1 to 100	speculative builds at once
Maximum to merge	1 to 100	largest batch
Minimum to merge	1 to 100	smallest batch
Wait time	minutes	how long to fill a batch

9. Merge method is configurable as `merge`, `rebase` or `squash`, and applies to the whole queue rather than per pull request.
10. “Only merge non-failing pull requests” controls batch semantics. When on, every entry must pass. When off, a group may merge if the final entry passes for the combined changes, which is faster and admits a change that never passed on its own.
11. On failure, GitHub removes the entry from the queue, records the reason on the pull request timeline, recreates the temporary branch without it, and continues with the rest.
12. Cost model. With batch size b , per-run time T , and independent failure probability p per change, a batch is green with probability $(1 - p)^b$. Expected builds per merged change falls with b while all is well, and rises sharply once $b * p$ approaches 1. Most teams land on batches of 2 to 8.
13. The older discipline is still available and still correct: branch protection offers “Require branches to be up to date before merging”, which forces each author to rebase or merge the latest target and re-run before the merge button unlocks.
14. That setting has two costs a queue does not: it serializes humans rather than machines, and it has a race. Between your last green run and your click, somebody else can merge. The window is small but not zero.
15. It also scales badly. On a busy repository, the mainline moves faster than your test suite runs, so you can never get to the front of the line. Teams hit this at roughly $\text{merges per hour} \times \text{test minutes} > 60$.
16. Comparison of approaches:

Approach	Mainline safety	Cost
Merge on green PR	not guaranteed	cheapest
Up-to-date required	guaranteed	humans serialize
Queue, serial	guaranteed	slow, no waste

Approach	Mainline safety	Cost
Queue, speculative	guaranteed	fast, wastes builds

17. Observing tools: `gh pr merge --auto`, `gh api repos/OWNER/REPO/merge-queue` for queue state, the `merge_group` payload inside the run, and `git ls-remote origin 'refs/heads/gh-readonly-queue/*'` to see live entries.

■ 41.9.6 WORDS – remember these

1. Merge queue — a line of changes joined one at a time — a serializing gate that tests the prospective merged state before merging.
2. Semantic conflict — two changes that clash without touching the same lines — a textually clean merge that fails to build or fails tests.
3. Speculative execution — testing entries assuming the ones ahead succeed — parallel builds of stacked prospective states, discarded on any failure.
4. Batch — several entries tested as one — a group merged together, requiring bisection to locate a culprit when it fails.
5. `merge_group` — the event a queue entry raises — the GitHub Actions trigger with activity type `checks_requested`.
6. Merge train — GitLab’s name for the same idea — sequential pipelines on the projected result of merging each queued request.
7. Not rocket science rule — always keep the mainline passing — the invariant a gating queue mechanically enforces.

41.10 mergeStateStatus, value by value

■ 41.10.1 PLAIN – in simple words

1. When you ask GitHub about a pull request, one field tells you why the merge button is or is not available. It is called `mergeStateStatus`.
2. It has exactly eight possible values, and they are not all the same kind of thing, which is why people misread them.
3. Some values are about the code itself: can these two branches be joined at all?
4. Some are about the rules: the code is joinable, but a policy says not yet.
5. One is about the pull request’s own state: it is a draft.
6. And one is about GitHub itself: I have not worked it out yet, ask again.
7. The reader saw three of them in one session: `CLEAN`, `BLOCKED` and `UNKNOWN`.
8. Two of these are worth learning before the rest.
9. `UNKNOWN` almost never means something is wrong. It means the answer is still being computed. The correct response is to ask again in a second.
10. `BLOCKED` does not mean a merge conflict. It means the branches join fine and a protection rule is not satisfied.
11. Getting those two right removes most of the confusion this field causes.

■ 41.10.2 PLAIN – a picture in your head

1. Think of a clerk at a counter deciding whether your form can be filed.
2. `DIRTY` is: your form physically will not fit in the folder. The paper is the wrong shape. Fix the paper.
3. `BEHIND` is: your form is on an old version of the template. Copy it onto the current template.

4. **BLOCKED** is: the form is perfect and the folder is ready, but a signature is missing. Nothing is wrong with your paper.
5. **UNSTABLE** is: everything is signed, but one optional report attached to it came back with a complaint. The clerk will still file it if you insist.
6. **DRAFT** is: you wrote “draft” across the top yourself. The clerk is obeying you.
7. **CLEAN** is: file it.
8. **UNKNOWN** is: the clerk has not finished reading it yet. Come back in a moment.

Where this comparison breaks: a clerk gives you one reason. `mergeStateStatus` gives you the first blocking reason it finds, in an order GitHub does not publish. A pull request can be behind and blocked and have failing checks all at once, and you will be shown a single word. Never treat that word as a complete list of what is wrong.

■ 41.10.3 PLAIN – a worked example

1. Asking for the field, together with the things that explain it:

```
gh pr view 42 --json \
  number,mergeable,mergeStateStatus,isDraft,headRef0id,\
  reviewDecision
```

2. A typical answer while GitHub is still thinking:

```
{
  "number": 42,
  "mergeable": "UNKNOWN",
  "mergeStateStatus": "UNKNOWN",
  "isDraft": false,
  "headRef0id": "3f1d02c9d5f0a1b2c3d4e5f60718293a4b5c6d7e",
  "reviewDecision": "APPROVED"
}
```

3. Wait one or two seconds and ask again. This is not a workaround. It is the documented way the field behaves.

```
{
  "mergeable": "MERGEABLE",
  "mergeStateStatus": "BLOCKED",
  "reviewDecision": "APPROVED"
}
```

4. Read those two lines together, because alone each is misleading.
5. `mergeable: MERGEABLE` says the branches join without conflict.
6. `mergeStateStatus: BLOCKED` says a rule is unsatisfied. The code is fine. The policy is not.
7. To find out which rule, ask the checks, not this field:

```
gh pr checks 42
gh api repos/OWNER/REPO/branches/main/protection \
  --jq .required_status_checks.contexts
```

8. Nine times out of ten the answer is a required check sitting in `Expected`, which is exactly the permanent block from 41.8.

■ 41.10.4 PLAIN – what is really happening inside

1. GitHub does not keep a permanent answer to “can this merge?”.
2. It computes one on demand, in the background, by attempting a test merge of the head into the base.
3. That computation takes time, and the API answers immediately whether or not it has finished.
4. So the first response after any change to either branch is very often UNKNOWN, with the REST equivalent field mergeable set to null.
5. Asking again triggers or picks up the computation. This is documented, and it is why every serious script polls this field rather than reading it once.
6. Once the test merge succeeds, GitHub knows the branches join, and moves on to the rules.
7. It then reports the first obstacle it finds: draft status, protection rules, check results, or nothing at all.
8. This is why the values are a mixture of categories. The field is not a classification of the pull request. It is a report of the first thing stopping the button from lighting up.

■ 41.10.5 TECHNICAL – the engineer’s version

1. mergeStateStatus is a GraphQL enum on the PullRequest type. GitHub’s documented values and descriptions, with the action each implies:

Value	GitHub’s description	Do this
BEHIND	head ref is out of date	update the branch
BLOCKED	the merge is blocked	find the unmet rule
CLEAN	mergeable, status passing	merge it
DIRTY	merge commit not creatable	resolve conflicts
DRAFT	blocked, PR is a draft	mark ready for review
HAS_HOOKS	mergeable, pre-receive hooks	merge, hooks may reject
UNKNOWN	state cannot be determined	re-query, conclude nothing
UNSTABLE	mergeable, status not passing	fix or override

2. UNKNOWN, precisely. The mergeability computation is asynchronous. In REST, GET /repos/{owner}/{repo}/pulls/{number} returns mergeable: null until the background job completes, and the documentation instructs you to retry. In GraphQL the same condition surfaces as UNKNOWN.
3. Therefore: UNKNOWN is not an error, not a conflict, and not a policy failure. It is “not yet”. Poll with a short delay, a few times, before treating it as anything else. Concluding anything from a single UNKNOWN is the commonest mistake made with this field.
4. BLOCKED, precisely. It means the branches merge cleanly and a branch protection or ruleset requirement is unmet. It is not a merge conflict. DIRTY is the merge conflict value.
5. Common causes of BLOCKED, none of which are visible in the field itself: a required review missing, a requested change outstanding, a required status check absent or failing, a CODEOWNERS review missing, a required conversation unresolved, or a required deployment or signature rule.
6. UNSTABLE versus BLOCKED is the distinction people most often get backwards. UNSTABLE means a check is not passing but that check is not required, so a user with permission can still merge. BLOCKED means a rule forbids it outright.
7. BEHIND appears only when the repository has “Require branches to be up to date before merging” enabled. Without that setting, an out-of-date branch reports CLEAN or UNSTABLE instead, and merges happily.

8. HAS_HOOKS is specific to GitHub Enterprise Server, where an administrator can install pre-receive hooks. It means everything is fine but a server-side hook still gets the final word at push time, so a merge can still be rejected after you click.
9. DIRTY means Git cannot construct the merge commit without conflict resolution. Nothing in continuous integration will fix it. A human must rebase or merge and resolve.
10. Companion fields you should always fetch alongside it, because mergeStateStatus alone is not diagnostic:

Field	Tells you
mergeable	conflict-free or not
reviewDecision	approved, changes needed
statusCheckRollup	per-check results
isDraft	explains DRAFT

11. On some GitHub Enterprise Server versions, mergeStateStatus sits behind a schema preview and requires the Accept header application/vnd.github.merge-info-preview+json. The gh CLI sets what it needs; a hand-written GraphQL client may not.
12. Practical polling pattern, which is what a release script should contain:

```
for i in 1 2 3 4 5; do
  S=$(gh pr view 42 --json mergeStateStatus \
    --jq .mergeStateStatus)
  [ "$S" != "UNKNOWN" ] && break
  sleep 2
done
echo "state: $S"
case "$S" in
  CLEAN|HAS_HOOKS) echo "safe to merge" ;;
  BLOCKED) echo "a rule is unmet; run gh pr checks" ;;
  UNSTABLE) echo "a non-required check is failing" ;;
  BEHIND) echo "update branch and re-run CI" ;;
  DIRTY) echo "resolve conflicts by hand" ;;
  DRAFT) echo "mark ready for review" ;;
  UNKNOWN) echo "still computing; do not conclude" ;;
esac
```

13. GitHub’s own documentation notes that the REST field mergeable_state, the lowercase sibling of this enum, has historically been treated as unofficial and subject to change. Prefer the GraphQL enum, and prefer reading the underlying facts over branching on this one word.

■ 41.10.6 WORDS – remember these

1. mergeStateStatus — why the merge button is or is not lit — a GraphQL enum on PullRequest with eight values.
2. mergeable — can the branches be joined at all — a separate tri-state field, null or UNKNOWN while still computing.
3. CLEAN — nothing is in the way — mergeable with passing commit status.
4. BLOCKED — a rule says no, not a conflict — branch protection or ruleset requirement unmet.
5. UNSTABLE — mergeable but something non-required is failing — merge is permitted, quality is not vouched for.
6. DIRTY — the branches genuinely conflict — Git cannot construct the merge commit.

7. **BEHIND** — your branch is on an old base — only reported when “require branches to be up to date” is enabled.
8. **UNKNOWN** — GitHub has not finished computing — re-query; it carries no information about the pull request.

41.11 What a good pipeline actually does, in order

■ 41.11.1 PLAIN – in simple words

1. A pipeline is a list of checks in a chosen order. The order is not decoration.
2. The rule is: cheapest and most likely to fail goes first.
3. A check that takes 8 seconds and catches a typo should never run after a check that takes 20 minutes.
4. So a sensible order looks like this.
5. **Lint**: read the code without running it, and complain about style and obvious mistakes. Seconds.
6. **Build**: turn source into something runnable. If it does not build, nothing after this matters.
7. **Unit tests**: test small pieces on their own, with nothing real attached. Fast, many, precise about where the fault is.
8. **Integration tests**: start real pieces together, a database, a queue, and check they talk correctly. Slower, fewer, vaguer about where the fault is.
9. **Security scanning**: look for known-bad dependencies, leaked keys, and dangerous code patterns.
10. **Artifact build**: package the thing you will actually ship, once, and keep it.
11. **Deploy to staging**: put that exact package on a copy of production.
12. **Smoke tests**: a handful of checks against the running copy. Does the home page load? Can one user log in?
13. **Production**: ship the same package that passed everything above.
14. Notice the package is built once and reused. Rebuilding before production would mean shipping something nobody tested.

■ 41.11.2 PLAIN – a picture in your head

1. Think of security at an airport, in the order they actually use.
2. First a glance at your ticket at the door. One second, catches most people who are in the wrong building.
3. Then the document check. Thirty seconds.
4. Then the bag scanner. Two minutes.
5. Then, for a few people, a hand search. Ten minutes.
6. Nobody hand-searches everybody first. It would be correct and it would be useless, because the queue would never move.
7. Each stage is more expensive and catches fewer people than the one before.

Where this comparison breaks: airport stages are independent, and a pipeline’s stages are not. A build failure makes every later stage meaningless, so a pipeline stops, while an airport keeps processing the rest of the queue. Also, the airport cannot rerun you from a cache; a pipeline can and should.

■ 41.11.3 PLAIN – a worked example

1. Real timings from a medium web project. Yours will differ; the shape holds.

Stage	Time	Catches
Lint	25 s	style, unused vars
Build	1 m 40 s	type and syntax errors
Unit tests	3 m	logic faults
Integration	7 m	wiring, SQL, contracts
Security scan	2 m	known bad dependencies
Package	1 m 10 s	nothing, it produces
Staging deploy	2 m	config and secrets faults
Smoke tests	40 s	it is alive

2. Run in strict order, that is about 18 minutes. Too slow.
3. Run lint, unit tests and the security scan in parallel after the build, and the critical path drops to about 12 minutes.
4. Caching the dependency download saves roughly 60 to 90 seconds of that on every single run.
5. A worked cache and artifact pair in GitHub Actions:

```

- uses: actions/cache@v4
  with:
    path: ~/.npm
    key: npm-${{ hashFiles('package-lock.json') }}
    restore-keys: npm-

- run: npm ci && npm run build

- uses: actions/upload-artifact@v4
  with:
    name: app-${{ github.sha }}
    path: dist/
    retention-days: 14

```

6. Note the cache key. It is a hash of the lock file, so a dependency change makes a new key automatically, and a stale cache can never be used.
7. Note the artifact name. It carries the commit SHA, so the package you deploy can be traced back to the exact commit that produced it.

■ 41.11.4 PLAIN – what is really happening inside

1. Two words that sound alike and are not: cache and artifact.
2. A **cache** is a speed trick. It holds things you could recreate, like downloaded dependencies. Losing it costs time and nothing else.
3. An **artifact** is a product. It holds the thing you built and will ship. Losing it means you cannot deploy without rebuilding.
4. Never treat a cache as a source of truth, and never rebuild an artifact between test and deploy.
5. **Parallelism** splits work across machines. Four machines running a quarter of the tests each finish in roughly a quarter of the time, plus the fixed startup cost of each machine.
6. That fixed cost is why splitting a 40-second suite into eight parts makes it slower, not faster.
7. **Matrix builds** are parallelism over configurations rather than over test files: the same suite on three operating systems and two language versions.
8. **Fail-fast** decides what happens when one parallel branch fails. On, the siblings are cancelled, saving money. Off, they finish, giving you the full picture.
9. Use fail-fast on for pull requests, where speed matters, and off for nightly matrix runs, where the full picture matters.

10. A **flaky test** is a test that passes and fails on the same code, with no change in between.
11. Flaky tests do something worse than waste time. They teach people that red means “press the button again”.
12. Once a team believes that, red stops carrying information, and the whole pipeline becomes decoration. This is the way continuous integration dies.

■ 41.11.5 TECHNICAL – the engineer’s version

1. The stage order above is the pipeline described in Continuous Delivery by Jez Humble and David Farley in 2010, where it is called a deployment pipeline, with the commit stage first and later stages progressively slower and more production-like.
2. The proportions come from the test pyramid, named by Mike Cohn in Succeeding with Agile in 2009: many fast unit tests, fewer integration tests, very few end-to-end tests.
3. The 10-minute build rule comes from Extreme Programming and is repeated in the Continuous Delivery literature. Past roughly 10 minutes, developers stop waiting for the result and context-switch, and the feedback loop that justifies the whole apparatus is gone.
4. GitHub Actions cache limits as documented in August 2026: 10 GB total per repository, with least-recently-used eviction, and entries removed after 7 days without access. Cache is keyed by an exact string, with restore-keys giving ordered prefix fallbacks.
5. Artifact retention on GitHub Actions defaults to 90 days, configurable from 1 to 90 days for public repositories and 1 to 400 days for private and enterprise repositories.
6. Caches are scoped by branch: a run on a branch can read caches from that branch and from the default branch, but not from unrelated branches. This is a deliberate isolation boundary, since a cache is a writable path shared between runs and therefore a cross-branch attack surface.
7. Security scanning splits into named categories, and mixing them up leads to thinking you are covered when you are not:

Kind	Looks at	Example tools
SAST	your source code	CodeQL, Semgrep
SCA	your dependencies	Dependabot, Trivy
Secret scanning	committed keys	Gitleaks, TruffleHog
DAST	the running system	OWASP ZAP

8. CodeQL came to GitHub through the acquisition of Semmle in September 2019. Dependabot came through the acquisition of Dependabot in May 2019. Both are now built into the platform.
9. Software bills of materials have two mainstream formats: SPDX, whose version 2.2.1 became ISO/IEC 5962:2021, and CycloneDX, standardized as ECMA-424 in 2024. Producing one is now a common late pipeline stage.
10. Flakiness, with a real figure: Google’s testing blog reported in May 2016 that almost 16 percent of their roughly 4.2 million tests showed some level of flakiness, and that flaky failures consumed a substantial share of engineering attention. Treat the exact percentage as specific to Google, and the phenomenon as universal.
11. Standard flakiness controls, in increasing order of honesty: retry the test and hope; quarantine it into a non-blocking suite and file a bug; fix the root cause, which is nearly always shared state, real time, real network, or unordered iteration.
12. Retrying without quarantining is the trap. It hides the signal and lets the flake rate grow until the suite is useless.

13. Required versus optional checks, restated in terms of 41.8: a required check must appear and must report success. An optional check appears and is advisory, and produces UNSTABLE rather than BLOCKED when it fails.
14. A workable policy: require the gate job, the build, and the unit tests. Leave slow end-to-end suites, performance benchmarks and advisory linters optional, and review them on a schedule instead.
15. Test time budgets, as targets rather than laws:

Stage	Budget	If exceeded
Lint plus build	under 3 min	cache, incremental build
Unit tests	under 5 min	shard across runners
Full PR pipeline	under 10 min	move work to nightly
Nightly full matrix	under 2 h	reduce matrix cells

16. The four DORA metrics from the 2018 book Accelerate by Nicole Forsgren, Jez Humble and Gene Kim are the standard way to judge whether the pipeline is actually helping: deployment frequency, lead time for changes, change failure rate, and time to restore service. Note that two of the four are about recovery, not prevention.
17. Observing tools: `gh run view --log`, the timing breakdown on a run page, `gh api repos/OWNER/REPO/actions/cache/usage`, and any test reporter that emits JUnit XML for trend analysis.

■ 41.11.6 WORDS – remember these

1. Deployment pipeline — the ordered set of checks from commit to production — the staged model set out in Continuous Delivery, 2010.
2. Cache — a recreatable speed-up — keyed storage of dependencies, safe to lose, never a source of truth.
3. Artifact — the built product you will ship — a retained output passed between jobs and to deployment, built once.
4. Matrix build — the same job across configurations — a cross product of variables expanded into parallel jobs.
5. Fail-fast — cancel siblings on first failure — a matrix strategy trading diagnostic completeness for speed and cost.
6. Flaky test — passes and fails on identical code — a non-deterministic test, usually caused by shared state, timing or ordering.
7. SAST, SCA, DAST — code scan, dependency scan, running-system scan — static analysis, software composition analysis, dynamic testing.
8. Test pyramid — many small tests, few large ones — the proportional model named by Mike Cohn in 2009.

41.12 Deployment strategies

■ 41.12.1 PLAIN – in simple words

1. You have a package that passed everything. Now you must put it in front of real users. How you do that is the deployment strategy.
2. **Recreate**: stop the old version, start the new one. Simple, and there is a gap where nothing works.
3. **Rolling**: you have ten copies running. Replace them a few at a time. No gap, but for a while both versions are live at once.

4. **Blue-green:** run two complete environments. Blue is serving users. Deploy to green, test it, then switch all traffic to green in one moment. Blue stays there, ready to take traffic back.
5. **Canary:** send 1 percent of users to the new version. Watch the error rate. If it looks fine, go to 5 percent, then 25, then everyone.
6. **Feature flags:** ship the new code to everyone but keep it switched off, then switch it on for chosen users later, without deploying anything.
7. That last one is the important idea, so say it clearly.
8. Deploying is putting code on machines. Releasing is letting users reach it.
9. Feature flags separate those two things, so a deploy stops being a scary event and becomes routine.
10. And turning a feature off is instant, while undoing a deploy is not.

■ 41.12.2 PLAIN – a picture in your head

1. Picture changing the menu at a restaurant with a hundred tables.
2. Recreate: close the restaurant, change everything, reopen. Everyone waits outside.
3. Rolling: change the menus table by table. Nobody waits, but for twenty minutes two menus exist and the kitchen must cook from both.
4. Blue-green: build an identical second dining room, set it up completely, check it, then walk everyone across in one go. Keep the old room furnished for a week in case.
5. Canary: give the new menu to two tables, watch what they send back, then widen it.
6. Feature flags: print every dish on every menu from the start, but mark the new ones “ask the waiter”. Turning them on is a word to the staff, not a reprint.

Where this comparison breaks: menus have no state. Software has databases, and a database cannot be walked across to a new room. That single difference is what makes rollback hard, and it is the subject of 41.12.4.

■ 41.12.3 PLAIN – a worked example

1. A service with 12 identical copies, a 90-second start time, and a rolling update replacing 25 percent at a time.
2. 12 copies, 25 percent surge means 3 new copies start while at most 3 old ones go away.
3. Four waves of 3, each about 90 seconds plus a health check, is roughly 7 to 8 minutes to fully roll out.
4. During those 8 minutes, both versions serve real traffic. Both must be able to read the same data and answer the same requests.
5. Compare the same release under four strategies:

Strategy	Downtime	Rollback speed
Recreate	60 to 120 s	full redeploy
Rolling	none	another full roll
Blue-green	none	seconds, flip back
Canary	none	seconds, shift traffic

6. Blue-green and canary buy fast rollback with double the running cost during the change. That is the trade, stated honestly.
7. A Kubernetes rolling update is configured with two numbers:

```
strategy:
  type: RollingUpdate
```

```
rollingUpdate:
  maxSurge: 25%
  maxUnavailable: 25%
```

8. `maxSurge` is how many extra copies may exist above the target. `maxUnavailable` is how many may be missing. Both default to 25 percent.
9. Setting `maxUnavailable: 0` guarantees no reduction in capacity and requires spare room to surge into.

■ 41.12.4 PLAIN - what is really happening inside

1. Rollback sounds symmetric. It is not.
2. Code rollback is easy: the old package still exists, so put it back.
3. Data rollback is often impossible, because the new version has already written data in a new shape.
4. Suppose the release renamed a column from `phone` to `phone_number` and copied the values across.
5. New code writes to `phone_number`. Users create records for twenty minutes.
6. Now roll the code back. The old code reads `phone`, which no longer receives writes. Those twenty minutes of phone numbers are invisible.
7. Nothing crashed. The data is simply wrong, which is worse.
8. The discipline that fixes this is called expand and contract, or parallel change, and it takes three releases instead of one.
9. **Expand**: add `phone_number` while keeping `phone`. Write to both. Read from `phone`. Deploy. This release is safe to roll back.
10. **Migrate**: switch reads to `phone_number`. Still writing both. Deploy. Still safe to roll back.
11. **Contract**: stop writing `phone`, then drop it, in a later release, once you are certain you will not roll back past this point.
12. The rule underneath: every deployment must be compatible with the version before it and the version after it, because during any rolling update both are running at once.
13. That rule is why database changes are the hard part of continuous deployment, and why teams that ignore it get exactly one bad night and then adopt it.

■ 41.12.5 TECHNICAL - the engineer's version

1. Blue-green deployment as a named practice was popularized by Dan North and Jez Humble and set out in Continuous Delivery in 2010. Canary releasing takes its name from the caged birds carried into coal mines to detect gas.
2. Feature toggles were described in detail in Pete Hodgson's 2016 article Feature Toggles on Martin Fowler's site, which classifies them into release toggles, experiment toggles, ops toggles and permission toggles, with very different lifetimes.
3. Flickr's 2009 engineering post Flipping Out is the widely cited early description of running continuous deployment behind flags, with more than ten deploys a day.
4. Strategy comparison with the properties that actually decide the choice:

Strategy	Extra capacity	Both versions live
Recreate	none	no
Rolling	small surge	yes, briefly
Blue-green	100 percent	at the switch only
Canary	small	yes, for a long time

5. Canary requires observability that most teams underestimate: per-version metrics. If your error rate is not broken down by build, a canary tells you nothing you did not already know.
6. Typical canary schedule: 1 percent for 10 minutes, 5 percent for 20 minutes, 25 percent for 30 minutes, then 100 percent, with automatic rollback on any guard metric breach. Guard metrics are usually error rate, latency at the 99th percentile, and a business counter such as checkouts per minute.
7. Kubernetes supports Recreate and RollingUpdate natively; blue-green and canary are built on top with service selectors, ingress weights, or a service mesh. Argo Rollouts and Flagger are the common controllers for this.
8. Expand and contract is documented as the ParallelChange pattern by Danilo Sato in 2014. Its formal requirement is that every schema state supports both the previous and the next application version, sometimes called N-1 compatibility.
9. Migrations that are not reversible in practice: dropping a column, dropping a table, narrowing a type, adding a NOT NULL constraint without a default, and any data transformation that loses the original value. Plan these as separate releases, never bundled with a behaviour change.
10. GitHub Actions models targets as **environments**, which carry their own secrets and variables plus protection rules:

Protection	Effect
Required reviewers	up to 6 approvers
Wait timer	delay up to 43,200 min
Branch policy	only named branches deploy
Custom rules	third-party gates

11. 43,200 minutes is 30 days, the documented maximum wait timer. A wait timer is a real control: it is the mechanical version of “let it bake in staging overnight”.
12. A job binds to an environment with `environment: production`, at which point the environment’s secrets become available and its protection rules apply before the job starts, not during it.
13. GitLab expresses the same idea with `environment: plus when: manual`, and protected environments with approval rules. Argo CD expresses it as a sync policy, manual or automated, per application.
14. Observing tools: `gh api repos/OWNER/REPO/deployments`, `gh api repos/OWNER/REPO/environments`, `kubectl rollout status`, `kubectl rollout undo`, and per-version dashboards in your metrics system.

■ 41.12.6 WORDS – remember these

1. Recreate — stop the old, start the new — a strategy with a deliberate outage window and no version overlap.
2. Rolling update — replace instances a few at a time — controlled by surge and unavailability limits, with both versions live.
3. Blue-green — two full environments, one switch — instant cutover and instant rollback at double running cost.
4. Canary — a small slice of traffic first — progressive delivery gated on per-version guard metrics.
5. Feature flag — code shipped but switched off — runtime toggle decoupling deploy from release, reversible in milliseconds.
6. Expand and contract — change the schema in compatible steps — the ParallelChange pattern giving N-1 compatibility across releases.

7. Environment — a named deployment target with rules — a scope holding secrets, reviewers, wait timers and branch policies.

41.13 Secrets in CI

■ 41.13.1 PLAIN – in simple words

1. A pipeline needs passwords. It signs in to a registry, uploads to a server, talks to a cloud account.
2. Those values cannot live in the repository, because everyone who can read the code can read them, forever, in every clone.
3. So they are stored separately, in a box the service keeps locked, and handed to the machine only while the job runs.
4. Inside the job they appear as environment variables, which are just named values the running program can read.
5. When the job ends, the machine is destroyed and the values go with it.
6. Two rules matter more than everything else.
7. Rule one: never print a secret. Not to the log, not in an error message, not in a debug dump.
8. The service tries to help by blacking out anything matching a known secret, but that is text matching. Change the text even slightly and the blackout fails.
9. Encode a key in base64 and print it, and it goes to the log in full, because the blacked-out pattern no longer matches.
10. Rule two: a stranger’s pull request gets no secrets at all.
11. That is why a build from an outside contributor can test the code and cannot publish anything.
12. And the modern advice goes further: stop storing long-lived cloud passwords at all.
13. Instead the job proves who it is, and the cloud hands it a temporary key that expires in an hour.
14. Nothing long-lived exists to steal, which changes the shape of the whole problem.

■ 41.13.2 PLAIN – a picture in your head

1. Think of a building that contractors visit.
2. The old way: give each contractor a copy of the master key. It works forever, it can be copied, and if one is lost nobody knows.
3. The new way: the contractor shows an identity card at reception. Reception checks it against a list, and issues a visitor badge valid for one hour, for one floor.
4. The badge cannot be reused tomorrow. Losing it costs almost nothing.
5. Reception never gives out the master key, because there is no need.
6. That is the difference between a stored cloud password and identity federation.

Where this comparison breaks: the contractor’s identity card is a physical thing they carry. In continuous integration the identity is issued fresh by the platform for each job, and its trustworthiness rests entirely on the platform not lying about which repository is asking. So you must pin the trust rule down to an exact repository and branch, or any repository on the platform can walk in with a valid card.

■ 41.13.3 PLAIN – a worked example

1. The wrong way, and it is written like this in real repositories:

```
- run: |  
    echo "Token is ${ secrets.API_TOKEN }"  
    curl -H "Authorization: Bearer $TOKEN" ...
```

2. Two faults. The value is interpolated into the script text, so it can appear in an error trace. And it is printed on purpose.
3. The right way passes secrets through the environment, never into the script body:

```
- env:
  API_TOKEN: ${ secrets.API_TOKEN }
run: |
  curl -sS -H "Authorization: Bearer $API_TOKEN" \
    "$API_BASE/v1/publish"
```

4. Now the shell receives a variable name. The value never becomes part of the command text that appears in logs and traces.
5. The identity-federation version needs no stored password at all:

```
permissions:
  id-token: write
  contents: read
steps:
  - uses: aws-actions/configure-aws-credentials@v4
    with:
      role-to-assume: arn:aws:iam::111122223333:role/ci
      aws-region: ap-south-1
```

6. There is no `secrets.AWS_SECRET_ACCESS_KEY` anywhere. The `id-token: write` permission lets the job ask GitHub for a signed identity document, and the cloud exchanges it for credentials lasting about an hour.
7. Pinning a third-party action to an exact commit, with the version in a comment so tools can still update it:

```
- uses: actions/checkout@11bd719 # v4.2.2
```

8. That short form is for the page. In a real file, write the full 40-character hash, because a tag can be moved and a full hash cannot.

■ 41.13.4 PLAIN – what is really happening inside

1. A secret is encrypted before it leaves your browser, stored encrypted, and decrypted only at the moment a job that is allowed to see it starts.
2. The service also registers each secret value with the log processor, which scans every line and replaces exact matches with asterisks.
3. That masking is genuinely useful and genuinely shallow. It matches strings.
4. It does not know that `base64 -w0 key.pem` produces a different string containing the same secret. It does not know that printing a JSON object containing the key is the same disclosure.
5. This is exactly how the March 2025 attack on a popular third-party action worked: the malicious code read secrets out of the runner process and printed them in an encoded form, and masking did not catch it.
6. Fork pull requests get no secrets because the code being tested is not yours. Section 41.5 covered why, and this is the other half of the same rule.
7. For identity federation the sequence is short and worth knowing.
8. The job asks GitHub for a signed token describing itself: which repository, which branch, which environment, which workflow.
9. The cloud provider has been configured in advance to trust tokens signed by GitHub, but only when the description matches a rule you wrote.

10. If it matches, the cloud issues short-lived credentials. If it does not, the request is refused and nothing is leaked.
11. The whole exchange takes under a second and leaves nothing behind.

■ 41.13.5 TECHNICAL – the engineer’s version

1. GitHub encrypts secrets client-side with a libsodium sealed box before upload, stores them encrypted, and decrypts them only when injecting into a runner. Documented limits as of August 2026: 48 KB per secret, 1,000 organization secrets, 100 repository secrets, 100 environment secrets.
2. A value larger than 48 KB must be encrypted into a file committed to the repository, with only the passphrase stored as a secret. This is the documented workaround, not a hack.
3. Masking is implemented by registering values with the log service. You can register more at run-time with the workflow command `::add-mask::value`, which is how you protect a secret derived inside the job.
4. Masking limitations, all real: it does not survive transformation such as base64 or URL encoding, it does not apply to values split across lines, and it does not protect artifacts, only logs.
5. Scoping: repository secrets, organization secrets with repository allow lists, and environment secrets which are only available to jobs bound to that environment and only after its protection rules pass.
6. `GITHUB_TOKEN` is an automatically issued installation token, valid for the duration of the job, invalidated at the end. Declare `permissions:` at workflow or job level and grant the minimum. For newly created repositories and organizations GitHub changed the default to read-only in 2023; older ones may still default to write, so check rather than assume.
7. OIDC federation, precisely. GitHub Actions gained support in a changelog entry on 27 October 2021 and was declared generally available in November 2021.
8. The job requests a JSON Web Token from the endpoint in `ACTIONS_ID_TOKEN_REQUEST_URL`, authenticating with `ACTIONS_ID_TOKEN_REQUEST_TOKEN`, both injected only when `permissions: id-token: write` is set.
9. The issuer is `https://token.actions.githubusercontent.com`. The claim that matters is `sub`, whose shape is one of:

```
repo:OWNER/REPO:ref:refs/heads/main
repo:OWNER/REPO:environment:production
repo:OWNER/REPO:pull_request
```
10. On AWS the exchange is `sts:AssumeRoleWithWebIdentity` against an IAM OIDC identity provider, producing credentials of at most one hour by default. On Azure it is a federated credential on an app registration. On Google Cloud it is Workload Identity Federation.
11. The critical misconfiguration is a trust policy that checks the issuer but not the sub claim, or checks it with a wildcard. That configuration lets any repository on GitHub assume your role. Always match the full sub, including the ref or environment.
12. Third-party action supply chain risk, with a real case. In March 2025 the action `tj-actions/changed-files` was compromised: its version tags were retargeted to a malicious commit that read secrets out of runner memory and printed them into the workflow log.

Fact about that incident	Value
Advisory	CVE-2025-30066
Affected versions	up to 45.0.7

Fact about that incident	Value
Related compromise	CVE-2025-30154
United States CISA alert	18 March 2025

13. The mechanism deserves attention: nothing was pushed to your repository. A tag in someone else’s repository was moved. `uses: owner/action@v4` resolves that tag at run time, on every run, with no record of what it pointed at yesterday.
14. Pinning to a full 40-character commit SHA removes that entire class of attack, because a SHA names immutable content. Moving a tag cannot change what a SHA resolves to.

Reference form	Mutable	Verdict
@main	yes, any push	never
@v4	yes, tag moves	avoid
@v4.2.2	yes, tag moves	avoid
@11bd719... full SHA	no	correct

15. Pinning has a cost: you stop receiving security fixes automatically. Dependabot understands SHA pins with a trailing version comment and raises pull requests to move them, which restores updates while keeping the review step.
16. Earlier incidents in the same family, worth knowing as precedent: the Codecov bash uploader compromise in April 2021, where a modified script exfiltrated environment variables from customers’ CI jobs, and the SolarWinds Orion build system compromise disclosed in December 2020.
17. Other controls that matter: run untrusted work on ephemeral, isolated runners; never use self-hosted runners on public repositories; set `permissions: {}` and add back only what a job needs; and enable secret scanning with push protection so a committed key is rejected at push time.
18. Observing tools: `gh secret list`, `gh api repos/OWNER/REPO/actions/permissions`, `gh api repos/OWNER/REPO/actions/permissions/selected-actions`, and a repository policy allowing only actions from verified creators or a pinned allow list.

■ 41.13.6 WORDS – remember these

1. Secret — a value the pipeline needs and must not reveal — encrypted at rest, injected as an environment variable for one job.
2. Masking — blacking out secret values in logs — exact string replacement by the log processor, defeated by any encoding.
3. `::add-mask::` — register a value for masking at runtime — a workflow command for secrets derived inside a job.
4. OIDC federation — proving identity instead of holding a key — a signed JWT exchanged for short-lived cloud credentials.
5. sub claim — which repository, branch or environment is asking — the field the cloud trust policy must match exactly.
6. `id-token: write` — permission to request an identity token — required before the OIDC endpoint variables are injected.
7. SHA pinning — naming an action by immutable content — `uses: owner/act@<40 hex>`, immune to tag retargeting.
8. Supply chain attack — compromising something you depend on — as in the March 2025 `tj-actions/changed-files` incident, CVE-2025-30066.

41.14 Reading a failed run like an engineer

■ 41.14.1 PLAIN – in simple words

1. A run went red. Most people open it, read the last line, and guess.
2. The last line is almost never the fault. It is usually the summary of the fault, several steps downstream.
3. Do this instead, in order.
4. Find which **step** failed. Not which job, not which line. The step.
5. Read that step from its beginning, not from its end.
6. The real message is usually in the first few lines after the step starts, and everything below it is consequence.
7. Ask one question before anything else: does this fail on my machine too?
8. If it fails locally, this is a normal bug and continuous integration did its job. Fix it and stop reading.
9. If it passes locally and fails in the pipeline, you have a different problem, and guessing will waste an hour.
10. Then the difference between the two environments is the fault, and there is a short list of things that difference can be.
11. Work through that list in order rather than changing things at random.
12. And if you still cannot see it, re-run with debug output switched on, which prints what the machine was actually doing.

■ 41.14.2 PLAIN – a picture in your head

1. A car will not start in your driveway but starts fine at the garage.
2. A bad mechanic replaces parts until it works.
3. A good mechanic writes down every difference between the driveway and the garage: colder, on a slope, different fuel, different battery charge.
4. Then tests the differences one at a time.
5. The car is the same. The environment is not. The fault lives in the gap.

Where this comparison breaks: you cannot drive a build to the garage, but you can bring the garage to the build. A pipeline runs a published machine image, so you can start the identical image locally, which is a luxury no mechanic has.

■ 41.14.3 PLAIN – a worked example

1. Getting the logs without opening a browser:

```
# which runs failed recently
gh run list --status failure --limit 5

# the whole log, all jobs, all steps
gh run view 11947722301 --log

# only the failing steps, which is what you want first
gh run view 11947722301 --log-failed

# one job's log
gh run view --job 33417290011 --log
```

2. A real failure the reader would meet, coming from macOS locally and Ubuntu in the pipeline:

```
Run npm test
> jest
```

```
FAIL src/Cart/index.test.ts
  Cannot find module './cartTotal' from 'src/Cart/index.ts'
```

3. The file on disk is `src/Cart/CartTotal.ts` and the import says `./cartTotal`.
4. On macOS this works, because the default file system is case-insensitive. On the Linux runner it does not, because ext4 is case-sensitive.
5. Nothing is wrong with the test, the runner, or the cache. The two machines disagree about whether two file names are the same name.
6. Confirming it without guessing:

```
git ls-files src/Cart | head
# src/Cart/CartTotal.ts      <- what git actually stores
grep -rn "cartTotal" src/Cart/index.ts
```

7. Git stores the name it was given. Your local file system hid the mismatch. The runner did not.

■ 41.14.4 PLAIN – what is really happening inside

1. Debug output is not on by default because it is enormous and it can leak information.
2. Two switches turn it on, both set as repository or environment variables, or as secrets, with the value `true`.
3. `ACTIONS_STEP_DEBUG` makes each step print its internal decisions.
4. `ACTIONS_RUNNER_DEBUG` makes the runner agent itself print how it set up the job, which is what you need when the failure happens before your code runs.
5. With `gh, gh run rerun 11947722301 --debug` sets these for one re-run, which is safer than leaving them on.
6. Reproducing locally has three levels, in increasing fidelity.
7. Level one: run the same command with the same environment variable, since many tools change behaviour when `CI=true` is set.
8. Level two: run the same command inside the same container image the pipeline uses, so the operating system and installed versions match.
9. Level three: run the whole workflow locally with a tool such as `act`, which interprets the workflow file and runs the jobs in containers. It is an approximation, not the real service, and it will differ on some actions.
10. One more trick for the truly stuck: a step that opens an interactive session on the runner, so you can look around while the job is paused. Use it on private repositories only, and never on a job holding production secrets.

■ 41.14.5 TECHNICAL – the engineer’s version

1. Log structure. A run contains jobs; a job contains steps; each step is a log group. The interface collapses groups, so the failing step may be closed and invisible until you expand it. `--log-failed` filters to failing steps and is the correct first command.
2. Read the step from the top. A stack trace prints the deepest frame first in some languages and last in others, and the actual message is at the boundary between your code and the library.
3. Exit code 1 is a generic failure. Some codes are informative: 127 is command not found, 126 is found but not executable, 137 is SIGKILL which on a runner almost always means the out-of-memory killer, and 143 is SIGTERM which usually means a cancellation or a timeout.
4. Ordered checklist for a job that fails only in CI. Work down it; do not skip.

#	Check	Command or setting
1	Same commit?	gh run view --json headSha
2	Reproduces locally?	run the same command
3	OS differs?	uname -a, runner label
4	Tool versions differ?	node -v, python -V
5	Case sensitivity?	git ls-files vs disk
6	File missing?	check .gitignore
7	Env var missing?	env sort in a step
8	Secret missing?	fork PRs get none
9	Locale or timezone?	CI runs UTC, C locale
10	Network blocked?	egress rules, proxies
11	Test order or parallelism?	run with a fixed seed
12	Clean checkout?	no untracked local files
13	Stale cache?	change the cache key
14	Resource limits?	memory, disk, df -h

5. Rows 5, 6, 9 and 12 are the four that catch most people, and all four have the same root cause: your working copy contains state that the repository does not, or your machine normalizes something the runner does not.
6. Case sensitivity in detail. macOS APFS is case-insensitive but case-preserving by default; Linux ext4 and xfs are case-sensitive; Windows NTFS is case-insensitive. Git stores the exact name. A rename that only changes case may not even be recorded unless you use `git mv` explicitly or set `core.ignorecase false`.
7. Time and locale. Hosted runners run in UTC with a minimal locale. A test that formats a date, sorts strings, or parses a decimal comma will behave differently from a laptop set to Asia/Kolkata. Pin TZ and LC_ALL explicitly in the workflow rather than hoping.
8. Diagnostic step worth adding permanently to a slow-to-debug pipeline:

```
- name: Environment fingerprint
  if: always()
  run: |
    uname -a
    node -v || true
    python3 -V || true
    echo "TZ=$TZ LANG=$LANG"
    df -h /
    free -m || vm_stat || true
    git rev-parse HEAD
```

9. Always upload evidence on failure. A failing run that kept no test report, no screenshot and no server log costs a second run to learn anything:

```
- uses: actions/upload-artifact@v4
  if: failure()
  with:
    name: failure-evidence-${{ github.run_id }}
    path: |
      reports/
      logs/
      screenshots/
```

10. `if: failure()` and `if: always()` are the two conditions that matter here. Without one of them the upload step is skipped, because a failed previous step stops the job by default.

11. Retention and download: artifacts are downloadable with `gh run download 11947722301`, and logs with `gh run view --log > run.txt` for grepping.
12. Debug variables: `ACTIONS_STEP_DEBUG` and `ACTIONS_RUNNER_DEBUG`, both set to `true`, as repository variables or secrets. `gh run rerun ID --debug` enables them for one attempt. Debug logs are larger and are retained the same way as normal logs.
13. Local reproduction with `act` from the `nektos/act` project runs workflows in Docker containers. It approximates hosted runners; differences in preinstalled tooling, services and some actions are expected. Treat a green `act` run as encouraging, not as verification.
14. GitLab’s equivalents: the job log with `CI_DEBUG_TRACE: "true"` for shell tracing, artifacts with `when: always`, and `gitlab-runner exec` for local execution. Jenkins exposes the console output plus the pipeline steps view.
15. One caution on `CI_DEBUG_TRACE` and on `set -x`: shell tracing prints every expanded command, and every expanded command may contain a secret. Never enable shell tracing on a job that holds credentials.

■ 41.14.6 WORDS – remember these

1. Step log — the output of one command in a job — a collapsible log group, filterable with `gh run view --log-failed`.
2. `ACTIONS_STEP_DEBUG` — extra detail about each step — a variable set to `true`, enabling verbose action and expression logging.
3. `ACTIONS_RUNNER_DEBUG` — extra detail about job setup — runner-agent level logging, for failures before your code runs.
4. Exit code 137 — the process was killed — `SIGKILL`, on a runner almost always the out-of-memory killer.
5. Case sensitivity — whether two names are the same name — differs between APFS, NTFS and ext4; Git stores the exact stored name.
6. `if: always()` — run this step even after a failure — the condition that makes failure evidence get collected.
7. `act` — run workflows on your own machine — a local interpreter of workflow files using Docker, approximate rather than exact.

41.15 The wider landscape

■ 41.15.1 PLAIN – in simple words

1. Every idea in this chapter exists in every tool. Only the words change.
2. **GitHub Actions** lives inside GitHub. You write YAML in your repository and the machines are supplied for you.
3. **GitLab CI** lives inside GitLab and works the same way, except GitLab is also the issue tracker, the registry and the deployment tool, all one product.
4. **Jenkins** is a program you install on your own server. It is older than the others, it does anything, and you maintain all of it yourself.
5. **CircleCI** is a service that only does pipelines. It is not your code host, so you connect it to one.
6. **Buildkite** splits the job in an unusual way: they run the web interface and the queue, you run the machines.
7. **Argo CD** does something different from all of the above. It does not build. It watches a repository describing what should be running, and makes the real system match it.
8. That last idea has a name: **GitOps**.

9. In GitOps, the repository is the statement of what should be true, and a program inside your system continuously fixes any difference.
10. Nobody deploys by pushing. Everybody deploys by changing a file and merging it.
11. The difference matters most for keys. If nothing pushes into your system, your pipeline never needs credentials to it.

■ 41.15.2 PLAIN – a picture in your head

1. Two ways to keep a garden the way you want it.
2. Push: you walk in with tools whenever you decide, and change things. You need a key to the gate, and so does anyone helping you.
3. Pull: you pin a drawing of the intended garden on the gate. A gardener who already lives inside reads the drawing every few minutes and fixes anything that differs.
4. Nobody outside needs a key. The drawing is public and versioned. Every change is an edit to the drawing.
5. If a storm knocks a plant over, the gardener notices and rights it, without anyone asking.

Where this comparison breaks: a gardener can only fix what the drawing describes. GitOps only reconciles resources under its control, so anything created by hand outside that scope drifts unnoticed. And some changes, like data migrations, are not describable as a desired end state at all.

■ 41.15.3 PLAIN – a worked example

1. The same idea, “run the tests”, in four configuration languages.

```
# GitHub Actions: .github/workflows/ci.yml
jobs:
  test:
    runs-on: ubuntu-latest
    steps:
      - uses: actions/checkout@v4
      - run: npm ci && npm test
```

```
# GitLab CI: .gitlab-ci.yml
test:
  image: node:22
  script:
    - npm ci
    - npm test
```

```
// Jenkins: Jenkinsfile
pipeline {
  agent { docker { image 'node:22' } }
  stages {
    stage('test') {
      steps { sh 'npm ci && npm test' }
    }
  }
}
```

```
# CircleCI: .circleci/config.yml
version: 2.1
jobs:
  test:
    docker: [{ image: cimg/node:22.0 }]
    steps:
      - checkout
      - run: npm ci && npm test
```

2. Four files, one idea: check out the code, get a Node environment, run two commands.
3. The differences that actually matter are not syntax. They are who owns the machines, who owns the upgrades, and what happens when you need something unusual.

■ 41.15.4 PLAIN – what is really happening inside

1. Push deployment and pull deployment are the real architectural fork, and every tool sits on one side of it.
2. In push deployment, the pipeline holds credentials to production and reaches in to change it.
3. That is simple, immediate, and means a compromised pipeline is a compromised production system.
4. In pull deployment, an agent runs inside production, reads a repository, and applies the difference.
5. Nothing outside holds production credentials. The pipeline’s only job is to update a file in a repository.
6. The agent also loops forever, so it repairs drift: someone changing something by hand is silently undone within minutes.
7. That loop is the part people underestimate. It converts deployment from an event into a continuously enforced statement.
8. The cost is indirection. You merge a change and then wait for a program you are not watching to notice it, which is harder to debug than a command that either worked or did not.

■ 41.15.5 TECHNICAL – the engineer’s version

1. Comparison on the three axes that decide the choice.

Tool	Hosting	Config	Strength
GitHub Actions	hosted or self	YAML	ecosystem, no setup
GitLab CI	hosted or self	YAML	one integrated product
Jenkins	self-hosted	Groovy	plugins, total control
CircleCI	mainly hosted	YAML	caching, orbs, speed
Buildkite	hybrid	YAML	your hardware, their UI
Argo CD	in your cluster	Git manifests	reconciliation, drift

2. Jenkins. Started as Hudson by Kohsuke Kawaguchi at Sun Microsystems in 2004, first released 2005, renamed Jenkins after a community vote concluded on 29 January 2011. Jenkins 2.0, released in April 2016, introduced Pipeline as code with the Jenkinsfile in a Groovy-based domain-specific language.
3. Jenkins’s strength and weakness are the same fact: well over a thousand plugins. Anything is possible, and the plugin set is your responsibility to patch, test and upgrade forever.
4. GitLab CI. Began in 2012 as a separate application and was merged into GitLab in version 8.0 in September 2015. Uses .gitlab-ci.yml with stages, and a separate gitlab-runner binary with pluggable executors.
5. CircleCI. Launched 2011, config in .circleci/config.yml, with reusable packages called orbs introduced in November 2018. CircleCI disclosed a security incident in January 2023 and instructed customers to rotate all secrets stored in the platform, which is a useful reminder that a hosted CI provider is part of your trust boundary.
6. Buildkite. From Melbourne, Australia, starting in 2013. The distinguishing model is hybrid: Buildkite hosts the control plane and interface, and you run the agents on your own machines, so source code and secrets stay on your infrastructure.

7. Argo CD. Created at Applatix, which Intuit acquired in January 2018. Argo became a CNCF project and graduated, together with Flux, in December 2022.
8. GitOps as a term was coined by Alexis Richardson of Weaveworks in 2017. The OpenGitOps project states four principles: the desired state is declarative; it is versioned and immutable; agents pull it automatically; and agents continuously reconcile actual state towards it.
9. Flux is the other main implementation, also CNCF-graduated. Weaveworks, the company that created Flux and coined the term, ceased trading in early 2024, and the project continued under the foundation. That separation of project from vendor is exactly why foundation governance matters.
10. Others worth recognizing by name: Travis CI, which popularized in-repository configuration from 2011; TeamCity from JetBrains, 2006; Bamboo from Atlassian; Azure Pipelines; AWS CodeBuild and CodePipeline; Google Cloud Build; Tekton, a Kubernetes-native pipeline engine under the CD Foundation; and Concourse, which models everything as resources and tasks.
11. The push versus pull distinction, in security terms:

Model	Credentials live	Blast radius
Push from CI	in the CI system	CI owns production
Pull by agent	inside the cluster	CI owns a Git repo

12. Combining them is the common modern arrangement: continuous integration builds and tests and publishes an image, then updates an image tag in a configuration repository; a cluster agent notices and rolls it out. The pipeline never holds a cluster credential.
13. Portability, honestly stated: pipeline configuration is not portable between these tools, and every migration is a rewrite. What is portable is the shell script your steps call. Teams that keep the real work in scripts and use the YAML only as an orchestrator migrate in days rather than months.
14. Where experts disagree: self-hosted Jenkins for control, or a hosted service for speed. Control genuinely matters in regulated environments and on unusual hardware. Against it, maintaining Jenkins is a permanent part-time job nobody plans for. The deciding factor is whether you have staff to own it.
15. Observing tools across all of them: `gh run`, `glab ci`, the Jenkins `api/json` endpoint per build, `circleci config validate`, `buildkite-agent logs`, and `argocd app get` plus `argocd app diff` for reconciliation state.

■ 41.15.6 WORDS – remember these

1. GitOps — the repository states what should be running — declarative desired state, pulled and continuously reconciled by an in-cluster agent.
2. Reconciliation loop — keep fixing the difference forever — the controller pattern comparing desired state to actual state on a timer.
3. Drift — reality quietly diverging from the file — manual changes to a system under declarative control, reverted on the next reconcile.
4. Push deployment — the pipeline reaches into production — outbound deploys requiring production credentials in the CI system.
5. Pull deployment — production reaches out for its own config — an agent inside the boundary, so no inbound credentials exist.
6. Orb — CircleCI’s reusable configuration package — a versioned bundle of jobs, commands and executors, introduced in 2018.

7. `Jenkinsfile` — Jenkins pipeline as code — a Groovy-based declarative or scripted pipeline definition stored in the repository.

41.98 Common wrong ideas

1. Wrong: continuous integration is a tool you install. Right: it is a habit of merging to the mainline at least daily; the tool only enforces the habit, and a team merging quarterly with Jenkins running is not doing it.
2. Wrong: the green tick means this code is good. Right: it means the checks somebody wrote passed on some commit. It says nothing about the tests that were never written, and nothing about the code you are looking at now.
3. Wrong: a passing branch means the head commit passed. Right: a run is bound to one `head_sha`. A branch is a moving label, so a branch-level tick may belong to a commit that is no longer the head.
4. Wrong: CD means continuous deployment. Right: it usually means continuous delivery, which is “always releasable, released by a human decision”. Continuous deployment removes the human. The two are different practices with the same initials.
5. Wrong: `pull_request_target` is just `pull_request` with more permissions. Right: it runs your trusted workflow file with your secrets, so checking out the pull request head and executing anything from it hands a stranger your credentials.
6. Wrong: `mergeStateStatus: BLOCKED` means there is a merge conflict. Right: it means the branches merge cleanly and a protection rule is unmet. The conflict value is `DIRTY`.
7. Wrong: `UNKNOWN` means something is wrong. Right: it means GitHub has not finished computing mergeability. Re-query after a short delay and conclude nothing from the first answer.
8. Wrong: a skipped check is the same as a passed check. Right: a job skipped by an `if: condition` reports success, while a workflow skipped by a path filter never reports at all and blocks the merge indefinitely.
9. Wrong: pinning an action to `@v4` is safe because it is a version. Right: a tag is a movable pointer in someone else’s repository. Only a full commit SHA is immutable, as the March 2025 `tj-actions/changed-files` compromise showed.
10. Wrong: re-running until it goes green is a fix. Right: it converts a flaky test into a permanent lie, and once people stop believing red, the entire pipeline stops carrying information.

41.99 Chapter summary in 20 lines

1. Continuous integration is a practice, not a product: merge to the mainline at least daily, verify every merge automatically, and fix a broken mainline before starting new work.
2. The term came from Grady Booch in 1991, became an Extreme Programming practice in 1999, and got its working definition from Fowler and Foemmel in 2000.
3. Continuous delivery means every change is always releasable; continuous deployment means every change that passes goes live without a human. Same initials, different practices.
4. A runner is a machine that claims a job, checks out one exact commit, runs your steps, and reports an exit code. Hosted runners are destroyed after each job, which is why “it works on my laptop” fails there.
5. The workflow file lives in the repository, so the pipeline is versioned, reviewable and bisectable like any other code, and a token needs the `workflow` scope to change it.

6. Triggers decide what starts a run: `push`, `pull_request`, `schedule`, `workflow_dispatch`, `repository_dispatch`, tags and releases, narrowed by branch and path filters.
7. `pull_request` runs a fork's code with no secrets and a read-only token. `pull_request_target` runs your file with full secrets, so executing the pull request's code under it is the pwn request vulnerability.
8. The central idea of the chapter: a run is bound to one commit SHA, never to a branch. A branch is a moving pointer, so “CI passed on main” is a statement about whichever commit main pointed at then.
9. The correct verification is four steps: resolve the head SHA from the server, list runs filtered by that SHA, read the specific run by ID, and confirm the run's `head_sha` matches.
10. A branch-level tick can lie in at least six ways: older commit, merge result rather than head, skipped rather than passed, posted by another app, overwritten by a re-run, or attached to a merge commit that no longer exists.
11. Two APIs report results on a commit: the older commit status API with four states, and the newer checks API with check suites, check runs, timings and line annotations.
12. Conclusions are success, failure, neutral, cancelled, skipped, timed_out, action_required, stale and startup_failure, and a required check that never arrives stays Expected and blocks forever.
13. Merge queues solve the semantic conflict: two changes that each pass alone and break together. The queue builds the prospective merged state, tests it, and only then merges, serializing the landing order.
14. Speculative execution tests several queued entries at once assuming those ahead succeed, which is fast when all pass and wasteful when one fails. GitHub's merge queue became generally available on 12 July 2023.
15. `mergeStateStatus` has eight values. CLEAN and HAS_HOOKS mean go, BEHIND means update, DIRTY means real conflict, DRAFT means you marked it, UNSTABLE means a non-required check failed.
16. BLOCKED means a protection rule is unmet, not a conflict; UNKNOWN means GitHub is still computing mergeability, so re-query and conclude nothing.
17. A good pipeline runs cheapest first: lint, build, unit tests, integration tests, security scanning, artifact build, staging deploy, smoke tests, production, with the artifact built once and reused.
18. Deployment strategies trade downtime against cost: recreate, rolling, blue-green, canary, and feature flags, which separate deploying code from releasing it. Database migrations make rollback hard, so expand and contract.
19. Secrets are injected per job and masked by string matching only; forks get none; OIDC federation replaces long-lived cloud keys with one-hour credentials; and third-party actions must be pinned to a full commit SHA.
20. Read a failure by finding the failing step, reading it from the top, reproducing locally, and working an ordered checklist of environment differences before changing anything at random.

SSH, HTTPS, Keys, Tokens and Scopes

42.0 What this chapter gives you

1. You will be able to explain the two ways git talks to a server, SSH and HTTPS, and say exactly what is different and what is identical.
2. You will be able to say what SSH is, who wrote it, in what year, and what dangerous older tools it was built to replace.
3. You will be able to explain a key pair in plain words and then precisely, including what the private key can do that the public key cannot.
4. You will be able to read a real `ssh-keygen` run, decode the public key file field by field, and choose between RSA, ECDSA and Ed25519 with reasons.
5. You will be able to explain `authorized_keys` and `known_hosts`, including why wrong file permissions break logins silently.
6. You will be able to explain why the reader's SSH on port 22 hung while HTTPS on port 443 worked, and apply both fixes.
7. You will be able to explain personal access tokens, their expiry, their prefixes, and why a leaked token is an emergency rather than an annoyance.
8. You will be able to explain a scope precisely, and explain the exact reason a push touching a file under `.github/workflows/` was refused.
9. You will be able to tell a permission failure from a network failure from a rejected push, even though all three print "push failed".
10. You will be able to diagnose at least eight real git authentication error strings from the text alone, and act on each one correctly.

42.1 The two transports git uses, and why there are two

■ 42.1.1 PLAIN – in simple words

1. Git keeps your project history on your own machine. All of it.
2. Sometimes you want to send that history to a server, or fetch new history from one. That is what `push` and `fetch` do.
3. To send anything over a network, two programs need a pipe between them.
4. Git does not build its own pipe. It borrows one that already exists.
5. There are two pipes it commonly borrows, and you choose which one by the shape of the address you type.
6. An address like `git@github.com:owner/repo.git` uses the **SSH** pipe.
7. An address like `https://github.com/owner/repo.git` uses the **HTTPS** pipe, the same kind of pipe your web browser uses.

8. Here is the part people get wrong. The repository on the server is the same repository in both cases. One box, one set of files.
9. Only the road to it changes. It is like posting a letter versus handing it over in person. Same letter, same house, different delivery.
10. So switching from one to the other never loses a commit, never rewrites history, and never needs a re-clone. It is a one-line change.
11. What does change is how the server works out who you are.
12. Over SSH you prove yourself with a key file on your laptop.
13. Over HTTPS you prove yourself with a token, which is a long secret string that behaves like a password with rules attached.

■ 42.1.2 PLAIN – a picture in your head

1. Imagine one library building with one collection of books.
2. There are two doors. The staff door at the back and the public door at the front. Both lead to exactly the same shelves.
3. The staff door has a lock. You carry a physical key that fits it. If your key fits, you walk in. Nobody asks your name.
4. The public door has a desk. You show a card with your name on it and a list of what you are allowed to do. The clerk reads the card and decides.
5. The books do not care which door you used. A book you borrow through the back door is the same book you would have borrowed through the front.
6. Now suppose the alley behind the building is closed for roadworks. The staff door is fine. You simply cannot reach it.
7. You walk round to the front and use the public door. Nothing about the library changed. Your route changed.
8. That is exactly the reader's situation in this chapter, and exactly the fix.

Where this comparison breaks:

9. A real key and a real card are both things you hand over. A private SSH key is never handed over. It stays in your pocket and answers a question.
10. And a library clerk can see your whole card. A well-built server only sees that your token is valid and what it is allowed to do, not your password.

■ 42.1.3 PLAIN – a worked example

1. Here is the same repository addressed both ways, on a real machine.

```
$ git remote add t git@github.com:octocat/Hello-World.git
$ git remote add t https://github.com/octocat/Hello-World.git
$ git remote add t \
    ssh://git@ssh.github.com:443/octocat/Hello-World.git
```

2. All three name one repository: the account octocat, the repository Hello-World.
3. The first is the short SSH form. The colon after the host name is not a port. It separates the host from the path.
4. The second is HTTPS, and it is an ordinary web address with a .git suffix.
5. The third is the long SSH form, written as a proper address with a scheme, which is the only form where you can write a port number.
6. Changing transport on an existing clone is one command:

```
$ git remote set-url origin https://github.com/owner/repo.git
$ git remote -v
origin https://github.com/owner/repo.git (fetch)
origin https://github.com/owner/repo.git (push)
```

7. Nothing else changes. Your branches, your commits and your stash are all still local files under `.git`, untouched.
8. Here is a real clone of a real public repository over HTTPS, from the machine used to write this chapter:

```
$ git clone https://github.com/octocat/Hello-World.git
Cloning into 'Hello-World'...
$ git log --oneline -1
7fd1a60 Merge pull request #6 from Spaceghost/patch-1
```

9. Over SSH the commit `7fd1a60` would be byte-identical, because a commit identity is a hash of its content, not of how it travelled.

■ 42.1.4 PLAIN – what is really happening inside

1. Git itself does not know how to speak to a network. It shells out.
2. When you give it an HTTPS address it runs a small helper program called `git-remote-https`. When you give it an SSH address it runs `ssh`.
3. You can watch it choose. Here is a real trace on the machine used for this chapter, with the timestamps trimmed for width:

```
$ GIT_TRACE=1 git ls-remote \
    https://github.com/octocat/Hello-World.git
trace: built-in: git ls-remote https://github.com/...
trace: run_command: git remote-https https://github.com/...
trace: exec: git-remote-https https://github.com/...
```

4. And here is what git runs for an SSH address. This is the real command line git built, wrapped for width:

```
$ GIT_TRACE=1 git ls-remote \
    ssh://git@ssh.github.com:443/octocat/Hello-World.git
trace: run_command: GIT_PROTOCOL=version=2 ssh
-o SendEnv=GIT_PROTOCOL -p 443 git@ssh.github.com
'git-upload-pack '\'/octocat/Hello-World.git'\''
```

5. Read that last line carefully, because it explains everything about SSH and git in one go.
6. Git asked SSH to log in as the user `git` on the host `ssh.github.com`, and then to run one command there: `git-upload-pack`.
7. SSH is not doing anything git-specific. It is doing what it always does: logging in and running a command on a remote machine.
8. The remote command's input and output are piped straight back down the encrypted connection to your local git.
9. Over HTTPS there is no login shell and no remote command. Instead git makes ordinary web requests. Here are the real ones, captured live:

```
GET /octocat/Hello-World.git/info/refs?service=git-upload-pack
Git-Protocol: version=2
<= HTTP/1.1 200 OK
<= Content-Type: application/x-git-upload-pack-advertisement
```

```
POST /octocat/Hello-World.git/git-upload-pack
Content-Type: application/x-git-upload-pack-request
<= HTTP/1.1 200 OK
<= Content-Type: application/x-git-upload-pack-result
```

10. One GET to ask what branches exist, then one POST carrying the real conversation. That is the whole thing.
11. Underneath both, the same objects flow: the same commits, trees, blobs and the same packfile format. The payload is identical.

■ 42.1.5 TECHNICAL – the engineer’s version

1. Git supports four transports. Two matter today.

Transport	Port	Authentication
SSH	TCP 22	public key, user git
HTTPS smart	TCP 443	token in Basic auth
git:// (dumb)	TCP 9418	none, removed by GitHub
local file path	none	filesystem permissions

2. GitHub removed support for the unencrypted git:// protocol as part of a protocol hardening programme that became permanent on 15 March 2022.
3. Over SSH, git uses the SSH connection protocol to request a single command execution, not an interactive shell. The remote side runs git-upload-pack for fetches and git-receive-pack for pushes.
4. The environment variable GIT_PROTOCOL=version=2 is passed with -o SendEnv=GIT_PROTOCOL. Protocol v2 was introduced in Git 2.18 in June 2018 and made the default for fetches in Git 2.26 in March 2020.
5. Protocol v2 matters on large repositories because it lets the client ask for a filtered reference advertisement instead of receiving every ref.
6. Over HTTPS, git speaks the **smart HTTP** protocol, defined in the Git documentation file http-protocol.txt. Two endpoints per operation: GET \$URL/info/refs?service=git-upload-pack then POST \$URL/git-upload-pack.
7. The media types are application/x-git-upload-pack-request and application/x-git-upload-pack-result, and the push equivalents replace upload with receive.
8. Rewriting one transport into the other is a supported config feature, and it is the cleanest fix for a blocked port:

```
$ git config --global \
  url."https://github.com/".insteadOf "git@github.com:"
$ git config --global \
  url."https://github.com/".insteadOf "ssh://git@github.com/"
```

9. On the machine used for this chapter that rewrite is active, and it is visible in a real check:

```
$ git remote add t git@github.com:octocat/Hello-World.git
$ git remote get-url t
https://github.com/octocat/Hello-World.git
```

10. That is worth knowing as a trap. If a colleague swears their SSH URL works on a machine where port 22 is blocked, check insteadOf before believing that port 22 is open.

11. `pushInsteadOf` is the write-only variant, letting you fetch anonymously over HTTPS while pushing over SSH.

■ 42.1.6 WORDS – remember these

Transport — the road the data takes — the protocol carrying the Git wire protocol, SSH or HTTPS.

Remote — a nickname for a server copy — a named URL plus fetch and push refsspecs stored in `.git/config`.

`git-upload-pack` — the program that sends you history — the server-side process serving fetch and clone.

`git-receive-pack` — the program that accepts your history — the server-side process serving push, and the one that runs the hooks that can refuse you.

Smart HTTP — git talking over web requests — the `info/refs` plus `git-upload-pack` request pair using `x-git-*` media types.

`insteadOf` — a rule that rewrites addresses — a `url.<base>.insteadOf` config key that substitutes URL prefixes before the transport is chosen.

42.2 What SSH actually is

■ 42.2.1 PLAIN – in simple words

1. SSH stands for Secure Shell. A shell is the text prompt where you type commands.
2. SSH lets you get a shell on a computer that is somewhere else, over a network, safely.
3. “Safely” means two separate promises, and both matter.
4. First, nobody in the middle can read what you type or what comes back. It is scrambled on the wire.
5. Second, you can be sure the machine you reached is the machine you meant. Not an impostor sitting in the middle.
6. Before SSH, people used tools called `telnet`, `rlogin` and `rsh` to do the same job. Those tools sent your password as plain readable text.
7. Anyone able to watch the network could simply read it. Not crack it. Read it, like reading a postcard.
8. In 1995 a researcher at a Finnish university discovered exactly that happening on his own network and wrote SSH in response.
9. Today SSH does far more than shells. It carries file copies, tunnels, and the git pushes in this chapter.
10. But underneath it is still the same thing: a safe way to run one command on another machine.

■ 42.2.2 PLAIN – a picture in your head

1. Think of the old way as shouting your order across a crowded market square.
2. The stallholder hears you. So does everyone else, including the person who writes down what people order and comes back later pretending to be you.
3. Now think of SSH as a sealed pneumatic tube running from your desk to the stall.
4. You put a written note in a capsule, it travels inside the tube, and only the stall can open it. Nobody in the square sees anything.
5. But a tube alone is not enough. What if somebody quietly re-routed your tube to a different stall last night?

6. So SSH adds a second step. Before you send anything, the stall shows you a seal that only that stall could have made.
7. You compare it against the seal you wrote down the first time you visited. If it matches, it is really them.
8. If it does not match, everything stops with a very loud warning.

Where this comparison breaks:

9. A pneumatic tube is a physical private path. SSH runs over the same shared public cables as everything else. The privacy is mathematical, not physical.
10. And the “seal you wrote down the first time” is a real weakness. On that first visit you had no way to check. You simply trusted. We will look straight at that in section 42.5.

■ 42.2.3 PLAIN - a worked example

1. A connection has three visible stages. Here is a real one against a small server, with the client asked to explain itself.

```
$ ssh -v -p 2222 root@127.0.0.1 'echo OK'
debug1: Authenticating to 127.0.0.1:2222 as 'root'
debug1: kex: algorithm: sntrup761x25519-sha512@openssh.com
debug1: kex: host key algorithm: ssh-ed25519
debug1: kex: server->client cipher:
      chacha20-poly1305@openssh.com MAC: <implicit>
debug1: Server host key: ssh-ed25519
      SHA256:fwKYxD4JEmBcHPHj3WkgxSLrRh6tXIzpi/K0xz2yNrA
debug1: Host '[127.0.0.1]:2222' is known and matches the
      ED25519 host key.
debug1: Authentications that can continue: publickey
debug1: Offering public key: id_ed25519 ED25519
      SHA256:WH1E2gSLhG6FgMsha//GINoquuvX3fLxFRdMA3KMrSU
debug1: Server accepts key: id_ed25519 ED25519
Authenticated to 127.0.0.1 using "publickey".
OK
```

2. Line by line, in order of what happened.
3. kex is short for key exchange. Both sides agreed on the maths they would use to create a shared secret. That is stage one.
4. Server host key is the server proving who it is. Host is known and matches means the client checked its own notes and was satisfied.
5. Authentications that can continue: publickey is the server saying which ways of proving yourself it will accept. Here, only keys.
6. Offering public key then Server accepts key is stage two, you proving who you are.
7. OK at the end is stage three, the actual work happening inside the now trusted, now encrypted connection.
8. Notice the order. Encryption is set up first, then the server proves itself, then you prove yourself. Your credentials never travel in the open.

■ 42.2.4 PLAIN - what is really happening inside

1. SSH version 2 is built as three stacked layers. Each has one job.
2. **Layer one, transport.** It runs immediately after the TCP connection opens. It has three tasks.
3. It agrees the algorithms both sides will use, it performs a key exchange to create a shared secret, and it verifies the server's host key.

4. From that point on, everything is encrypted and every message carries an integrity check so tampering is detected.
5. Importantly, the shared secret is created fresh for this connection. It is never sent over the wire, by either side. Both sides compute it.
6. **Layer two, user authentication.** Now that the pipe is safe, you prove who you are. Public key, password, keyboard-interactive, or host-based.
7. This layer runs inside the encrypted tunnel, which is why a password sent over SSH is not exposed the way a telnet password was.
8. **Layer three, connection.** One SSH connection can carry many independent streams, called channels, at once.
9. A shell is a channel. A file copy is a channel. A forwarded port is a channel. They share the one encrypted pipe.
10. That is how you can be editing a file over SSH while a port forward runs in the background, on one connection and one login.
11. For git, exactly one channel is opened, of type “exec”, carrying one command: `git-upload-pack` or `git-receive-pack`.

■ 42.2.5 TECHNICAL - the engineer's version

1. SSH was written by Tatu Ylonen at Helsinki University of Technology in 1995, after a password-sniffing attack on the university network.
2. He released the first version in July 1995, and founded SSH Communications Security in December 1995 to commercialize it.
3. The protocol it replaced was the Berkeley r-commands: `rlogin` (TCP 513), `rsh` (TCP 514) and also `telnet` (TCP 23), all of which sent credentials in clear text.
4. Those tools also trusted a file called `.rhosts`, which authenticated by source IP address alone. Address spoofing therefore meant login.
5. **SSH-1** and **SSH-2** are different protocols, not versions of one protocol. SSH-1 has a structural integrity flaw.
6. SSH-1 used CRC-32 for integrity, which is a checksum, not a cryptographic authentication code. In 1998 this was shown to allow an insertion attack, and in 2001 the widely reported “SSH CRC-32 compensation attack detector” vulnerability made it worse. SSH-1 is dead and should never be enabled.
7. SSH-2 is specified in a set of IETF documents published in January 2006: RFC 4250 assigned numbers, RFC 4251 architecture, RFC 4252 authentication, RFC 4253 transport, RFC 4254 connection.
8. **OpenSSH** is a separate implementation, from the OpenBSD project. The history is precise and worth knowing.

Date	Event
July 1995	Ylonen releases ssh 1.x
early 1999	Gronvall's OSSH from 1.2.12
26 Sep 1999	OpenBSD forks OSSH
1 Dec 1999	OpenSSH 1.2.2 in OpenBSD 2.6
15 Jun 2000	SSH-2 support, OpenSSH 2.0

9. The fork happened because releases after ssh 1.2.12 carried increasingly restrictive licence terms. Bjorn Gronvall's OSSH revived the last freely licensed release, and the OpenBSD team took it from there.
10. SSH-2 support was written by Markus Friedl and shipped in OpenSSH 2.0 with OpenBSD 2.7 on 15 June 2000.
11. Port 22 is the IANA-assigned port for SSH. Ylonen requested it because it sat unused between ftp on 21 and telnet on 23.
12. Modern algorithm defaults on the OpenSSH 9.6 used for this chapter: key exchange `sntrup761x25519-sha512@openssh.com`, which combines the post-quantum lattice scheme NTRU Prime with X25519, and cipher `chacha20-poly1305@openssh.com`.
13. That hybrid key exchange became the OpenSSH default in version 9.0, in April 2022. The reason given was harvest-now-decrypt-later: an attacker recording traffic today and decrypting it after quantum computers arrive.

■ 42.2.6 WORDS – remember these

SSH — a safe way to use a distant computer — the Secure Shell protocol suite specified in RFC 4251 through RFC 4254.

Key exchange (kex) — the step where both sides build a shared secret — a Diffie-Hellman style agreement producing session keys without transmitting them.

Host key — the server's own identity key — the long-term key pair a server uses to sign the key exchange and prove it is itself.

Channel — one stream inside the connection — a multiplexed logical stream in the SSH connection protocol, with independent flow control.

telnet — an old unsafe remote login tool — a clear-text remote terminal protocol on TCP 23, RFC 854, with no encryption or integrity.

OpenSSH — the SSH program almost everyone runs — the OpenBSD implementation, first released 1 December 1999 with OpenBSD 2.6.

42.3 Public key cryptography for SSH

■ 42.3.1 PLAIN – in simple words

1. A key pair is two files made at the same time, mathematically joined.
2. One is called the **private key**. It stays on your machine and you never send it anywhere, ever.
3. The other is called the **public key**. It is meant to be handed out. You paste it into web forms and email it to people.
4. The private key can do one special thing: it can make a **signature** on a piece of data.
5. The public key cannot make a signature. It can only check one, and answer yes or no.

6. That asymmetry is the whole trick. Publishing the public key gives an attacker nothing, because checking signatures is not making them.
7. So when GitHub wants to know you are you, it does not ask for a password.
8. It sends your computer a piece of data and says: sign this.
9. Your computer signs it with the private key. GitHub checks the signature with the public key it already stored under your account.
10. If the check passes, only the holder of that private key could have produced it. You are in.
11. Nothing secret ever crossed the network. The private key stayed in a file on your laptop the entire time.
12. That is why a public key on a public web page is not a leak, and why a private key in a chat message is a catastrophe.

■ 42.3.2 PLAIN – a picture in your head

1. Imagine a very unusual rubber stamp.
2. Only you own the stamp. It presses a pattern so intricate that nobody can carve a copy from looking at an impression.
3. You give everyone a printed picture of the pattern. That is the public key.
4. Now anyone can send you a fresh sheet of paper with today's date and a random number on it and ask you to stamp it.
5. You stamp it and hand it back. They compare the impression with the printed picture. It matches, so it was you.
6. The random number matters more than it looks. If the paper always said the same thing, someone could keep an old stamped sheet and reuse it.
7. Because the paper is fresh every time, an old stamped sheet proves nothing about today.

Where this comparison breaks:

8. A rubber stamp makes the same mark every time. A real signature depends on both the key and the exact data, so it is different for every message.
9. And a rubber stamp can be physically stolen and used. A private key can be locked with a passphrase, so stealing the file is not always enough.
10. The honest version: some key types, RSA in particular, can also be used the other way round, to encrypt something that only the private key can open. In SSH user authentication, modern practice is signing, not encrypting.

■ 42.3.3 PLAIN – a worked example

1. Here is a real key being made on the machine used for this chapter. Nothing is edited except line width.

```
$ ssh-keygen -t ed25519 -C "kedbyte@laptop"
Generating public/private ed25519 key pair.
Enter file in which to save the key (~/ssh/id_ed25519):
Enter passphrase (empty for no passphrase):
Enter same passphrase again:
Your identification has been saved in ~/ssh/id_ed25519
Your public key has been saved in ~/ssh/id_ed25519.pub
The key fingerprint is:
SHA256:WH1E2gSLhG6FgMsha//GINoquvX3fLxFRdMA3KMrSU
kedbyte@laptop
The key's randomart image is:
+--[ED25519 256]--+
```

```
| ... 0. .+B0.0 |
|. 0 0..0 E0+0 .|
| + 0 . .0 + * 0 |
|..0 00 0 .|
|. . . S . .|
|. 0 0 |
|... = . . .|
|+ .. = 0 .0 .|
|0+. . 0. .|
+----[SHA256]-----+
```

- Two files came out. `id_ed25519` is private, 411 bytes. `id_ed25519.pub` is public, 96 bytes.
- The fingerprint is a short hash of the public key, for humans to compare by eye. It is not a key and it is not secret.
- The randomart is the same fingerprint drawn as a picture, because humans spot a changed picture faster than a changed string of letters.
- Now let us prove what a private key can actually do. Sign a file:

```
$ echo "hello kedbyte" > msg.txt
$ ssh-keygen -Y sign -f ~/.ssh/id_ed25519 -n file msg.txt
Signing file msg.txt
Write signature to msg.txt.sig
```

- Check it with only the public key:

```
$ ssh-keygen -Y verify -f allowed_signers -I kedbyte@laptop \
-n file -s msg.txt.sig < msg.txt
Good "file" signature for kedbyte@laptop with ED25519 key
SHA256:WH1E2gSLhG6FgMsha//GINoquvX3fLxFRdMA3KMrSU
```

- Now change one word of the message and check the same signature again:

```
$ ssh-keygen -Y verify -f allowed_signers -I kedbyte@laptop \
-n file -s msg.txt.sig < msg2.txt
Signature verification failed: incorrect signature
Could not verify signature.
```

- That is the entire idea, demonstrated. The signature is bound to the exact bytes. Change one character and it stops matching.

■ 42.3.4 PLAIN – what is really happening inside

- Look at the public key file. It is one line with three fields separated by spaces. Here it is, wrapped for the page:

```
ssh-ed25519 AAAAC3NzaC1lZDI1NTE5AAAAIIpK1C+6wSQAKCH1
gza1Sb50MnBwsPXPd6FAeelzkUGS kedbyte@laptop
```

- Field one, `ssh-ed25519`, is the key type. Field three, `kedbyte@laptop`, is a comment. It is a label for humans and has no effect on anything.
- Field two is the key itself, encoded in base64 so it can be pasted into a text box. Decoded, it is 51 bytes with a strict internal structure.
- That structure is a repeating pattern: a four-byte length, then that many bytes of data. Here is the real decode of the key above:

```
total bytes: 51
field 1: length 11 -> 'ssh-ed25519'
```

```
field 2: length 32 -> 8a4a942fbac124009021e58336b549be
                        74327070b0f5cf0fa14079e973914192
```

5. So the type name appears twice: once in plain text outside the base64, and once inside it. The inside copy is the one that counts.
6. The 32 bytes are the actual Ed25519 public key. That is the whole secret-free half of the pair, and it really is only 32 bytes.
7. Now the login exchange, in order.
8. Your client tells the server: I would like to authenticate as this user with this public key. Would you accept it at all?
9. The server looks the key up in that user's `authorized_keys` file. If it is not there, the server says no and your client tries the next key.
10. If it is there, the server says yes, that key is acceptable. Note that nothing has been proven yet.
11. Your client now builds a block of data to sign. It contains the session identifier from the key exchange, the user name, the service name, and the public key.
12. The session identifier is the crucial part. It is unique to this one connection and could not have been known in advance.
13. Your client signs that block with the private key and sends the signature.
14. The server verifies the signature against the stored public key. If it verifies, you are authenticated.
15. Because the signed block includes the session identifier, a signature captured from an old session cannot be replayed into a new one.
16. And because the server also binds its own host key into the session identifier, a man-in-the-middle cannot forward your signature to the real server. That property is why host key checking is not optional.

■ 42.3.5 TECHNICAL - the engineer's version

1. Three key types are in real use, plus a dead one. Real measurements from the OpenSSH 9.6 machine used for this chapter.

Type	Bits	Public file size
Ed25519	256	96 bytes
ECDSA nistp256	256	182 bytes
RSA 4096	4096	744 bytes
DSA	1024	removed everywhere

2. Generation cost, averaged over five runs on the same machine:

Type	Average generation time
Ed25519	0.010 s
ECDSA nistp256	0.008 s
RSA 2048	0.229 s
RSA 4096	2.160 s

3. **RSA.** Published by Rivest, Shamir and Adleman in 1978. Security rests on the difficulty of factoring a large number into two primes.
4. 1024-bit RSA is broken in practice for well-funded attackers and is refused by modern software. 2048 bits is the floor, and is what NIST Special Publication 800-57 treats as acceptable to roughly 2030.

5. 4096 bits is common because it costs almost nothing for a key you generate once, and pushes the estimated strength well past the 2030 line.
6. Beyond 4096 the returns collapse. RSA key strength grows very slowly with size while signing cost grows fast, which is why 8192 is rare.
7. The critical modern detail is the signature algorithm, not the key size. The old `ssh-rsa` algorithm uses SHA-1, which has been considered unsafe since the 2017 SHAttered collision by CWI Amsterdam and Google.
8. RFC 8332, published in March 2018, defines `rsa-sha2-256` and `rsa-sha2-512` for the same RSA keys. OpenSSH disabled `ssh-rsa` by default in version 8.8 in September 2021.
9. **ECDSA**. The elliptic curve digital signature algorithm, standardized in FIPS 186. In SSH it is used with the NIST curves P-256, P-384 and P-521.
10. ECDSA works and is widely supported, but it has two known unhappy properties. It needs a fresh random value for every signature, and a repeated or biased value leaks the private key outright.
11. That is not theoretical. The 2010 Sony PlayStation 3 signing key recovery was exactly this bug, a fixed nonce.
12. Also, some cryptographers distrust the provenance of the NIST curve constants. This is a genuine expert disagreement. One side says the constants are unexplained and should be avoided, the other says no attack has ever followed from them and the curves are fine.
13. **Ed25519**. EdDSA over the twisted Edwards curve Curve25519, from the 2011 paper “High-speed high-security signatures” by Bernstein, Duif, Lange, Schwabe and Yang. Curve25519 itself is Bernstein’s, from 2006.
14. It is the current recommendation for SSH, for four reasons that are concrete rather than fashionable.
15. It is deterministic: the per-signature value is derived from the key and the message, so the ECDSA nonce failure mode cannot happen.
16. It is small and fast: 32-byte public keys, 64-byte signatures, and verification that is quick on tiny hardware.
17. Its parameters were chosen by a published rule with stated rationale, so there are no unexplained constants.
18. Its implementations are naturally constant-time, which resists timing side-channel attacks without special care.
19. Ed25519 in SSH is standardized in RFC 8709, February 2020, though OpenSSH shipped it in version 6.5 in January 2014, six years earlier.
20. **DSA**. `ssh-dss`, 1024 bits, roughly 80-bit security. GitHub removed support for DSA keys entirely, permanently enforced on 15 March 2022.
21. The complete list your OpenSSH understands is one command:

```
$ ssh -Q key
ssh-ed25519
sk-ssh-ed25519@openssh.com
ecdsa-sha2-nistp256
ecdsa-sha2-nistp384
ecdsa-sha2-nistp521
sk-ecdsa-sha2-nistp256@openssh.com
ssh-dss
ssh-rsa
```

22. The `sk-` prefixed types are hardware security key types, added in OpenSSH 8.2 in February 2020. The private key half lives on a physical device such as a YubiKey and cannot be copied off it.
23. Fingerprints default to SHA-256 in base64 since OpenSSH 6.8, March 2015. The older MD5 hex

form is still available and still seen in old documentation:

```
$ ssh-keygen -lf id_ed25519.pub
256 SHA256:WH1E2gSLhG6FgMsha//GINoquuvX3fLxFRdMA3KMrSU
kedbyte@laptop (ED25519)

$ ssh-keygen -lf id_ed25519.pub -E md5
256 MD5:74:36:b8:87:74:1d:49:9c:09:81:62:6b:89:eb:26:ad
kedbyte@laptop (ED25519)
```

24. Practical recommendation, and it is not controversial: `ssh-keygen -t ed25519 -C "you@machine"`. Use RSA 4096 only when you must talk to something old that cannot do Ed25519.

■ 42.3.6 WORDS – remember these

Key pair — two matched files, one secret one public — an asymmetric keypair where the public half is derivable from the private half but not the reverse.

Private key — the file you never share — the secret scalar or exponent, stored under `~/.ssh/`, optionally encrypted with a passphrase.

Public key — the file you paste everywhere — the shareable half, safe to publish, stored on the server in `authorized_keys`.

Fingerprint — a short code for comparing keys by eye — the base64 SHA-256 hash of the public key blob, printed by `ssh-keygen -l`.

Signature — proof that the holder of the key saw this data — the output of a signing algorithm over specified bytes, verifiable with the public key alone.

Ed25519 — the recommended modern key type — EdDSA over Curve25519, RFC 8709, 32-byte public keys, deterministic signatures.

Nonce — a number used once — a per-signature random or derived value whose reuse in ECDSA leaks the private key.

42.4 `authorized_keys` and how it works

■ 42.4.1 PLAIN – in simple words

1. On the server there is one plain text file that decides who may log in as a given user with a key.
2. It is called `authorized_keys` and it lives in that user's home directory, inside a folder called `.ssh`.
3. Each line of the file is one public key. If your public key is on a line, you may log in as that user.
4. That really is the entire mechanism. There is no database and no clever service. It is a text file that gets read.
5. To give someone access, you append their public key as a new line. To remove access, you delete that line.
6. There is one rule that catches everybody. The file and its folder must not be writable by anyone other than the owner.
7. If they are, the server refuses to use the file at all, and says nothing useful about why.
8. The reason is sound. If any other user could edit that file, they could add their own key and become you. So SSH refuses to trust it.
9. The failure is silent from the client's side. You get "permission denied" and no explanation.
10. GitHub has a variant of this idea for a single repository, called a **deploy key**. Same file format, narrower reach.

■ 42.4.2 PLAIN – a picture in your head

1. Think of a guest list on a clipboard at the door of a private room.
2. The doorman does not know anyone's face. He only checks the list.
3. To let someone in, you write their name on the list. To stop them, you cross it off. There is no other step.
4. Now add the rule that catches people out. The clipboard hangs on a hook in the public corridor.
5. If anyone walking past can write on it, the list is worthless. Anyone could add themselves.
6. So the doorman has a standing instruction: if the clipboard is not locked in its case, ignore the list entirely and let nobody in.
7. And he does not explain. He just says "not on the list", because telling you about the broken case would help an attacker more than it helps you.

Where this comparison breaks:

8. A name on a list can be claimed by anyone who knows the name. A public key on a line can only be used by whoever holds the matching private key.
9. So the list being publicly readable is fine. Only the list being publicly writable is fatal.

■ 42.4.3 PLAIN – a worked example

1. This is a real server, a real key, and a real failure, produced on the machine used for this chapter.
2. First, correct permissions. The connection works.

```
$ ls -l ~/.ssh/authorized_keys
-rw----- 1 root root 96 Aug 13 08:22 authorized_keys
$ ssh -i ~/.ssh/id_ed25519 -p 2222 root@127.0.0.1 'echo OK'
OK
```

3. Now make the file writable by everyone, which is exactly the mistake people make when they get frustrated and run `chmod 666`.

```
$ chmod 666 ~/.ssh/authorized_keys
$ ls -l ~/.ssh/authorized_keys
-rw-rw-rw- 1 root root 96 Aug 13 08:22 authorized_keys
$ ssh -i ~/.ssh/id_ed25519 -p 2222 root@127.0.0.1 'echo OK'
root@127.0.0.1: Permission denied (publickey).
```

4. The key did not change. The user did not change. Only the permission bits changed, and the login broke.
5. Nothing in the client message says so. It says `Permission denied (publickey)`, which is the same message you get for a completely wrong key.
6. Now the server's own log, from the same moment:

```
Connection from 127.0.0.1 port 48576 on 127.0.0.1 port 2222
Authentication refused: bad ownership or modes for file
/root/.ssh/authorized_keys
Failed publickey for root from 127.0.0.1 port 48576 ssh2:
ED25519 SHA256:WH1E2gSLhG6FgMsha//GINoquovX3fLxFRdMA3KMrSU
Connection closed by authenticating user root [preauth]
```

7. There it is: `bad ownership or modes`. The truth exists, but only on the server side.
8. This is the single most useful piece of knowledge in this section. When public key login fails and you control the server, read the server log.
9. The fix is two commands:

```
$ chmod 700 ~/.ssh
$ chmod 600 ~/.ssh/authorized_keys
```

■ 42.4.4 PLAIN - what is really happening inside

1. Here is the exchange as a numbered sequence, with a diagram after it.
2. The client opens TCP to port 22 and the two sides complete the encrypted transport layer, including the server proving its host key.
3. The client sends an authentication request naming the user, the service, the method `publickey`, and one public key. A flag says "this is only a query".
4. The server takes the user name and looks up that user's home directory.
5. It checks the ownership and permission bits on the home directory, on `~/.ssh`, and on `~/.ssh/authorized_keys`.
6. If any of them is writable by group or by others, the server abandons the file and behaves as if no key matched. This is the silent failure.
7. Otherwise it reads the file line by line, skipping blanks and comments, looking for a line whose key blob equals the one offered.
8. If none matches, the server replies "failure" and the client tries its next key, then finally gives up with `Permission denied (publickey)`.
9. If one matches, the server replies "this key is acceptable, now prove it".
10. The client builds the signature block, signs it, and sends it. The server verifies with the stored public key.
11. On success the server applies any options written in front of that key on that line, then starts the session.

12. Steps 3 and 4 are where nearly all real-world failures live, and neither of them tells the client anything.

■ 42.4.5 TECHNICAL - the engineer's version

1. Default path is `~/.ssh/authorized_keys`, set by the `AuthorizedKeysFile` directive in `sshd_config`. It accepts multiple paths and the tokens `%h` for home directory and `%u` for user name.
2. Required modes, enforced when `StrictModes yes` is set, which is the default:

Path	Required
~	not group/other writable
~/.ssh	700 recommended
~/.ssh/authorized_keys	600, owner only
~/.ssh/id_* private key	600, client side too

- The client enforces its own modes as well. A private key readable by others produces UNPROTECTED PRIVATE KEY FILE and is refused.
- Each line is: optional comma-separated options, then key type, then base64 key, then optional comment. No line continuation exists, so a wrapped paste is the second most common cause of failure after permissions.
- The options that matter in production:

Option	Effect
command="..."	force this command only
from="host,pattern"	restrict source addresses
no-port-forwarding	block tunnels
no-agent-forwarding	block agent reuse
no-pty	no interactive terminal
restrict	all restrictions at once
expiry-time="YYYYMMDD"	key stops working

- restrict was added in OpenSSH 7.2, February 2016, and is the safe default because it enables all current and future restrictions, letting you re-enable individually with permit* options.
- A real forced command, tested on the machine used for this chapter:

```
$ cat ~/.ssh/authorized_keys
command="echo forced: you may only run this",
no-port-forwarding,no-agent-forwarding,no-pty
ssh-ed25519 AAAAC3NzaC1lZDI1NTE5AAAA... kedbyte@laptop

$ ssh -i ~/.ssh/id_ed25519 -p 2222 root@127.0.0.1 \
  'rm -rf /important'
forced: you may only run this
```

- The destructive command was sent and simply not run. The original command is still available to the forced command in the environment variable SSH_ORIGINAL_COMMAND, which is how restricted git servers work.
- That is precisely the mechanism behind git-shell, the login shell that permits only git-upload-pack, git-receive-pack and git-upload-archive.
- Deploy keys** are GitHub's per-repository variant. The public key is attached to one repository, not to a user account.
- Deploy keys are read-only by default and can be granted write access when added. One key cannot be reused across repositories: GitHub rejects a duplicate.
- GitHub lists five alternatives to deploy keys: SSH agent forwarding, HTTPS with OAuth tokens, GitHub App installation access tokens which expire after one hour, machine users, and personal access tokens.
- On GitHub, all SSH access uses the single account name git. Your identity comes entirely from which key signed, not from the user name in the URL.

14. That is why `git@github.com` is the same for every person on earth, and why `ssh -T git@github.com` greets you by your own name.

■ 42.4.6 WORDS – remember these

`authorized_keys` — the list of keys allowed in — a per-user file of public key lines consulted by `sshd` during publickey authentication.

`StrictModes` — the rule that file permissions must be tight — an `sshd` directive making the server refuse key files writable by group or others.

`Forced command` — a key that can only do one thing — the `command="..."` option overriding whatever the client requested.

`SSH_ORIGINAL_COMMAND` — what the client actually asked for — the environment variable holding the requested command when a forced command is in effect.

`Deploy key` — a key for one repository, not one person — a public key attached to a single GitHub repository, read-only unless granted write.

`git-shell` — a login shell that only allows git — a restricted shell shipped with Git permitting only the three pack transfer commands.

42.5 known_hosts and host key verification

■ 42.5.1 PLAIN – in simple words

1. Everyone thinks about proving themselves to the server. Almost nobody thinks about the server proving itself to them.
2. But that half exists, it runs first, and it is the half that stops somebody sitting invisibly in the middle of your connection.
3. Every SSH server has its own key pair, separate from any user's. It is called the **host key**.
4. During setup, the server signs part of the conversation with its private host key. Only the real server could do that.
5. Your client checks that signature against a copy of the server's public key it saved earlier, in a file called `known_hosts`.
6. And here is the awkward truth. The first time you ever connect, your client has no saved copy, so it cannot check anything.
7. So it asks you. It shows you a fingerprint and asks whether to trust it. Most people type yes without looking.
8. That approach has a name: **trust on first use**. You are trusting that nobody was interfering during that one first moment.
9. After that first yes, the key is saved and every later connection is properly checked.
10. If the saved key ever stops matching, SSH stops everything and prints a very loud warning. That warning is doing its job. Read it, do not delete it.

■ 42.5.2 PLAIN – a picture in your head

1. You are meeting someone you have only spoken to by letter, and you must be sure it is really them.
2. The first meeting is the hard one. They show you a birthmark. You have no way to check it, so you write it down and decide to believe it.
3. Every meeting afterwards is easy. You look for the birthmark you wrote down. Match means it is them.

4. Now imagine you turn up and the birthmark is different.
5. Three explanations. They had it removed and told nobody. They have an identical twin who came instead. Or somebody is impersonating them.
6. You cannot tell which from looking. What you can do is stop, and go and check through a different channel before saying anything private.

Where this comparison breaks:

7. A birthmark cannot be changed at will. A host key can be legitimately replaced, and sometimes must be. So a mismatch is not automatically an attack.
8. And a person can be phoned to confirm. A server cannot. You have to find the fingerprint published somewhere trustworthy instead.

■ 42.5.3 PLAIN – a worked example

1. All of the following is real output from the machine used for this chapter, against a small server started for the purpose.
2. The first connection, with nothing saved yet:

```
$ ssh -p 2222 root@127.0.0.1
The authenticity of host '[127.0.0.1]:2222' can't be
established.
ED25519 key fingerprint is
SHA256:nu2laRCiSw3wMTbG6hoH8tKukC952d+/PbR0tgsD5vU.
This key is not known by any other names.
Are you sure you want to continue connecting
(yes/no/[fingerprint])?
```

3. Answer yes and the client writes one line into known_hosts. Here it is, truncated for page width:

```
$ cat ~/.ssh/known_hosts
[127.0.0.1]:2222 ssh-ed25519 AAAAC3NzaC1lZDI1NTE5AAAA
IJJmXI2wR7keztPI78nlxu2ooGFa2+d/ke5qLMBiy5...
```

4. Three fields: which host, which key type, and the key. Note the host is in square brackets with the port, because it is not port 22.
5. Now the server's host key was deliberately replaced and the same connection tried again. This is the real, complete warning:

```
@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@
@  WARNING: REMOTE HOST IDENTIFICATION HAS CHANGED!  @
@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@
IT IS POSSIBLE THAT SOMEONE IS DOING SOMETHING NASTY!
Someone could be eavesdropping on you right now
(man-in-the-middle attack)!
It is also possible that a host key has just been changed.
The fingerprint for the ED25519 key sent by the remote
host is
SHA256:fwKYxD4JEmBcHpHj3WkgxSLrRh6tXIzpi/K0xz2yNrA.
Please contact your system administrator.
Add correct host key in ~/.ssh/known_hosts to get rid of
this message.
Offending ED25519 key in ~/.ssh/known_hosts:1
    remove with:
    ssh-keygen -f '~/.ssh/known_hosts' -R '[127.0.0.1]:2222'
Host key for [127.0.0.1]:2222 has changed and you have
```

```
requested strict checking.
Host key verification failed.
```

6. Notice the message even tells you the exact line number and the exact command to remove it. That convenience is why people delete first and think never.
7. Notice also that the connection stopped. No password prompt appeared. SSH refused to send anything to a server it could not identify.

■ 42.5.4 PLAIN – what is really happening inside

1. The host key check happens during the key exchange, before any authentication method is even offered.
2. The two sides compute a shared secret, then a hash covering both version strings, both algorithm lists, both key exchange values and the shared secret. That hash is the **session identifier**.
3. The server signs the session identifier with its private host key and sends the signature plus its public host key.
4. The client verifies the signature using the public host key it was just sent. That proves the far end holds the matching private host key.
5. But it does not prove the far end is the right machine. Anyone can generate a key pair and sign with it.
6. So the client separately compares that public host key against `known_hosts`. That is the step that ties the maths to a name you care about.
7. Four outcomes. Not found means prompt the user. Found and matching means proceed. Found and different means abort loudly.
8. The fourth outcome is subtler: found for a different key type. If you have an Ed25519 entry and the server offers RSA, OpenSSH says “this key is not known by any other names” rather than warning of a change.
9. When a mismatch happens, SSH refuses to continue in the default configuration, because continuing means handing your credentials to something unverified.
10. If you use password authentication and click through such a warning, you have just typed your password into whatever is in the middle. With key authentication you would have leaked a signature, which is far less valuable, but still not nothing.

■ 42.5.5 TECHNICAL – the engineer’s version

1. `known_hosts` lives at `~/.ssh/known_hosts` for the user and `/etc/ssh/ssh_known_hosts` for the system. Controlled by `UserKnownHostsFile` and `GlobalKnownHostsFile`.
2. Line format: host patterns, key type, base64 key, optional comment. Host patterns may be comma-separated, may use `*` and `?`, and non-default ports are written `[host]:port`.
3. `HashKnownHosts yes` stores hosts as HMAC-SHA-1 hashes so a stolen file does not enumerate every server you use. Debian and Ubuntu enable this by default; upstream OpenSSH does not.
4. `StrictHostKeyChecking` has four values, and choosing correctly matters more than people think:

Value	Behaviour on new host
ask	prompt (upstream default)
accept-new	add, but warn on change
no	add silently, allow change
yes	refuse unless already known

5. `accept-new` was added in OpenSSH 7.6, October 2017, and is the correct choice for scripts. `no` is dangerous because it also tolerates a changed key, which is the case you actually care about.
6. Useful commands, all real:

```
$ ssh-keyscan -t ed25519 -p 2222 127.0.0.1 >> known_hosts
$ ssh-keygen -F '[127.0.0.1]:2222' -f known_hosts
# Host [127.0.0.1]:2222 found: line 1
$ ssh-keygen -R '[127.0.0.1]:2222' -f known_hosts
```

7. A warning that must be stated plainly: `ssh-keyscan` asks the server what its key is. If something is impersonating the server, `ssh-keyscan` will faithfully record the impostor's key.
8. So `ssh-keyscan` is a convenience for populating a file, not a verification tool. Verification means comparing against a fingerprint published by the operator through a different channel.
9. **The GitHub 2023 rotation is the textbook legitimate change.** At approximately 05:00 UTC on 24 March 2023, GitHub replaced its RSA SSH host key.
10. The cause was not a compromise of GitHub's systems. GitHub's RSA SSH private key had been briefly exposed in a public GitHub repository, and they rotated it as a precaution.
11. Every user with an RSA entry for `github.com` in `known_hosts` then saw the REMOTE HOST IDENTIFICATION HAS CHANGED warning. The remedy GitHub published was `ssh-keygen -R github.com` followed by re-adding the new key.
12. Users whose `known_hosts` held the Ed25519 or ECDSA entry saw nothing, because only the RSA key changed.
13. GitHub's current published fingerprints, which you should compare against rather than trusting a prompt:

Type	SHA-256 fingerprint
RSA	uNiVztksCsDhcc0u9e8Bu...
ECDSA	p2QAMXNICITJYWelOtr...
Ed25519	+DiY3wvvV6TuJJhbpZis...

14. The full Ed25519 fingerprint is SHA256:+DiY3wvvV6TuJJhbpZisF/zLDA0zPMSvHdkr4UvC0qU, and the full RSA one is SHA256:uNiVztksCsDhcc0u9e8BuJQXVUpKZIDTMczCvj3tD2s.
15. GitHub publishes these machine-readable at the `/meta` endpoint of its API, under the `ssh_keys` field, which is what automation should consume.
16. When is a changed host key benign? When the operator announced it, when the server was rebuilt or migrated, when you connected to a load-balanced pool with inconsistent keys, or when your DNS now resolves to a different machine because you changed networks.
17. When is it alarming? When nothing changed on your side, when it happens on an untrusted network such as public wifi, when only some connections show it, or when the operator's published fingerprint does not match.
18. The stronger long-term answer is **SSH certificates**. A certificate authority signs host keys, clients trust the CA once with a `@cert-authority` line, and individual host key changes stop mattering. OpenSSH has supported this since version 5.4, March 2010.

■ 42.5.6 WORDS - remember these

`known_hosts` — your notebook of server identities — a client-side file mapping host patterns to accepted host public keys.

Host key — the server's identity key — the long-term key pair `sshd` uses to sign the session identifier during key exchange.

Trust on first use — believing the first answer you get — the TOFU model, where the initial unverified key is pinned and all later ones checked against it.

`ssh-keyscan` — a tool that fetches a server's key — a scanner that records whatever key is offered, with no verification of authenticity.

Session identifier — a fingerprint of this one connection — the exchange hash from the first key exchange, bound into every authentication signature.

`@cert-authority` — trust a signer instead of each server — a `known_hosts` marker line naming a CA key that may vouch for host keys.

42.6 The SSH agent

■ 42.6.1 PLAIN - in simple words

1. A private key should be protected by a passphrase, so that stealing the file is not enough to steal the key.
2. But that means typing a long passphrase every single time you connect.
3. Git makes this unbearable. A fetch, a push, a status check against the server: each one is a fresh connection and a fresh prompt.
4. People solve this the worst possible way. They remove the passphrase.
5. The **SSH agent** is the right solution. It is a small program that runs in the background and holds your unlocked keys in memory.
6. You type the passphrase once. The agent keeps the unlocked key. Every later connection asks the agent instead of asking you.
7. Here is the important detail. The agent does not hand the key to `ssh`.
8. `ssh` sends the agent the data that needs signing. The agent signs it and sends back only the signature.
9. So the key never leaves the agent's memory, not even to another program on your own computer.
10. The agent forgets everything when it stops, which normally means when you log out or shut down.

■ 42.6.2 PLAIN - a picture in your head

1. Think of a notary who keeps your official seal in a locked drawer.
2. You unlock the drawer once in the morning with your combination.
3. All day, whenever you need a document sealed, you hand the document to the notary. He seals it and hands it back.
4. You never carry the seal around, and nobody else ever holds it. They only ever receive sealed documents.
5. At the end of the day the drawer locks itself and the combination is forgotten.
6. Now consider **agent forwarding**, which is the dangerous feature.
7. It means: when I visit another office, let that office phone my notary and ask for seals on their documents.

8. That is wonderfully convenient. It also means anyone with power over that office, while you are visiting, can phone your notary and get anything sealed.
9. They cannot steal the seal. They can use it, on whatever they like, for as long as you are connected.

Where this comparison breaks:

10. A notary would notice being asked to seal something outrageous. The agent signs opaque data and cannot tell a git push from a login to your bank's build server.

■ 42.6.3 PLAIN – a worked example

1. Real output, in order, from the machine used for this chapter.
2. Start an agent and look inside it. Empty.

```
$ eval "$(ssh-agent -s)"
Agent pid 14148
$ ssh-add -l
The agent has no identities.
```

3. Add a key that genuinely has a passphrase. The passphrase is typed once, here and nowhere else.

```
$ ssh-add ~/.ssh/id_pass
Enter passphrase for ~/.ssh/id_pass:
Identity added: ~/.ssh/id_pass (with-passphrase)
$ ssh-add -l
256 SHA256:cY2TWmZ8NY6LT0x9/BYw2D8XxqpmW4+M/C5K7i+nn0I
with-passphrase (ED25519)
```

4. Now connect with no `-i` flag naming a key, and with prompting explicitly disabled so it cannot secretly ask for anything.

```
$ ssh -o BatchMode=yes -p 2222 root@127.0.0.1 \
'echo CONNECTED USING AGENT KEY'
CONNECTED USING AGENT KEY
```

5. That worked with no passphrase typed and no key file named. The agent supplied the signature.
6. Add a key with an automatic expiry, which is a habit worth building:

```
$ ssh-add -t 300 ~/.ssh/id_pass
Identity added: ~/.ssh/id_pass (with-passphrase)
Lifetime set to 300 seconds
```

7. And empty the agent when you walk away:

```
$ ssh-add -D
All identities removed.
```

■ 42.6.4 PLAIN – what is really happening inside

1. The agent listens on a Unix domain socket, which is a file on disk used as a communication end-point between programs on the same machine.
2. Its path is put in the environment variable `SSH_AUTH_SOCK`. That variable is how every other program finds it. There is no other discovery mechanism.
3. When `ssh` needs to authenticate, it connects to that socket and asks: what identities do you hold? The agent replies with public keys only.
4. `ssh` offers those public keys to the server. If the server accepts one, `ssh` builds the data to be signed and sends it to the agent.

6. On macOS, the system agent is integrated with the login keychain. Since macOS 10.12.2 the correct configuration is explicit:

```
Host *
    UseKeychain yes
    AddKeysToAgent yes
    IdentityFile ~/.ssh/id_ed25519
```

7. `UseKeychain yes` stores the passphrase in the login keychain and retrieves it automatically, so the agent is repopulated after a reboot. It is a macOS-only option and will error on Linux.
8. On Linux, `gnome-keyring` and KDE's `ksshaskpass` provide similar integration. On Windows, OpenSSH ships an `ssh-agent` Windows service.
9. The safer alternative to agent forwarding is `ProxyJump`, added in OpenSSH 7.3, August 2016:

```
Host internal
    HostName 10.0.5.20
    ProxyJump bastion.example.com
```

10. `ProxyJump` tunnels a new SSH connection through the intermediate host. The intermediate host sees only encrypted bytes and never touches your agent.
11. A complete, realistic `~/.ssh/config`. This file must be mode 600 and OpenSSH applies the first matching value for each key, so specific hosts must come before `Host *`:

```
# GitHub over the HTTPS port, for blocked networks
Host github.com
    HostName ssh.github.com
    Port 443
    User git
    IdentityFile ~/.ssh/id_ed25519_github
    IdentitiesOnly yes

# A work server on an odd port, through a bastion
Host build
    HostName 10.0.5.20
    Port 2222
    User deploy
    ProxyJump bastion.example.com
    IdentityFile ~/.ssh/id_ed25519_work
    IdentitiesOnly yes

# Everything else
Host *
    AddKeysToAgent yes
    ServerAliveInterval 60
    ServerAliveCountMax 3
    HashKnownHosts yes
```

12. You never have to guess what that file computed. `ssh -G` prints the final resolved settings. Real output from this chapter's machine:

```
$ ssh -G demo
user root
hostname 127.0.0.1
port 2222
identitiesonly yes
identityfile /tmp/sshdemo/.ssh/id_ed25519
```

13. `ServerAliveInterval 60` with `ServerAliveCountMax 3` sends a keepalive every 60 seconds and gives up after three unanswered ones. This is the fix for connections silently dying behind a NAT device that expires idle entries.

■ 42.6.6 WORDS - remember these

SSH agent — a background helper holding unlocked keys — a daemon exposing a signing oracle over a Unix socket, never releasing key material.

`SSH_AUTH_SOCK` — the address of your agent — the environment variable naming the agent's Unix domain socket path.

Agent forwarding — letting a remote host use your agent — an SSH channel exposing your local agent socket on the remote machine, usable by its root.

ProxyJump — hop through a middle machine safely — a client directive tunnelling a fresh SSH session through an intermediate host without agent exposure.

`IdentitiesOnly` — only try the key I named — a directive suppressing the agent's other keys, avoiding Too many authentication failures.

`UseKeychain` — let macOS remember the passphrase — an Apple-specific `ssh_config` option storing and retrieving passphrases from the login keychain.

42.7 Why SSH on port 22 can be blocked when 443 is not

■ 42.7.1 PLAIN - in simple words

1. A port is a number attached to a connection saying which service you want on that machine.
2. Web traffic over HTTPS uses port 443. SSH uses port 22.
3. Many networks do not let you reach every port on the outside world. They allow a short list and block the rest.
4. Port 443 is always on that list. If you block 443, the web stops working, and somebody complains within seconds.
5. Port 22 is often not on the list. Blocking it upsets developers, and only developers, and usually not loudly enough to matter.
6. There are also two real reasons a network operator gives for filtering 22.
7. First, port 22 is scanned constantly by automated programs looking for servers with weak passwords. Filtering it reduces that noise.
8. Second, an outbound SSH connection can carry anything at all inside it, in a form nobody can inspect. It is a perfect way to move data out unseen.
9. So the block is not aimed at you. You are collateral.
10. And the way it fails is cruel. A blocked port 22 usually does not say "no". It says nothing at all, and your command hangs.
11. This is exactly the shape of the reader's own fault in this book, and the fix is one of two lines of configuration.

■ 42.7.2 PLAIN - a picture in your head

1. A building with many numbered delivery bays. Bay 443 is the main goods entrance, open all day, huge queues, everyone uses it.
2. Bay 22 is a small side entrance used by maintenance staff.

3. Management decides to weld bay 22 shut. Almost nobody notices. Bay 443 cannot be welded shut, because then the business stops.
4. Now, welding shut has two possible styles.
5. The polite style is a sign on the door: “closed, use the main entrance”. You read it, turn around, and lose ten seconds.
6. The unhelpful style is no sign at all. You stand there. You knock. You wait. You knock again. Eventually you give up, knowing nothing.
7. Networks overwhelmingly choose the second style, on purpose, because a sign tells a stranger which doors exist.

Where this comparison breaks:

8. A welded door is permanent and obvious on inspection. A network filter can be selective by time, by source address or by destination, so the same command can work for your colleague and hang for you.

■ 42.7.3 PLAIN – a worked example

1. This is real, measured on the machine used to write this chapter, which happens to sit behind exactly this kind of filtering.
2. Port 22 to GitHub, with a generous timeout:

```
$ time ssh -o ConnectTimeout=30 -T git@github.com
ssh: connect to host github.com port 22: Connection timed out

real    0m30.057s
```

3. Thirty seconds, and then a timeout. Nothing came back at any point.
4. Port 443 to the same host name, in the same shell, one second later:

```
$ time bash -c 'exec 3<>/dev/tcp/github.com/443 && echo OPEN'
OPEN

real    0m0.021s
```

5. Twenty-one milliseconds. The network is fine. DNS is fine. GitHub is fine. Only port 22 is unreachable.
6. Now compare that with a port where something actively refuses. Nothing is listening on port 2200 on the local machine:

```
$ time ssh -o ConnectTimeout=10 -p 2200 root@127.0.0.1
ssh: connect to host 127.0.0.1 port 2200: Connection refused

real    0m0.015s
```

7. Fifteen milliseconds and a clear refusal. That is what a healthy “no” looks like.
8. Put the three side by side and the diagnosis writes itself.

Case	Message	Time
Nothing listening	Connection refused	0.015 s
Port 443 reachable	connects	0.021 s
Port 22 filtered	Connection timed out	30.057 s

9. The timing is the tell. Milliseconds means somebody answered. Tens of seconds means silence.

■ 42.7.4 PLAIN – what is really happening inside

- Chapter 34 of this book covered two ways to block a packet, and the difference decides your whole afternoon. Here it is again in one line each.
- REJECT** means refuse and say so. The filter sends back a TCP reset or an ICMP error. Your program fails instantly with “connection refused”.
- DROP** means refuse and say nothing. The packet is deleted. No reply is generated at all.
- With DROP, your computer does not know anything happened. It assumes the packet was lost, so it does what TCP always does: it sends it again.
- The retries are spaced out with doubling gaps. One second, two, four, eight, sixteen. Then it gives up and reports a timeout.
- That is why a blocked port 22 hangs for tens of seconds rather than failing instantly. Every second of that wait is your machine politely retrying.
- Firewall administrators choose DROP deliberately. A REJECT confirms that a host exists at that address, which helps someone mapping your network.
- So silence is a security choice that costs you diagnosis time.
- Applying it to the reader’s own session: `curl -v https://github.com` printed Trying 20.207.73.82:443... and then produced nothing for fifteen seconds. That is the same signature at a different port.
- What that proves is narrow and must be stated carefully. It proves no response arrived. It is consistent with a silent drop somewhere on the path. It does not identify who dropped it, and it does not prove the server was down.
- What made the reader’s case conclusive was the same request succeeding over mobile data seconds later. Same destination, different path, different result.

■ 42.7.5 TECHNICAL – the engineer’s version

- The exact test to determine whether port 22 is blocked, in order, and each step distinguishes something specific.

```
# 1. Does the name resolve? (rules out DNS)
$ dig +short github.com
20.207.73.82

# 2. Can TCP reach port 22 at all? (the real question)
$ nc -vz -w 5 github.com 22

# 3. Same for 443, as a control
$ nc -vz -w 5 github.com 443

# 4. If nc is absent, bash can do it
$ time bash -c 'exec 3<>/dev/tcp/github.com/22'

# 5. GitHub's own SSH check, most direct of all
$ ssh -vT -o ConnectTimeout=10 git@github.com
```

- Read the results this way:

Observation	Conclusion
22 refused fast	reachable, nothing there
22 silent, 443 ok	port 22 filtered
both silent	path or host problem
both fast, auth fails	network fine, key wrong

Observation	Conclusion

3. **Fix one: switch the remote to HTTPS.** One command per repository, or a global rewrite for all of them.

```
$ git remote set-url origin \
    https://github.com/owner/repo.git

# or globally, for every GitHub remote at once
$ git config --global \
    url."https://github.com/".insteadOf "git@github.com:"
```

4. **Fix two: use GitHub's SSH over the HTTPS port.** GitHub runs an SSH endpoint on port 443 at a different host name.
5. The host name is `ssh.github.com`, not `github.com`. This matters. GitHub's documentation states it explicitly because people get it wrong.
6. Test it first:

```
$ ssh -T -p 443 git@ssh.github.com
Hi USERNAME! You've successfully authenticated, but GitHub
does not provide shell access.
```

7. Then make it permanent with the exact block GitHub publishes, in `~/.ssh/config`:

```
Host github.com
    Hostname ssh.github.com
    Port 443
    User git
```

8. After that block, your existing `git@github.com:owner/repo.git` remotes need no change at all. `ssh` rewrites the destination before connecting.
9. This is real SSH, not SSH wrapped in TLS. It is the SSH protocol speaking on TCP port 443. A firewall filtering by port number is satisfied.
10. Therefore it does not help against a proxy that inspects protocols, only against a port-number filter. GitHub's own documentation notes that proxy servers may interfere.
11. Comparison of the two fixes, since they are not equivalent:

Aspect	HTTPS remote	SSH on 443
Credential	token	SSH key
Works via HTTP proxy	yes	usually not
Survives deep inspection	yes	no
Config scope	per repo or global	one config block

12. A third option exists and is worth knowing: `ProxyCommand` with a tool such as `corkscrew` or `nc` tunnels SSH through an HTTP proxy using the `CONNECT` method. It is fiddly and usually not needed if fix one works.
13. On the honest side: none of this is a way around a policy that forbids the traffic. Using SSH on 443 to evade a corporate control is a conversation with your employer, not a technical question.

■ 42.7.6 WORDS – remember these

Port — a number naming a service on a machine — a 16-bit TCP or UDP endpoint identifier; 22 for SSH, 443 for HTTPS by IANA assignment.

DROP — block and say nothing — a filter action discarding the packet with no reply, producing a client-side timeout after retries.

REJECT — block and say so — a filter action returning a TCP RST or ICMP unreachable, producing an immediate Connection refused.

Egress filtering — controlling what may leave a network — outbound firewall policy, commonly permitting only 80, 443 and DNS.

ssh.github.com — GitHub's SSH server on the web port — the host name serving the SSH protocol on TCP 443 for networks blocking 22.

ProxyCommand — a custom way to reach a host — an ssh_config directive running an external program to establish the transport.

42.8 HTTPS authentication for git

■ 42.8.1 PLAIN – in simple words

1. When git talks over HTTPS, it makes ordinary web requests, and it proves who you are the way web requests always have: a user name and a secret.
2. For many years that secret was your actual GitHub account password.
3. That stopped. On 13 August 2021, GitHub stopped accepting account passwords for git operations entirely.
4. The reason is straightforward. Your account password unlocks everything you own, cannot be limited, cannot be given to one script, and cannot be cancelled without changing it everywhere.
5. In its place you use a **token**, which is a long random string that acts like a password but has rules attached to it.
6. A token can be limited to certain actions. It can expire. It can be cancelled on its own without touching anything else.
7. Now the practical problem. You cannot type a forty-character random string before every push.
8. So git has **credential helpers**. A credential helper is a small program that stores your token and hands it back when git asks.
9. Where it stores it depends on the helper, and the differences matter. Some put it in your operating system's encrypted vault. One writes it to a plain text file.
10. Knowing which helper you use, and being able to look inside it and clear it, is a basic skill.

■ 42.8.2 PLAIN – a picture in your head

1. Think of a building where the receptionist checks a pass every time you go through a door.
2. Carrying the pass in your hand and showing it forty times a day is tiring.
3. So you give it to a locker at the entrance. Whenever you approach a door, the locker sends the pass details for you.
4. There are different lockers. A steel one with a combination that only opens when you are logged in. And a cardboard box on the counter with your pass sitting in it, visible to anyone who looks.
5. Both work. Both save you the same effort. Only one is a good idea.
6. And when you lose your pass, or you suspect somebody copied it, you need to do two separate things.

7. Cancel the pass at the security office, so the old one stops working. And empty the locker, so your own building stops trying to use the dead one.

Where this comparison breaks:

8. A physical pass is one object. A token can be copied silently and used from anywhere in the world at the same time as you are using it, with no sign at the door.

■ 42.8.3 PLAIN – a worked example

1. Real output from the machine used for this chapter, using git's own `credential` commands. These are the exact operations a helper performs.
2. Choose a helper. Here the insecure store helper is chosen deliberately, so we can look at what it writes:

```
$ git config --global credential.helper \  
    'store --file=/tmp/demo/.git-credentials'
```

3. Save a credential. This is what happens automatically the first time you push and type a token:

```
$ printf 'protocol=https\nhost=github.com\nusername=reader  
password=ghp_EXAMPLEexampleEXAMPLEexample1234\n\n' \  
| git credential approve
```

4. Now look at what landed on disk:

```
$ ls -l /tmp/demo/.git-credentials  
-rw----- 1 root root 63 Aug 13 08:24 .git-credentials  
$ cat /tmp/demo/.git-credentials  
https://reader:ghp_EXAMPLEexampleEXAMPLE...@github.com
```

5. That is your token, in a plain readable file. The permissions are 600, owner only, but there is no encryption at all.
6. Ask git what it would send for a given host. This is the command to run when you suspect a stale credential:

```
$ printf 'protocol=https\nhost=github.com\n\n' \  
| git credential fill  
protocol=https  
host=github.com  
username=reader  
password=ghp_EXAMPLEexampleEXAMPLEexample1234
```

7. And clear it, which is what you do the moment a token is rotated or leaked:

```
$ printf 'protocol=https\nhost=github.com\nusername=reader  
password=ghp_EXAMPLEexampleEXAMPLEexample1234\n\n' \  
| git credential reject  
$ wc -c < /tmp/demo/.git-credentials  
0
```

8. The file is now empty. Note carefully: this cleared the local copy. It did nothing whatsoever to the token on GitHub's side.

■ 42.8.4 PLAIN – what is really happening inside

1. Git never asks a helper for a credential until it needs one.
2. It first makes the request without any credential. If the server is happy, nothing else happens. This is why cloning a public repository never prompts.
3. If the server responds with HTTP status 401 and a WWW-Authenticate header, git knows a credential is required.
4. Git then runs the configured helper with the subcommand `get`, feeding it the protocol, host and path on standard input.
5. The helper replies with `username=` and `password=` lines, or says nothing if it has none stored.
6. If no helper has one, git prompts you on the terminal.
7. Git then retries the request with an `Authorization: Basic` header. That header is the user name and token joined with a colon and base64-encoded.
8. Base64 is an encoding, not encryption. It hides nothing. What protects the token is that the whole request travels inside TLS.
9. If the retried request succeeds, git runs the helper again with `store`, so a working credential is remembered.
10. If it fails with 401, git runs the helper with `erase`, so a wrong credential is not offered forever.
11. That last step is why a bad cached token often self-corrects, and why a token that is valid but lacks a permission does not: that is a 403, not a 401, so git does not erase it.

```
git ---> GET /repo.git/info/refs      ---> server
git <--- 401 + WWW-Authenticate      <--- server
git ---> helper "get" (host, protocol)
git <--- helper "username=..., password=..."
git ---> GET again + Authorization: Basic ...
git <--- 200 OK
git ---> helper "store" (remember this one)
```

■ 42.8.5 TECHNICAL – the engineer's version

1. The credential helper protocol is a documented text protocol. A helper is any executable named `git-credential-NAME`, invoked with one of `get`, `store` or `erase`.
2. The helpers you will actually meet:

Helper	Storage	Encrypted
osxkeychain	macOS keychain	yes
manager (GCM)	OS vault per platform	yes
libsecret	GNOME keyring	yes
wincred	Windows Cred Manager	yes
cache	memory, 900 s default	n/a
store	~/.git-credentials	no

3. `store` is documented by git itself as insecure. Its own manual page says the credentials are stored unencrypted. Use it only on a machine where the whole disk is encrypted and single-user, and preferably not then.
4. `cache` keeps credentials in memory in a background daemon with a default timeout of 900 seconds, adjustable with `--timeout`.
5. Git Credential Manager, formerly Git Credential Manager Core, is the cross-platform helper maintained by GitHub. It handles OAuth device flow, so you get a browser login instead of pasting a token.

6. Configuration is layered, and this catches people out:

```
$ git config --show-origin --get-all credential.helper
file:/etc/gitconfig      manager
file:~/.gitconfig       osxkeychain
```

7. Multiple helpers are tried in order until one returns a credential. An empty value, `credential.helper=`, resets the list, which is the way to disable an inherited system-level helper.
8. Per-host configuration is possible and is the right way to keep work and personal accounts separate:

```
[credential "https://github.com"]
    username = work-account
    helper = osxkeychain
```

9. Inspecting and clearing on macOS, which is the reader's platform:

```
# see it
$ printf "protocol=https\nhost=github.com\n\n" \
| git credential-osxkeychain get

# delete it
$ printf "protocol=https\nhost=github.com\n\n" \
| git credential-osxkeychain erase
```

10. The graphical route on macOS is the Keychain Access application, searching for `github.com` and deleting the internet password entry.
11. On Windows: `cmdkey /list` in a command prompt, or Credential Manager in Control Panel, under Windows Credentials.
12. On Linux with libsecret: `secret-tool search server github.com`.
13. The HTTP conversation is worth seeing once. Real capture from this chapter's machine against a public repository, so no credential was needed:

```
GET /octocat/Hello-World.git/info/refs?service=git-upload-pack
Git-Protocol: version=2
<= HTTP/1.1 200 OK
<= Content-Type: application/x-git-upload-pack-advertisement
```

14. Against a repository the requester cannot see, unauthenticated, the same endpoint returns 401 rather than 404. Real result:

```
$ curl -s -o /dev/null -w "status=%{http_code}\n" \
"https://github.com/octocat/not-a-real-repo.git/info/refs\
?service=git-upload-pack"
status=401
```

15. That 401 for a repository that does not exist is deliberate. GitHub will not confirm or deny the existence of a private repository to an anonymous requester. Remember this when we reach Repository not found.
16. The user name in an HTTPS git URL is almost always ignored by GitHub when a token is supplied. `x-access-token`, your login, or anything else usually works. The token identifies you.
17. Never put a token in the remote URL itself. It lands in `.git/config` in plain text, in your shell history, and in the output of `git remote -v`, which people paste into bug reports.

■ 42.8.6 WORDS - remember these

Credential helper — a program that remembers your token — an executable implementing git's get/store/erase credential protocol.

Basic authentication — user name and secret sent in a header — HTTP authentication, RFC 7617, sending base64 of user:secret, safe only inside TLS.

401 versus 403 — “who are you” versus “not allowed” — 401 means no or invalid credential and triggers a prompt; 403 means the credential is valid but insufficient.

store helper — the one that writes plain text — a helper persisting credentials unencrypted in ~/.git-credentials.

Keychain — the operating system's encrypted vault — macOS Keychain, Windows Credential Manager or a libsecret provider, unlocked with your login.

git credential fill — ask git what it would send — a plumbing command running the helper chain and printing the resolved credential.

42.9 Personal access tokens

■ 42.9.1 PLAIN - in simple words

1. A token is a long random string that stands in for you when a program talks to a service.
2. It is not derived from your password. Cancelling it does not affect your password, and changing your password does not necessarily cancel it.
3. That independence is the point. A token is a separate identity you can hand to one script, on one machine, for one purpose.
4. A token has three properties a password does not have, and each one matters.
5. It can be **scoped**, meaning limited to a specific list of things it is allowed to do.
6. It can **expire**, meaning it stops working on a date you chose, whether or not you remember it exists.
7. It can be **revoked individually**, meaning you cancel this one without disturbing the other nine tokens on your other nine machines.
8. GitHub offers two kinds. The older **classic** tokens, which use a list of broad permission names. And **fine-grained** tokens, which pick individual repositories and individual permissions.
9. A leaked token is an emergency, not an inconvenience. Anyone holding it is you, for everything that token can reach, immediately.
10. There is no clever recovery. You revoke it, you create a new one, you replace it everywhere, and you check what was done while it was out.

■ 42.9.2 PLAIN - a picture in your head

1. Think of a hotel with two kinds of key.
2. The master key opens every room, the safe, the office and the roof. That is your account password.
3. The other is a plastic card cut for room 412 only, valid until Friday, and the front desk can cancel it in one click without recutting anyone else's.
4. If a cleaner needs into room 412 on Tuesday, you give them the card, not the master key.
5. If the card is lost, you cancel it. Nothing else changes. Nobody else is inconvenienced.
6. If the master key is lost, the entire hotel has to be rekeyed.
7. Now add the part that has no hotel equivalent. A copied card is invisible. The lock cannot tell the difference and neither can you.

8. So the card also has a printed expiry date, so that a copy you never learned about dies on its own.

Where this comparison breaks:

9. A hotel card must be physically present at the door. A token can be used from another continent, by a program, thousands of times a minute.
10. And a hotel lock logs the card number. Token use is logged too, but you have to go and look, and almost nobody does until something breaks.

■ 42.9.3 PLAIN – a worked example

1. GitHub tokens begin with a short prefix that tells you what kind they are. This is a deliberate design so that scanners can find them.

Prefix	What it is
ghp_	classic personal token
github_pat_	fine-grained personal token
gho_	OAuth app user token
ghu_	GitHub App user token
ghs_	GitHub App server token
ghr_	refresh token

2. Using one at the command line, once, without saving it anywhere:

```
| $ git clone https://TOKEN@github.com/owner/repo.git
```

3. That works, and it is a bad habit, because the token is now in the shell history and in `.git/config`.
4. The better single-use form pipes it in and never stores it:

```
| $ echo "TOKEN" | gh auth login --with-token
```

5. Rotating a token is a fixed procedure. Do these in order, because the order prevents an outage:
6. One: create the new token with the same scopes, and note the expiry.
7. Two: update every place that uses it. Your keychain, your CI secrets, the `.netrc` on the build box, the deployment config.
8. Three: verify the new one works, with an actual operation, not a guess.
9. Four: only now, revoke the old one.
10. Five: watch for failures for a day, because there is always one forgotten machine.
11. If instead the token has leaked, that order inverts. Revoke first, immediately, and accept the outage. A live leaked token is worse than downtime.

■ 42.9.4 PLAIN – what is really happening inside

1. A token is a record in GitHub's database. It has an owner, a creation time, an expiry time, a list of permissions and a last-used timestamp.
2. What you are shown once, at creation, is the token string. GitHub does not store that string in a readable form; it stores a hash of it.
3. That is why the page says you will never see it again. They genuinely cannot show it to you.
4. When you use it, the server hashes what you sent and looks up the record. If the record exists, is not expired and is not revoked, you are authenticated.
5. Then, and only then, does it check whether the permissions on that record allow the specific operation you asked for. Those are two separate steps.

6. Keeping them separate explains the whole of section 42.10. Being authenticated does not mean being allowed.
7. **Secret scanning** is GitHub scanning content pushed to it, looking for strings that match known credential patterns.
8. This is why the prefixes exist. `ghp_` followed by the right number of base62 characters with a checksum is machine-recognisable with almost no false positives.
9. GitHub runs the same scanning for over five hundred partner patterns: cloud provider keys, payment provider keys, and so on.
10. When GitHub finds its own token in a public repository, it revokes it automatically. When it finds a partner's, it notifies the partner, who typically revokes it too.
11. **Push protection** is the same detection moved earlier. Instead of finding the secret after it is pushed, the push itself is refused.
12. That distinction is enormous. A secret that reached the server must be treated as leaked forever, even after you rewrite history, because the object may have been fetched or cached.
13. A secret blocked by push protection never arrived. Nothing leaked. You fix your commit and move on.
14. Push protection has been enabled by default for public repositories since 2024. For private repositories it is part of GitHub's paid secret protection product.

■ 42.9.5 TECHNICAL - the engineer's version

1. Classic versus fine-grained, precisely:

Property	Classic	Fine-grained
Scope model	broad named scopes	per-permission
Repository limit	all you can access	chosen list
Owner limit	all orgs	one user or org
Org approval	no	can be required
Expiry	optional	policy-controlled

2. GitHub's own documentation states the case bluntly: a classic token "will grant access to all repositories within the organizations that you have access to, as well as all personal repositories".
3. That sentence is the whole argument for fine-grained tokens. A classic token on a laptop is a key to everything that laptop's owner can reach.
4. Fine-grained tokens are limited to resources owned by a single user or organization, can be limited to specific repositories, and are granted specific permissions rather than broad scopes.
5. Organization owners can require approval before a fine-grained token may act on organization resources, which is a control classic tokens never had.
6. Expiry: GitHub supports preset periods and a custom date. Fine-grained tokens gained optional non-expiring lifetimes and rotation policies in a change announced on 18 October 2024, and enterprises can enforce maximum lifetimes.
7. GitHub automatically removes personal access tokens that have not been used for a year. That is a useful backstop, not a strategy.
8. Practical expiry guidance, and this is a convention rather than a rule:

Use	Suggested lifetime
Interactive laptop use	90 days

Use	Suggested lifetime
A one-off script	7 days
A long-running service	do not; use an App
CI pipeline	do not; use OIDC

9. Token format, since GitHub's April 2021 redesign: a fixed prefix, an underscore, then base62 characters, ending in a checksum. The checksum lets a scanner reject a random-looking string cheaply before doing any lookup.
10. Auditing what a token can do, without guessing. The response headers of an authenticated API call name the scopes:

```
$ curl -sI -H "Authorization: Bearer $TOKEN" \
  https://api.github.com/user | grep -i x-oauth
x-oauth-scopes: repo, read:org
x-accepted-oauth-scopes:
```

11. x-oauth-scopes is what your token has. x-accepted-oauth-scopes is what that particular endpoint would accept. Comparing the two diagnoses most permission failures in one command.
12. With the GitHub CLI the equivalent is `gh auth status`, which prints the scopes of the stored token.
13. Leak response, in order, and treat this as a checklist:
14. Revoke the token in GitHub settings. This is instant and unconditional.
15. Rotate anything the token could have reached: deploy keys, downstream secrets, database passwords stored in repositories it could read.
16. Review the account's security log and, for organizations, the audit log, filtering by the period the token was live.
17. Check for new SSH keys, new deploy keys, new webhooks, new collaborators and changed workflow files. Those are the standard persistence mechanisms.
18. Rewriting git history does not undo a leak. Assume the secret is public from the moment it was pushed.
19. Never commit a token, even to a private repository. Private repositories get forked, made public, and cloned onto laptops that later get lost.

■ 42.9.6 WORDS - remember these

Personal access token (PAT) — a password substitute you can limit and cancel — a server-side credential record with scopes, expiry and independent revocation.

Classic token — the older broad kind — a PAT carrying OAuth-style scopes across every repository and organization the user can reach.

Fine-grained token — the newer narrow kind — a PAT limited to one owner, a chosen repository list and individual permissions.

Revocation — cancelling one credential — deleting the server-side token record, taking effect immediately and independently of other credentials.

Secret scanning — the service that hunts for leaked credentials — pattern matching over pushed content, with automatic revocation for GitHub's own tokens.

Push protection — refusing the push instead of cleaning up after it — pre-receive secret detection that blocks the write, so nothing ever leaks.

42.10 Scopes, properly

■ 42.10.1 PLAIN – in simple words

1. A **scope** is a named permission attached to a credential.
2. The name is a short string, like `repo` or `workflow`. It sits in the token's record on the server, not in anything you hold.
3. The server checks it at the exact moment you try to do something. Not when you log in. At the moment of the action.
4. That timing is the thing to understand. You can be perfectly, provably authenticated and still be refused.
5. Authentication answers "who are you". Authorization answers "may you do this". They are separate questions asked at different times.
6. So a token with no `workflow` scope will happily let you clone, fetch, and push ordinary changes. It will refuse one specific kind of push.
7. The reader hit exactly this. A push that changed a file under `.github/workflows/` was refused, while everything else worked.
8. The reason is not arbitrary. A file under `.github/workflows/` is not ordinary content. It is instructions for GitHub's own machines.
9. Those machines run with access to the repository's secrets. So changing that file is changing what code runs with those secrets.
10. GitHub therefore treats it as a separate, higher permission that you must ask for on purpose.

■ 42.10.2 PLAIN – a picture in your head

1. Imagine an office pass that opens the front door, the stairs and your own floor.
2. You walk in, you go up, you work. Everything is fine. You are definitely a recognised employee.
3. Then you try the server room. The reader flashes red. Not because your pass is fake, but because your pass does not include that room.
4. Nobody has questioned your identity. They know exactly who you are. The answer is still no.
5. Now the important part: why is the server room separate at all?
6. Because inside it you could reconfigure the machines that everyone else's work runs on, and give yourself access to everything they touch.
7. That is precisely the relationship between a normal file and a CI workflow file. One is a document. The other is a change to the factory.

Where this comparison breaks:

8. A door either opens or it does not, and it decides in one instant. A scope check can depend on the content of what you are pushing, which path it touches, and even whether an identical file already exists on another branch.

■ 42.10.3 PLAIN – a worked example

1. The scopes that actually matter in daily work. These are the exact names GitHub uses.

Scope	What it grants
<code>repo</code>	full read/write, private too
<code>public_repo</code>	same, public repos only
<code>workflow</code>	add/update workflow files
<code>read:org</code>	read org and team membership

Scope	What it grants
write:packages	publish packages
read:packages	download packages
admin:repo_hook	manage repository webhooks
gist	write access to gists

2. GitHub's own words for the two that cause the most confusion.
3. repo "grants full access to public and private repositories including read and write access to code, commit statuses, repository invitations, collaborators, deployment statuses, and repository webhooks".
4. workflow "grants the ability to add and update GitHub Actions workflow files". And then a detail almost nobody knows, quoted exactly.
5. "Workflow files can be committed without this scope if the same file (with both the same path and contents) exists on another branch in the same repository."
6. That exception explains a confusing symptom. Merging a branch that already contains the workflow file can succeed while the original push failed.
7. Note that repo does not include workflow. It is not a hierarchy. The broadest normal scope still stops at the workflow directory.
8. read:org is the one people forget. Without it, a token cannot list the organizations you belong to, so tools report you as having no organizations at all.

■ 42.10.4 PLAIN – what is really happening inside

1. Here is the reader's exact failure, and the message is worth reading character by character.

```
$ git push origin main
Enumerating objects: 7, done.
Writing objects: 100% (4/4), 412 bytes, done.
To https://github.com/owner/repo.git
! [remote rejected] main -> main (refusing to allow a
  Personal Access Token to create or update workflow
  `.github/workflows/ci.yml` without `workflow` scope)
error: failed to push some refs to
'https://github.com/owner/repo.git'
```

2. Read what already succeeded before the refusal, because it tells you where the failure was not.
3. Enumerating objects and Writing objects both completed. The network worked. TLS worked. Authentication worked.
4. Your commits were transmitted to GitHub. All of them. The bytes arrived.
5. The refusal came from git-receive-pack on GitHub's side, after receiving everything, when it inspected what was about to be applied.
6. Then it declined to update the branch reference. Nothing was written. The objects were transmitted and discarded.
7. That is what ! [remote rejected] means, and it is why this is not a transport failure. A transport failure cannot produce a sentence about scopes, because a broken transport cannot produce sentences at all.
8. The phrasing refusing to allow is also deliberate. GitHub is not saying it failed. It is saying it decided.
9. Here is the same shape reproduced locally on the machine used for this chapter, with a server-side hook standing in for GitHub's own check. Real output:

```
$ git push origin main
remote: error: refusing to allow a Personal Access Token
remote: to create or update workflow
remote: `.github/workflows/ci.yml` without `workflow` scope
To /tmp/gitgate/srv/repo.git
! [remote rejected] main -> main (pre-receive hook declined)
error: failed to push some refs to '/tmp/gitgate/srv/repo.git'
```

10. And the push immediately before it, which touched only README.md, succeeded:

```
$ git push origin main
To /tmp/gitgate/srv/repo.git
* [new branch]      main -> main
```

11. Same server, same credential, same network, same second. The only variable was which file the commit touched.
12. That comparison is the proof that this is a content-dependent authorization decision, taken on the server.

■ 42.10.5 TECHNICAL – the engineer’s version

1. The fix, in order, and it is short:
2. Open GitHub, Settings, Developer settings, Personal access tokens, Tokens (classic). Select the token in use.
3. Tick workflow. Save. The scope is added to the existing token; you do not have to create a new one for classic tokens.
4. If the token was already cached, git will keep using the same string, and it now has the scope. No local change is needed.
5. If you create a new token instead, clear the cached one first, or git will keep sending the old one:

```
$ printf "protocol=https\nhost=github.com\n\n" \
| git credential reject
```

6. With the GitHub CLI, re-authorize with the extra scope in one command:

```
$ gh auth refresh -h github.com -s workflow
```

7. For fine-grained tokens, the equivalent is the repository permission “Workflows: Read and write”.
8. For a GitHub App, it is the workflows repository permission, and the app must be installed on the repository.
9. Verify before retrying, rather than pushing and hoping:

```
$ curl -sI -H "Authorization: Bearer $TOKEN" \
https://api.github.com/user | grep -i x-oauth-scopes
x-oauth-scopes: repo, workflow
```

10. **Now generalise, because all three failures print “push failed”.** This table is the most useful thing in the chapter.

Layer	Symptom	Proof
Network	hangs then times out	no bytes sent
Auth	asks again, or 401	Invalid username
Authorization	refused with a reason	[remote rejected]
Non-fast-forward	refused, no credential talk	[rejected]

11. Distinguish them by four observations, in this order.
12. Did objects transfer? Writing objects: 100% means the network and the credential both worked. Everything after that is a policy decision.
13. Was a credential requested? A prompt or a 401 means authentication failed, not authorization.
14. Is there a reason in parentheses after ! [remote rejected]? A sentence means a server rule. A bare [rejected] with non-fast-forward means your branch is behind and no permission is involved.
15. How long did it take? Instant means somebody answered. Fifteen to thirty seconds of silence means the network.
16. A worked triage, applying the table to the four cases:

```
Case A: 30 s, "Connection timed out"
-> network. Port filtered. See 42.7.

Case B: "remote: Invalid username or password"
-> authentication. Token wrong, expired or revoked.

Case C: "! [remote rejected] ... without `workflow` scope"
-> authorization. Credential fine. Add the scope.

Case D: "! [rejected] ... (non-fast-forward)"
-> neither. Fetch and rebase or merge.
```

17. One further separation the reader met in the same session. Plain git kept working while the GitHub API did not.
18. That is the same split at a larger scale: git the tool, running locally against local objects, versus GitHub the service, reachable only over the network and enforcing its own rules.
19. The honest version: the workflow scope is not a complete defence. Someone with repo scope can still change a file that a workflow executes, such as a build script the workflow calls. The scope protects the workflow definition, not everything the workflow does.
20. That is why serious repositories also use branch protection, required reviews on the .github/ path with a CODEOWNERS file, and environment protection rules on the jobs that hold real secrets.

■ 42.10.6 WORDS - remember these

Scope — a named permission on a credential — a string in the token record that the server checks per operation, such as repo or workflow.

Authentication — establishing who you are — verifying a credential against a stored record; failure produces 401.

Authorization — establishing what you may do — checking permissions for a specific operation; failure produces 403 or a rejection message.

! [remote rejected] — the server chose not to apply this — a per-ref failure from git-receive-pack, always accompanied by a reason.

Non-fast-forward — your branch is behind, not forbidden — a rejection because the update would discard commits, unrelated to any permission.

x-oauth-scopes — the header that lists what your token has — a GitHub API response header naming the token's granted scopes.

42.11 OAuth, tokens, SSH keys and GitHub Apps

■ 42.11.1 PLAIN – in simple words

1. There are four different ways a program or a person can be identified to GitHub, and people mix them up constantly.
2. An **SSH key** identifies a machine you sit at. It lives in a file on that machine and never moves.
3. A **personal access token** identifies you as a person, to a program you gave it to. It is a string, so it can be copied.
4. An **OAuth authorization** is what happens when you click “sign in with GitHub” on someone else’s website. You grant that site permission to act as you.
5. A **GitHub App** is a separate identity of its own. It is not you. It is installed on specific repositories and acts in its own name.
6. The difference that matters most is **blast radius**: if this credential leaks, how much can the finder reach, and for how long.
7. An SSH key with no passphrase, sitting on a stolen laptop, reaches every repository you can reach, forever, until you notice.
8. A classic token reaches the same, from anywhere in the world, with no laptop required.
9. A GitHub App installation token reaches only the repositories the app is installed on, only with the permissions granted, and it dies after one hour.
10. For automated systems there is a fifth and better option that involves no stored secret at all. We come to it at the end of this section.

■ 42.11.2 PLAIN – a picture in your head

1. Four ways to get a package delivered into a building.
2. The SSH key is a key cut for your own front door. It works only when you are standing there. Losing it is bad but local.
3. The personal token is your signature on a delivery authorization. Anyone with a photocopy can use it anywhere, until you cancel it.
4. The OAuth grant is you signing a standing instruction that a courier company may collect on your behalf. You can withdraw it, but while it stands, they act as you.
5. The GitHub App is a contractor with their own uniform, their own badge, and a written list of which rooms they may enter. When they do something, the log says the contractor did it, not you.
6. That last property is underrated. When a person leaves the company, their key, token and OAuth grants all die with their account. The contractor keeps working.

Where this comparison breaks:

7. A contractor can be phoned and asked what they are doing. An app acts in milliseconds, thousands of times, and the only record is the audit log.

■ 42.11.3 PLAIN – a worked example

1. The four identities compared on the properties that decide which to use.

Identity	Acts as	Typical lifetime
SSH key	you	years, until removed
Classic PAT	you	30 to 90 days
OAuth grant	you, via an app	until revoked
App install token	the app	1 hour

2. And the blast radius if each one leaks:

Identity	Reach if leaked
SSH key	all repos you can access
Classic PAT	all repos, plus scopes
Fine-grained PAT	listed repos only
App install token	installed repos, 1 hour

3. Choosing, as a short decision list:

4. A human on their own laptop, working daily: an SSH key with a passphrase, held in the agent.
5. A human running a script occasionally: a fine-grained token, short expiry, limited to the repositories the script touches.
6. A server that must pull one repository: a deploy key, read-only, on that server only.
7. A product integrating with GitHub for many customers: a GitHub App.
8. A CI pipeline talking to a cloud provider: neither of these. Use OIDC, which is the next block.

■ 42.11.4 PLAIN - what is really happening inside

1. The problem with a long-lived credential in a CI system is that it must be stored somewhere the CI system can read.
2. Which means anyone who can make the CI system print things, or run arbitrary code, can read it. And CI systems exist to run code that people wrote today.
3. The modern answer removes the stored secret entirely. It is called **OIDC federation**, and the idea is simple even if the acronyms are not.
4. When a job starts, GitHub creates a short-lived signed statement describing that exact job. Which repository, which branch, which workflow, which run.
5. That statement is signed by GitHub, and anyone can check the signature against GitHub's published verification keys.
6. The job hands that statement to the cloud provider and says: I am this workflow in this repository, please give me credentials.
7. The cloud provider has been told in advance which statements to accept. For example, only jobs from owner/repo on the main branch.
8. It verifies the signature, checks the description matches its rule, and issues its own short-lived credential, valid for perhaps an hour.
9. Nothing long-lived was ever stored. There is no secret in the repository, no secret in the CI settings, and nothing to rotate.
10. If someone steals the statement, it expires in minutes and only works for that one narrow rule.

```

GitHub Actions job
| 1. request token for audience "aws"
v
GitHub OIDC issuer
| 2. signed JWT: repo, ref, workflow, run_id
v
the job
| 3. present JWT to the cloud provider
v
cloud provider
| 4. verify signature, match trust policy
| 5. issue short-lived credentials
v
the job now has 1-hour credentials, no stored secret

```

■ 42.11.5 TECHNICAL – the engineer’s version

1. **SSH keys** authenticate a client to a server using public key cryptography. On GitHub they are attached to a user account or, as deploy keys, to a repository. They carry no scopes: an account SSH key can do whatever that account can do over git.
2. That is a genuine limitation. There is no such thing as a read-only account SSH key on GitHub. If you need read-only, you need a deploy key or a fine-grained token.
3. **Personal access tokens** are bearer credentials. Possession is authorization. They carry scopes and expiry as covered in 42.9 and 42.10.
4. **OAuth** is the delegation framework in RFC 6749, October 2012, with the current best-practice profile in RFC 9700, January 2025. Three parties: you the resource owner, the app, and GitHub the authorization server.
5. The user-facing difference from a token is that you never hand the app your credential. You are redirected to GitHub, you approve a named list of scopes, and the app receives a token bound to that grant.
6. OAuth App tokens act entirely as you. Every action appears in the audit log as your action. Revoking the grant kills the token.
7. **GitHub Apps** are first-class actors. Key properties:

Property	Value
Identity	the app, not a user
Install scope	chosen repositories
Permissions	per-resource read/write
Install token life	1 hour
Rate limit	scales with installation

8. A GitHub App authenticates in two stages. It signs a JSON Web Token with its own private key to prove it is the app, then exchanges that for an installation access token scoped to one installation.
9. That installation token expires after one hour, which is stated in GitHub’s own documentation as one of the reasons to prefer apps over deploy keys.
10. Apps also survive staff turnover. A token or key tied to a departing employee dies when the account is deprovisioned, usually at three in the morning, in the middle of a deployment.
11. **OIDC federation for CI.** OpenID Connect is an identity layer on top of OAuth 2.0. GitHub Actions runs an OIDC provider that issues a JSON Web Token per job.
12. Claims in that token include sub, which encodes the workflow context such as repo:octo-org/octo-repo:environment:prod, plus aud, repository, actor, ref, workflow and run_id.
13. The cloud side is configured with a trust policy matching those claims. A correct policy pins at least the repository and usually the branch or environment.
14. GitHub states three benefits: no cloud secrets duplicated as long-lived GitHub secrets, granular control through the provider’s own access tools, and automatic rotation because each token expires when the job ends.
15. A minimal workflow needs one permission block and one action:

```
permissions:  
  id-token: write  
  contents: read
```

16. Without id-token: write the job cannot request an OIDC token at all, and the failure message is unhelpful, so this is worth memorizing.

17. `GITHUB_TOKEN`, the automatic token inside every Actions run, is itself an installation token for a GitHub App. Its permissions are set by the `permissions: key`, and any action in the job can read it via `github.token` even if you never pass it.
18. A common trap follows from that. The workflow scope discussion in 42.10 applies here too: `GITHUB_TOKEN` deliberately cannot push changes to workflow files, and cannot trigger further workflow runs, to prevent infinite loops and privilege escalation.
19. The honest version, and it is a real trade-off. OIDC federation is more setup than pasting a token. For a one-person hobby project a short-lived fine-grained PAT is a reasonable choice. For anything with real secrets, the setup cost is paid once and removes a whole class of incident.

■ 42.11.6 WORDS – remember these

Bearer credential — whoever holds it, is you — a token requiring no proof of possession beyond presenting it.

OAuth — letting an app act for you without your password — the delegation framework of RFC 6749, exchanging a user approval for a scoped token.

GitHub App — a robot with its own identity and badge — an installable actor with per-repository permissions and one-hour installation tokens.

Installation access token — an app's short-lived key to one installation — a token valid for 1 hour, scoped to the repositories the app is installed on.

OIDC federation — proving who you are instead of holding a secret — exchanging a signed job description for short-lived cloud credentials.

Blast radius — how much damage one leak causes — the set of resources and the time window a compromised credential can affect.

42.12 Practical hardening for a developer's own machine

■ 42.12.1 PLAIN – in simple words

1. Most security advice is too long to follow. Here is the short version that actually pays for itself.
2. Put a passphrase on every private key. It is the difference between a stolen laptop being embarrassing and being catastrophic.
3. Use the SSH agent so the passphrase costs you one typing per day, not one per push.
4. Make a different key on every machine. Never copy a private key between machines, not even your own.
5. The reason is simple. If you lose one machine, you remove one key. If you copied one key everywhere, you have to replace it everywhere at once, in a hurry, while panicking.
6. Look at your list of keys and tokens once or twice a year and delete the ones you cannot account for.
7. On any server you run yourself, turn password logins off entirely. Keys only.
8. Install a small program that bans addresses which repeatedly fail to log in. It is not clever, but it removes most of the noise.
9. Moving SSH to a port other than 22 stops the automated scanning almost completely. Be honest that this hides the door, it does not lock it.
10. And know in advance what you will do when a key or token leaks, because the first ten minutes decide how bad it gets.

■ 42.12.2 PLAIN – a picture in your head

1. Think of the difference between a bicycle lock and a bicycle in a locked shed.
2. A passphrase on your key is the lock. Someone who takes the bicycle still cannot ride away immediately.
3. Separate keys per machine is owning three cheap bicycles instead of one expensive one. Losing one is annoying, not ruinous.
4. Disabling password login on your server is removing the letterbox that people keep pushing lock-picks through.
5. Banning repeat offenders is a doorman who remembers faces.
6. Changing the port is painting the shed to look like a hedge. Any determined person who walks the whole street still finds it.
7. That last one is worth doing anyway, not because it stops attackers, but because it stops your log file filling with thousands of pointless entries and hiding the one that matters.

Where this comparison breaks:

8. A thief must be physically present. An attacker scans the entire internet's address space in hours, so "nobody would bother with my little server" is simply false. Everything is scanned, all the time, automatically.

■ 42.12.3 PLAIN – a worked example

1. A complete setup for a new machine, in order, with real commands.

```
# 1. one key, this machine, with a passphrase
$ ssh-keygen -t ed25519 -C "you@laptop-2026"

# 2. keep it in the agent so you type it once
$ ssh-add -t 8h ~/.ssh/id_ed25519

# 3. check what the agent holds
$ ssh-add -l
256 SHA256:WH1E2gSLhG6FgMsha//GINoq... (ED25519)

# 4. add the public half to GitHub, then test
$ ssh -T git@github.com
```

2. A minimal safe ~/.ssh/config for that machine:

```
Host *
    AddKeysToAgent yes
    IdentitiesOnly yes
    ServerAliveInterval 60
    HashKnownHosts yes
```

3. On a server you own, the three lines in /etc/ssh/sshd_config that matter most:

```
PasswordAuthentication no
KbdInteractiveAuthentication no
PermitRootLogin prohibit-password
```

4. Always test in a second terminal before closing the first one. Locking yourself out of a remote machine is a rite of passage that is best skipped.
5. Adding a passphrase to a key that has none, without regenerating it:

```
$ ssh-keygen -p -f ~/.ssh/id_ed25519
Enter old passphrase:
Enter new passphrase:
```

6. Checking whether a key file is encrypted at all. An unencrypted OpenSSH private key contains the string `none` twice near the start of the base64, for the cipher and the key derivation function.

■ 42.12.4 PLAIN – what is really happening inside

1. A passphrase does not scramble the whole key file with the passphrase directly. That would be weak, because people choose short passphrases.
2. Instead the passphrase is fed through a slow, deliberately expensive function to derive an encryption key. Then that derived key encrypts the private key.
3. Slow is the point. If each guess costs a fraction of a second instead of a microsecond, a guessing attack becomes hundreds of thousands of times more expensive.
4. When you type the passphrase, the same derivation runs, the file is decrypted in memory, and the plain key is handed to the agent.
5. From then until the agent is emptied or stopped, the unlocked key exists in that process's memory and nowhere else on disk.
6. A ban tool such as `fail2ban` works by reading the authentication log, matching failure lines with a pattern, counting them per source address, and inserting a firewall rule when a threshold is crossed.
7. It is not intelligent and it does not need to be. Automated scanners do not adapt; they move to the next address.
8. Changing the port works for the same unglamorous reason. Mass scanners prioritise port 22 because that is where the yield is. A different port is still found by a full port scan, just far less often.

■ 42.12.5 TECHNICAL – the engineer's version

1. Key encryption in the OpenSSH format uses `bcrypt_pbkdf`, a password-based key derivation function built on `bcrypt`, introduced with the new private key format in OpenSSH 6.5, January 2014.
2. The work factor defaults to 16 rounds and is adjustable at generation time:

```
$ ssh-keygen -t ed25519 -a 100 -C "you@laptop"
```

3. `-a 100` sets 100 KDF rounds. It makes unlocking take noticeably longer for you, and proportionally longer for anyone brute-forcing the file.
4. Since OpenSSH 7.8, August 2018, the OpenSSH format is the default for all key types, replacing the old PEM format which used a weak MD5-based derivation.
5. Server hardening, the directives that matter and what each removes:

Directive	Value	Removes
<code>PasswordAuthentication</code>	<code>no</code>	guessing attacks
<code>PermitRootLogin</code>	<code>prohibit-password</code>	direct root by password
<code>MaxAuthTries</code>	<code>3</code>	long guessing sessions
<code>AllowUsers</code>	<code>list</code>	logins by other accounts
<code>PermitEmptyPasswords</code>	<code>no</code>	the worst case
<code>LoginGraceTime</code>	<code>30</code>	held-open connections

6. Validate before restarting, every time:

```
$ sudo sshd -t
$ sudo systemctl reload ssh
```

7. fail2ban reads `/var/log/auth.log` on Debian-family systems or the journal on others. A typical jail:

```
[sshd]
enabled = true
port    = 22
maxretry = 4
findtime = 600
bantime  = 3600
```

8. That bans an address for one hour after four failures within ten minutes. With PasswordAuthentication no already set, the practical benefit is log volume rather than security, which is still a real benefit.
9. sshguard and CrowdSec are alternatives; CrowdSec additionally shares reputation data across participants.
10. Changing the port. State the honest position clearly, because both exaggerations are common.
11. It is **security through obscurity**. It provides no protection against anyone who scans your ports, which any real attacker does.
12. It does reliably remove the overwhelming majority of automated noise, because mass scanners target 22 by default. Measured on typical internet-facing hosts, failed login attempts commonly drop by more than 95 percent.
13. So the correct framing is: it is a log hygiene measure with a security side effect, and it must never be the only measure.
14. Note also that ports below 1024 require root to bind, so a high port such as 2222 is bindable by an unprivileged process, which is a small argument against picking a high port on a shared machine.
15. Key rotation, as a routine rather than an emergency:

Credential	Suggested cycle
SSH key, laptop	yearly, or on loss
SSH key, server	on rebuild
Classic PAT	90 days
Deploy key	yearly
App private key	yearly

16. **Leak response**, and this is the part to rehearse. The order matters more than the speed.
17. For an SSH key: remove the public key from every account and server that has it. GitHub's SSH key page shows a last-used date for each key, which is the fastest way to spot one you do not recognise.
18. For a token: revoke it in settings. Instant.
19. Then, in both cases, review what was done. Check the account security log, the organization audit log, and the repository's recent pushes.
20. Look specifically for the standard persistence tricks: a newly added SSH key, a new deploy key, a new webhook, a new collaborator, a changed workflow file, or a new GitHub App installation.

21. Then rotate everything the compromised credential could read. A token with repo scope could read every secret ever committed to any repository it reached, including ones you deleted from the working tree but not from history.
22. Finally, write down what happened and how the credential got out. Almost every leak is one of four things: committed to a repository, pasted into a chat or ticket, printed in CI logs, or left on a machine that was lost.

■ 42.12.6 WORDS – remember these

Passphrase — a secret that unlocks your key file — a user secret fed through a KDF to derive the key that encrypts the private key at rest.

`bcrypt_pbkdf` — the slow function guarding your key file — the KDF used by the OpenSSH private key format, with an adjustable rounds parameter.

`fail2ban` — a doorman that remembers repeat offenders — a log-scanning daemon inserting temporary firewall bans after repeated authentication failures.

Security through obscurity — hiding rather than locking — a measure that raises the cost of finding a service without raising the cost of attacking it.

Key rotation — replacing credentials on a schedule — periodic reissue and retirement, limiting the useful lifetime of an undetected compromise.

Persistence — what an attacker leaves behind — added keys, hooks, collaborators or workflow changes that survive the original credential being revoked.

42.13 A diagnosis table for git authentication failures

■ 42.13.1 PLAIN – in simple words

1. Almost every git authentication problem announces itself with one specific sentence.
2. If you learn to read those sentences, you stop guessing and start fixing.
3. There are three questions to ask in order, and they narrow it down fast.
4. First: how long did it take? Instant means somebody replied. Half a minute of silence means the network.
5. Second: did it ask for a user name or password? That means it wanted a credential and either had none or was told the one it had was wrong.
6. Third: did it mention SSH keys, or a repository name, or a scope? Each of those points at a different layer.
7. The most misleading message of all is `Repository not found`, because it usually does not mean the repository is missing.
8. It usually means your credential is not allowed to see it, and the server is refusing to confirm that it exists.

■ 42.13.2 PLAIN – a picture in your head

1. Think of a doctor listening to a description of symptoms.
2. “It hurts when I press here” narrows things down enormously, far more than “I feel unwell”.
3. Error messages are the same. `Permission denied (publickey)` is “it hurts when I press here”. `Push failed` is “I feel unwell”.
4. So the first job is always to find the most specific line in the output, not the last line.

- Git prints the summary last and the cause first. People read the last line and miss the answer three lines above it.

Where this comparison breaks:

- A patient can be asked follow-up questions. A one-shot error message cannot, which is why the verbose flags exist.

■ 42.13.3 PLAIN – a worked example

- Get more information before guessing. Two flags do almost everything.

```
# for SSH remotes, ask ssh to narrate
$ GIT_SSH_COMMAND="ssh -vvv" git push origin main

# for HTTPS remotes, ask git to narrate
$ GIT_TRACE=1 GIT_CURL_VERBOSE=1 git push origin main
```

- And the single most useful check for SSH, which tests only the connection and touches no repository:

```
$ ssh -T git@github.com
Hi USERNAME! You've successfully authenticated, but GitHub
does not provide shell access.
```

- That message is a success. The words “does not provide shell access” alarm people every time. GitHub is not a shell server; it only runs git commands.
- If that greets you by name, your key and your network are both fine, and any remaining problem is about a specific repository or a specific push.

■ 42.13.4 PLAIN – what is really happening inside

- The reason one problem produces several different messages is that several independent programs are involved, each with its own vocabulary.
- Your kernel produces `Connection refused` and `Connection timed out`. These are TCP-level outcomes and mention no names.
- ssh produces `Permission denied (publickey)` and `Host key verification failed`. These are SSH-level and mention keys.
- curl inside git produces HTTP status codes and TLS errors.
- GitHub’s own server produces every line beginning with `remote:.` Those are the only messages that reflect a decision by GitHub rather than a failure of plumbing.
- So the prefix tells you the layer. A line starting with `remote:` came from the far end and means you got there. A line starting with `ssh:` means you did not.

■ 42.13.5 TECHNICAL – the engineer’s version

- The table. Each row is an exact string you will see.

Error text	Meaning
Permission denied (publickey)	key not accepted
Invalid username or password	token wrong or gone
without workflow scope	scope missing
Host key verification failed	known_hosts mismatch
Connection timed out	packets dropped

Error text	Meaning
port 22: Connection refused	reached, nothing there
Repository not found	usually no permission
non-fast-forward	branch behind, not auth

2. Now each one in full, with the action to take.
3. **git@github.com: Permission denied (publickey)**. SSH connected and the server rejected every key offered. Causes, in order of likelihood: the public key was never added to the account; the agent is empty; the wrong key is being offered; IdentityFile points at the public key by mistake; on your own server, wrong permissions on ~/.ssh or authorized_keys. Check with `ssh -T git@github.com` and `ssh-add -l`. On a server you control, read the server log, which is the only place bad ownership or modes appears.
4. **remote: Invalid username or password.** or **remote: Support for password authentication was removed on August 13, 2021.** The HTTPS credential is not valid. Either it is an account password, which has not worked since that date, or the token expired, was revoked, or was for a different account. Clear the cached credential with `git credential reject` or the platform keychain command, then retry so you are prompted afresh.
5. **! [remote rejected] main -> main (refusing to allow a Personal Access Token to create or update workflow ... without workflow scope)** The credential is valid. The push touched .github/workflows/. Add the workflow scope to the token, or the Workflows write permission to a fine-grained token, then push again. Nothing was written; the branch is unchanged.
6. **Host key verification failed.** The server's key does not match the saved one, or you declined the prompt. Compare the printed fingerprint against the operator's published one before doing anything else. If and only if it matches, remove the stale entry with `ssh-keygen -R github.com` and reconnect. Never delete the file wholesale to make a warning go away.
7. **ssh: connect to host github.com port 22: Connection timed out** Nothing replied. Port 22 is filtered on this network, or the path is broken. Test 443 as a control. Fix with an HTTPS remote or the `ssh.github.com` port 443 configuration in 42.7. Expect roughly 15 to 130 seconds before this message appears, depending on the system.
8. **ssh: connect to host X port 22: Connection refused** The opposite of the above and far friendlier. Something answered and said no. The host is reachable and nothing is listening on 22. Either sshd is not running, or it listens on another port. Measured in milliseconds, not seconds.
9. **remote: Repository not found.** followed by **fatal: repository ... not found**. Read this as "not found for you". Causes: a typo in the owner or repository name; the repository is private and your credential lacks access; you are authenticated as a different account than you think; a classic token without repo scope, which cannot see private repositories at all; an organization with SAML single sign-on where the token has not been authorized for that organization.
10. Why 404 rather than 403? Because returning 403 would confirm the repository exists. GitHub deliberately returns "not found" to anyone not permitted to know. We measured this directly in 42.8: an anonymous request for a nonexistent repository returned 401, not 404.
11. **! [rejected] main -> main (non-fast-forward) or (fetch first)**. Not an authentication problem at all. Your branch is behind the remote. `git fetch` then rebase or merge. If you push after a rebase, use `--force-with-lease`, never plain `--force`.
12. **send-pack: unexpected disconnect while reading sideband packet** The connection died while git was reading the server's response. This is the error the reader saw twice during a network outage.

13. It deserves a paragraph of its own because it is the most dangerous message in this list, and for a reason that is not obvious.
14. It tells you the response was lost. It tells you nothing about whether the write landed. The server may have applied your push completely and then failed to tell you.
15. So never assume either outcome. Re-query the actual state: `git ls-remote origin refs/heads/main` and compare the hash against your local commit.
16. Do not trust `origin/main` in your local repository either. That is a remote-tracking reference, which is a cached copy of what the remote said last time you successfully spoke to it. During an outage it is stale by definition.
17. Two more you will meet:
18. **Too many authentication failures** The agent offered more keys than the server's `MaxAuthTries` allows before you got to the right one. Fix with `IdentitiesOnly yes` and an explicit `IdentityFile` for that host.
19. **sign_and_send_pubkey: signing failed: agent refused operation** The agent has the public key but cannot use the private key. Usually a key added from a file that has since changed, or a hardware key that needs a touch. Run `ssh-add -D` then re-add.
20. A general ordering rule that resolves most confusion: read the output from the top, find the first line that names a cause, and ignore the summary at the bottom. `error: failed to push some refs` is never the reason.

■ 42.13.6 WORDS - remember these

`remote:` prefix — a line that came from the server — output relayed from the far end, proving the connection and authentication both worked.

Sideband — the side channel carrying server messages — the multiplexed stream in the pack protocol used for progress and error text.

Remote-tracking reference — your cached note of what the server said — `refs/remotes/origin/main`, updated only on a successful fetch or push.

`--force-with-lease` — force push, but safely — a push that refuses if the remote moved since your last fetch, unlike plain `--force`.

`ls-remote` — ask the server what it actually has — a command querying live references without touching your working tree.

SAML SSO authorization — an extra approval step for org access — an organization requirement that a token be separately authorized before it can reach that organization's repositories.

42.98 Common wrong ideas

1. Wrong: SSH and HTTPS reach different copies of the repository, so switching loses work. Right: it is one repository. Only the road changes. Switching is one `git remote set-url` and nothing is lost.
2. Wrong: the private key is sent to the server, so publishing the public key is risky too. Right: the private key never moves. The server sends data, your machine signs it, and only the signature crosses the network. The public key is designed to be pasted into web forms on purpose.
3. Wrong: `Permission denied (publickey)` means the key is wrong. Right: it also appears when `~/.ssh` or `authorized_keys` has loose permissions, when the agent is empty, and when too many wrong keys were offered first. Only the server log distinguishes them.

4. Wrong: the host key warning is a nuisance, so delete `known_hosts`, and anyway a change always means an attack. Right: both halves are wrong. It is the one warning that detects an interceptor, so compare the fingerprint against a published one and remove only the stale entry. And GitHub legitimately rotated its RSA host key at about 05:00 UTC on 24 March 2023.
5. Wrong: port 22 being blocked means GitHub is down, and a blocked port fails immediately. Right: on the machine used for this chapter, port 22 timed out after 30.057 seconds while port 443 connected in 0.021 seconds to the same host. A DROP sends nothing back, so your machine retries with doubling gaps and hangs. Only a REJECT fails fast, with `Connection refused`.
6. Wrong: a token is just a password with extra steps. Right: a token can be scoped to specific actions, expire on a date, and be revoked alone. A password can do none of those things, which is why GitHub stopped accepting passwords for git on 13 August 2021.
7. Wrong: the repo scope includes everything, so a push cannot be refused for permissions. Right: repo does not include workflow. A push touching `.github/workflows/` is refused without it, even though authentication succeeded and every object transferred.
8. Wrong: `remote rejected` means the network dropped the push. Right: the word `remote:` proves you reached the server and it answered in sentences. That is a policy decision, not a transport failure.
9. Wrong: `Repository not found` means the repository does not exist. Right: it usually means your credential may not see it. GitHub returns “not found” rather than “forbidden” so it does not confirm that a private repository exists.
10. Wrong: changing the SSH port secures a server, and agent forwarding is just a convenience toggle. Right: a different port only removes automated scanning noise, since a real attacker scans all ports. And root on the machine you forwarded to can use your agent silently, against every server your keys open, for as long as you stay connected. Prefer ProxyJump.

42.99 Chapter summary in 20 lines

1. Git borrows two transports: SSH on TCP 22 and HTTPS on TCP 443. The repository is identical either way; only the road and the credential differ.
2. Over SSH, git logs in as the user `git` and runs one command remotely, `git-upload-pack` or `git-receive-pack`. Over HTTPS it makes one GET and one POST.
3. SSH was written by Tatu Ylonen at Helsinki University of Technology in 1995 after a password-sniffing attack, replacing telnet, rlogin and rsh, which sent passwords in clear text.
4. SSH-2 replaced the structurally flawed SSH-1 and is specified in RFC 4251 to RFC 4254. OpenSSH forked from Bjorn Gronvall’s OSSSH on 26 September 1999 and shipped with OpenBSD 2.6 on 1 December 1999.
5. SSH-2 has three layers: transport for encryption and host key verification, user authentication, and connection for multiplexed channels.
6. A key pair splits into a private key that signs and a public key that only verifies. Publishing the public half is safe; the private half never leaves your machine.
7. Authentication is challenge-response: the client signs a block containing the session identifier, so an old signature cannot be replayed and a man-in-the-middle cannot forward yours.
8. Ed25519 is the current recommendation: deterministic signatures, 32-byte public keys, published parameter rationale, RFC 8709. RSA 2048 is the floor and 4096 is common. DSA is removed everywhere.
9. `authorized_keys` is a plain text file of public keys. Wrong permissions make the server ignore it and return `Permission denied (publickey)` with no explanation to the client.

10. Options in front of a key restrict it: `command=`, `from=`, `no-port-forwarding`, and `restrict` for everything at once. Deploy keys are the per-repository variant.
11. `known_hosts` is the other half nobody reads. The server proves itself first, and the first connection is trust on first use, which is the model's honest weakness.
12. GitHub rotated its RSA host key at about 05:00 UTC on 24 March 2023 after the private key was briefly exposed publicly. That is what a legitimate change looks like.
13. The agent holds unlocked keys and signs on request, so the key never leaves its memory. Agent forwarding lets root on the remote host use your keys and should be replaced by ProxyJump.
14. Port 22 is commonly filtered outbound because it is heavily scanned and useful for exfiltration, while 443 must stay open or the web breaks. A DROP hangs for tens of seconds; a REJECT refuses in milliseconds.
15. The two fixes are switching the remote to HTTPS, or using GitHub's SSH endpoint `ssh.github.com` on port 443 with a four-line `~/.ssh/config` block.
16. GitHub removed password authentication for git operations on 13 August 2021. Credential helpers now store tokens, in the OS keychain if you are careful and in plain text if you use `store`.
17. A token can be scoped, can expire and can be revoked alone. Its prefix, `ghp_` or `github_pat_`, exists so that secret scanning can find it, and push protection blocks it before it ever leaks.
18. A scope is a named permission checked at the moment of the operation. Pushing a file under `.github/workflows/` needs `workflow`, because changing CI changes what runs on GitHub's runners with the repository's secrets.
19. Distinguish the three "push failed" cases by evidence: silence and a long wait is network, a credential prompt or `Invalid username is authentication`, and `! [remote rejected]` with a sentence is authorization.
20. Four identities with four blast radii: SSH keys, personal access tokens, OAuth grants and GitHub Apps. CI should hold no long-lived secret at all and use short-lived OIDC-federated credentials instead.

Cloud Computing, the Bezos Mandate, AWS and Azure

43.0 What this chapter gives you

1. You will be able to say what “the cloud” actually is in one plain sentence, without any mystery, and say exactly what it changed and what it did not.
2. You will be able to describe a real datacentre from the outside wall to the individual server, including power, cooling and what a rack unit is.
3. You will be able to explain regions, availability zones and edge locations precisely, and name the real regions the big three run inside India.
4. You will be able to explain what a hypervisor does, why virtual machines became cheap, and how special hardware removed the last of the overhead.
5. You will be able to state clearly that a container is a process, not a small virtual machine, and name the exact Linux features that make it work.
6. You will be able to read a Dockerfile, a Kubernetes manifest and a Terraform file line by line, and say what each line causes to happen.
7. You will be able to quote the 2002 Bezos API mandate, explain why it forced Amazon to build a platform, and say honestly what it cost.
8. You will be able to tell the true story of how AWS started, and correct the popular myth about spare retail capacity with evidence.
9. You will be able to name the eighteen AWS services you meet in real work, say what problem each solves, and map each to Azure and Google Cloud.
10. You will be able to read a cloud bill, predict where it will explode, and argue both sides of the buy-versus-rent question with real numbers.

43.1 What the cloud actually is

■ 43.1.1 PLAIN – in simple words

1. The cloud is somebody else’s computers, sitting in somebody else’s building.
2. You rent them by the hour or by the second, instead of buying them.
3. You reach them over the internet, and you never touch them physically.
4. That is the whole idea. There is nothing floating in the sky.
5. The word “cloud” came from old network drawings, where people drew a fuzzy cloud shape to mean “the internet, and we are not going to draw the details”.
6. So “in the cloud” originally just meant “over there, past our own wires”.
7. Four things genuinely changed when this became a business you could buy.

8. First, **elasticity**: you can ask for 200 machines at 9am and give them back at 11am, and pay only for those two hours.
9. Second, **pay per use**: no big purchase up front, no machine sitting idle.
10. Third, **self-service**: you get the machines by making a request from a program, in seconds, with nobody's approval and no phone call.
11. Fourth, somebody else deals with the building, the power, the cooling, the broken disks and the security guard at the door.
12. Here is what did not change. These are still real physical computers.
13. They still overheat, lose power, lose disks and lose network cables.
14. Your program can still be slow, still be wrong, and still fall over.
15. The cloud moved the pain. It did not delete the pain.

■ 43.1.2 PLAIN - a picture in your head

1. Think about how you get electricity in your home.
2. You do not own a generator. You do not buy fuel or service a machine.
3. You plug in, you use what you need, and once a month a meter reading turns into a bill.
4. If you buy an air conditioner, you do not have to also buy a bigger generator. You just use more, and the bill goes up.
5. If you go away for a month, you use almost nothing, and you pay almost nothing.
6. Somebody else runs enormous power stations so that you can avoid running a small one badly.
7. Renting computers works the same way. Amazon, Microsoft and Google run the enormous machine rooms so that you can avoid running a small one badly.
8. This comparison is not new. The writer Nicholas Carr made it the centre of his 2008 book *The Big Switch*, comparing cloud computing with the way factories stopped running their own power plants a century earlier.

Where this comparison breaks: electricity is one product. One volt is like any other volt, and you can change supplier without rewiring your house. Cloud services are all different from each other, and moving from one supplier to another means rewriting real code. Also, electricity is metered on one dimension. A cloud bill meters compute time, storage, requests, data movement, addresses and dozens of other things at once, and the surprise is almost always in a dimension you were not watching.

■ 43.1.3 PLAIN - a worked example

1. You are two students launching a website for a college festival.
2. Old way: you buy one server. Say it costs 90,000 rupees, plus a rack space rental, plus a person to look after it.
3. You must guess the busiest moment months in advance and buy for that.
4. On the festival night 40,000 people arrive at once. Your one server dies.
5. For the other 360 days of the year, the server is 3 per cent busy, and you have paid for all of it anyway.
6. Cloud way: you rent two small machines for the quiet months. On festival night you rent forty machines for six hours, then give them back.

Approach	Quiet month	Festival night
Own one server	Paid in full	Site falls over
Rent, fixed size	Pay 2 machines	Site falls over

Approach	Quiet month	Festival night
Rent, elastic	Pay 2 machines	Pay 40 for 6 hours

7. Real prices, from the AWS public price list for the North Virginia region in August 2026: a small t3.medium machine costs 0.0416 US dollars per hour.
8. Forty of them for six hours is $40 \times 6 \times 0.0416 = 9.98$ US dollars.
9. That is the actual thing that changed. Ten dollars, decided at 7pm, with no purchase order and no meeting.

■ 43.1.4 PLAIN – what is really happening inside

1. You send a small message over the internet to the provider’s control system. It says, in effect, “give me one machine of this size, in this place”.
2. That message is a normal web request, signed with your secret key so the provider knows it is really you.
3. A piece of software called the **control plane** takes the request. Its job is to decide and to record, not to run your program.
4. It finds a physical server in the right building that has room, and picks it.
5. On that physical server, a program called a **hypervisor** carves out a slice: some processor time, some memory, some disk, one network address.
6. It boots an operating system into that slice from a saved disk image.
7. Within about 30 to 60 seconds, that slice answers to a network address, and you can log in as if it were a computer on your desk.
8. Everything after that is ordinary computing. The slice does not know or care that it is a slice.
9. A separate meter records that this slice existed, second by second, and that record eventually becomes a line on your bill.
10. When you say “delete it”, the hypervisor throws the slice away and the physical server is offered to the next customer.

■ 43.1.5 TECHNICAL – the engineer’s version

1. The working definition of cloud computing is not marketing. It is a standard document: NIST Special Publication 800-145, published September 2011 by the United States National Institute of Standards and Technology.
2. It names five essential characteristics. A service is only cloud computing if it has all five.
3. On-demand self-service: the consumer provisions capacity unilaterally, with no human interaction with the provider.
4. Broad network access: capabilities are available over the network through standard mechanisms.
5. Resource pooling: physical and virtual resources are pooled and assigned to many consumers, with location independence at some level of abstraction.
6. Rapid elasticity: capabilities can be scaled outward and inward, in some cases automatically, and appear unlimited to the consumer.
7. Measured service: use is metered and reported, giving transparency to both sides.
8. The same document names three service models, IaaS, PaaS and SaaS, and four deployment models: private, community, public and hybrid.
9. That test is genuinely useful. A rented server with a two-week ticket queue fails point three and point six, and is therefore hosting, not cloud.
10. Scale of the industry, from published company filings. Amazon reported AWS net sales of 128,725 million US dollars for the full year 2025, with segment operating income of 45,606 million.

11. In the quarter ending June 2026 AWS reported 42.2 billion US dollars, up 37 per cent year on year, an annualized run rate near 169 billion.
12. Microsoft first disclosed Azure's own revenue for its fiscal year 2025, at 75 billion US dollars, and reported that Azure passed 100 billion for fiscal 2026, growing 41 per cent.
13. Alphabet reported Google Cloud revenue of 17.664 billion US dollars for the quarter ending December 2025, up 48 per cent, and said the business ended 2025 at an annual run rate above 70 billion.

Provider	Latest disclosed figure	Period
AWS	128.7 bn USD	Full year 2025
Azure	Over 100 bn USD	Fiscal year 2026
Google Cloud	17.7 bn USD	Q4 2025 quarter

14. Commands that make the abstraction visible: `aws ec2 describe-instances`, `az vm list`, `gcloud compute instances list`. Each is a signed web request to a control plane, nothing more.

■ 43.1.6 WORDS – remember these

1. Cloud — renting computers you reach over the internet — on-demand, self-service, metered, pooled and elastic computing per NIST SP 800-145.
2. Elasticity — getting more and giving it back quickly — automatic or manual scaling of provisioned capacity in both directions.
3. Control plane — the part that decides and records — the API and orchestration layer that provisions and tracks resources.
4. Data plane — the part that does the actual work — the running instances, packets and stored bytes themselves.
5. Provisioning — asking for and receiving a resource — the allocation of capacity to a tenant in response to an API call.
6. Tenant — one paying customer sharing the hardware — an isolated account whose workloads share pooled physical resources.

43.2 Inside a real datacentre

■ 43.2.1 PLAIN – in simple words

1. A datacentre is a warehouse full of computers, built so they never stop.
2. Inside, computers are not on desks. They are bolted into tall metal frames called **racks**, like books on a shelf but lying flat.
3. Each computer is a flat metal tray about as wide as a shelf and as thick as a few textbooks. Rows of them fill each rack from floor to head height.
4. Every rack has a small switch at the top that all its computers plug into.
5. Those switches plug into bigger switches, which plug into the internet.
6. Power comes in from the electricity grid, on two separate paths, so that one failure does not stop the room.
7. Between the grid and the computers sit big batteries, which cover the few seconds of a cut, and diesel generators, which cover the hours.
8. All that electricity turns into heat, so a large part of the building is machinery for taking heat away.
9. Cold air is pushed up through the floor into one aisle, sucked through the computers, and comes out hot into the next aisle.

10. Getting in is hard on purpose: fences, cameras, guards, card and fingerprint doors, and a locked cage around your own rack.
11. These buildings are enormous. A big one holds tens of thousands of computers and uses as much electricity as a small city.

■ 43.2.2 PLAIN – a picture in your head

1. Think of a very large library.
2. The racks are the shelves, standing in long parallel rows.
3. Each server is one book lying flat on the shelf, and the shelf spacing is fixed so books of standard thickness always fit.
4. Every row of shelves has a librarian at the end of it, the top-of-rack switch, who handles all messages in and out of that row.
5. The librarians all report to a small group of head librarians, and any librarian can reach any other through any head librarian.
6. The reading rooms alternate: one cold room, one warm room, one cold, one warm, because readers give off heat and you keep the cold air away from the warm exhaust.
7. The building has its own power station in the yard, in case the city cuts supply, and a battery room that keeps the lights on while it starts.

Where this comparison breaks: a library's books are the point of the library. Here, the servers are interchangeable and expected to die. Roughly two to five per cent of servers fail in a year, and staff replace them without anybody noticing. Also, a library is quiet. A datacentre hall is loud enough that long-stay staff wear ear protection, because thousands of fans are running.

■ 43.2.3 PLAIN – a worked example

1. Take one standard rack. The width of the mounting rails is 19 inches, which is 482.6 millimetres. This is the EIA-310 standard, and it dates from telephone equipment in the 1920s.
2. Height is measured in **rack units**, written U. One U is 1.75 inches, which is 44.45 millimetres, exactly.
3. A common rack is 42U tall, about 1.87 metres of usable height.
4. A basic web server is 1U thick. So 42 of them fit, minus space for switches and cable management. In practice you plan for about 38 servers plus 2 switches.
5. Now the power. Suppose each server draws 350 watts on average.
6. $38 \times 350 \text{ W} = 13,300 \text{ W}$, which is 13.3 kilowatts for one rack.
7. An older datacentre was designed for 5 to 10 kilowatts per rack, so that rack would not fit its power budget. You would fill the rack only half full.
8. A modern rack of graphics processors for artificial intelligence work is a different animal. An NVIDIA GB200 NVL72 rack draws up to about 120 kilowatts, which is roughly what forty Indian homes use at peak.
9. Air cannot carry that much heat away. Those racks are water-cooled, with cold liquid piped directly onto the chips.

Rack type	Power per rack	Cooling
Legacy enterprise	5 to 10 kW	Air
Modern cloud	10 to 20 kW	Air, contained
AI training rack	Up to 120 kW	Direct liquid

■ 43.2.4 PLAIN – what is really happening inside

1. Grid electricity arrives at high voltage and is stepped down by transformers outside the building.
2. It passes through switchgear that can move the whole load from one source to another in a fraction of a second.
3. It then reaches the uninterruptible power supply, the UPS. This is a bank of batteries or a spinning flywheel.
4. The UPS is not there to run the building for hours. It is there to hold the load for the 10 to 30 seconds a diesel generator needs to start and take over.
5. Generators keep enough fuel on site for a day or more, with contracts for refuelling after that.
6. From the UPS, power goes to rack-level power strips, called PDUs. Servers have two power supplies, plugged into two independent strips, fed from two independent paths.
7. Cooling runs in a loop. Computer room air handlers blow cold air under a raised floor or through overhead ducts into the cold aisle.
8. Server fans pull that air front to back, over the hot parts, and blow it into the hot aisle behind.
9. Physical barriers, doors and roofs, seal the aisles so cold and hot air never mix. Mixing is the single biggest waste in a machine room.
10. The hot air returns to the coolers, gives its heat to a water loop, and the water carries the heat to chillers or to outdoor cooling towers.
11. For very hot racks, air is skipped entirely. A cold plate sits directly on the chip and water takes the heat out of the rack.
12. Meanwhile the network: each server has one or two cables to the switch at the top of its own rack, and those switches connect upwards to a layer of larger switches, so that any server can reach any other in a small, fixed number of hops.

■ 43.2.5 TECHNICAL – the engineer's version

1. Rack mechanics follow EIA-310-D. Rail spacing 19 inches, 1U equals 44.45 mm, common heights 42U, 45U, 48U and 52U, common depths 1000 to 1200 mm.
2. Rackmount servers are 1U, 2U or 4U. A 1U dual-socket server today typically holds 2 CPUs of 32 to 128 cores each, 12 to 32 memory slots and a handful of NVMe drives.
3. Blade servers put many thinner server modules into a shared chassis, sharing power supplies, fans and network fabric. They win on density and cabling and lose on vendor lock-in. Hyperscale operators mostly use custom rackmount designs instead, following the Open Compute Project, which Facebook founded in 2011.
4. Network topology is **spine-leaf**, also called a folded Clos network after Charles Clos's 1953 telephone switching paper. Every leaf connects to every spine, and no leaf connects to another leaf.

Any server to any server: leaf -> spine -> leaf. Two hops.
Add a spine to add bandwidth. Add a leaf to add racks.

5. Leaf switches are the top-of-rack switches, typically 48 ports of 25 or 100 gigabits per second down to servers, and 4 to 8 uplinks of 100 to 400 gigabits per second up to the spine.

6. The ratio of downlink to uplink bandwidth is the **oversubscription ratio**. 3:1 is common in general fleets. Storage and AI clusters are built at 1:1, meaning non-blocking.
7. Power redundancy is described as N, N+1 or 2N. The Uptime Institute Tier classification runs Tier I to Tier IV, where Tier III allows concurrent maintenance and Tier IV is fault tolerant.
8. ASHRAE Thermal Guidelines class A1 recommends an inlet temperature of 18 to 27 degrees Celsius. Operators run near the top of that band deliberately, because warmer air needs less chilling.
9. **Power usage effectiveness**, PUE, is total facility power divided by IT equipment power. A PUE of 2.0 means one watt of overhead for every watt of computing. The theoretical floor is 1.0.

Operator or group	PUE	Source year
Global average	1.54	Uptime 2025 survey
Hyperscale range	1.10 to 1.15	Uptime 2025 survey
Google fleet, TTM	1.09	Reported Q1 2026
Colocation and enterprise	1.58 to 1.80	Uptime 2025 survey

10. Google's published history shows fleet PUE falling from about 1.23 in 2008 to 1.09 today. The global average has been stuck near 1.54 since 2019, which is an honest and unflattering industry fact.
11. Physical security is audited, not asserted. The relevant reports are SOC 2 Type II, ISO/IEC 27001 and, for cardholder data, PCI DSS. Controls include perimeter fencing, vehicle barriers, two-factor mantrap entry, biometric readers, per-page access lists and asset destruction on decommission.
12. Scale and cost, from 2026 construction cost surveys: roughly 11.3 million US dollars per megawatt of IT capacity for a standard facility, and 20 million or more per megawatt for an AI-optimized build.
13. On that basis a 500 megawatt campus costs about 5.5 to 6 billion US dollars standard, or over 10 billion for a dense AI build. Electrical systems alone are 40 to 50 per cent of construction cost.
14. Microsoft stated that it deployed about 2 gigawatts of new datacentre capacity during its fiscal year 2025. That single year of one company is comparable to the entire generating capacity of a large power station.

■ 43.2.6 WORDS - remember these

1. Rack unit (U) — one shelf slot — 44.45 mm of vertical mounting height under EIA-310-D.
2. Top-of-rack switch — the small switch every server in a rack plugs into — the leaf layer of a Clos fabric, typically 48 x 25G with 100G uplinks.
3. Spine-leaf — a wiring plan where any machine is two hops from any other — a folded Clos topology with full leaf-to-spine meshing.
4. UPS — the battery that covers a power cut — an uninterruptible power supply sized to bridge to generator start, typically 10 to 30 seconds.
5. Hot and cold aisle — keeping cold air and hot exhaust apart — containment of supply and return airflow to prevent recirculation.
6. PUE — how much extra power the building wastes — total facility power divided by IT load, global average 1.54, hyperscale 1.10 to 1.15.
7. CRAC and CRAH — the room's air conditioners — computer room air conditioner with its own compressor, versus air handler fed by chilled water.

43.3 Regions, availability zones and edge locations

■ 43.3.1 PLAIN – in simple words

1. A **region** is a place on the map where a provider has built capacity. Mumbai is a region. Frankfurt is a region. Ohio is a region.
2. Regions are far apart, and they are run as almost separate businesses. Prices differ, and some services exist in one region and not another.
3. Inside a region there are **availability zones**. A zone is one or more buildings with its own power, its own cooling and its own network links.
4. Two zones in one region are close enough that talking between them is fast, but far enough apart that one flood, fire or substation failure cannot take out both.
5. That is the whole point. A zone is a **failure domain**: a boundary that damage is not supposed to cross.
6. So you never put your only copy of anything in one zone. You run at least two copies, in two zones, and something in front that sends traffic to whichever is alive.
7. An **edge location** is a third thing and much smaller. It is a small set of machines in many cities that hold copies of files and terminate connections close to users.
8. Edge locations make things feel fast. They do not run your application. Do not confuse them with regions.
9. Rule of thumb: zones protect you from a building. Regions protect you from a city or a country. Edge locations protect you from distance.

■ 43.3.2 PLAIN – a picture in your head

1. Think of a bank with branches.
2. A region is a city where the bank operates.
3. Availability zones are three separate branch buildings in that city, on different streets, on different electrical supplies.
4. If one branch burns down, your money is still in the other two, because the bank writes every transaction to all three before confirming it.
5. An edge location is an ATM. There are hundreds of them, in many towns, and they are fast to reach.
6. But an ATM cannot open an account or approve a loan. It holds cash and handles simple requests. For anything real it talks back to a branch.
7. Countries also have rules: some money must stay inside the country. That is data residency.

Where this comparison breaks: bank branches in a city are genuinely independent businesses that can run alone. Cloud availability zones share a regional control plane, and some regional services have components that live in only one zone. In the AWS event of 20 October 2025, one subsystem in one region failed and the effect was felt across the whole region and by customers worldwide, even though the individual zones had power and cooling the entire time.

■ 43.3.3 PLAIN – a worked example

1. You run a shop website for Indian customers. You pick the AWS Mumbai region, whose code name is `ap-south-1`.
2. That region has three availability zones, named `ap-south-1a`, `ap-south-1b` and `ap-south-1c`.
3. You place two web servers in zone a and two in zone b, with a load balancer in front that spreads traffic across both.
4. You place your database as a primary in zone a and a standby copy in zone b, with automatic promotion if the primary is lost.
5. Now zone a loses power. The load balancer stops sending traffic to the two dead servers within about 30 seconds. The database standby is promoted in one to two minutes. Customers see a short blip.
6. Cost of that safety: you run four servers where two would do, and you pay for traffic that crosses between zones, at 0.01 US dollars per gigabyte in each direction.
7. Now suppose the whole Mumbai region fails. Nothing you have deployed helps. Surviving that needs a second region, which needs a second copy of your data kept up to date, which is a much larger project.

■ 43.3.4 PLAIN – what is really happening inside

1. Zone names are shuffled per account on purpose. Your `ap-south-1a` and my `ap-south-1a` are usually different physical zones, so that customers do not all crowd into the alphabetically first one.
2. The stable identifier is a zone ID such as `aps1-az1`, which is the same for everyone. That is what you compare when you need to know two accounts are truly in the same building.
3. Between zones, the provider runs its own dedicated fibre, usually many redundant paths. Round trip time is typically well under two milliseconds.
4. Between regions, traffic crosses the provider's private long-distance backbone. Mumbai to Singapore is roughly 60 to 70 milliseconds round trip. Mumbai to North Virginia is roughly 190 to 220 milliseconds.
5. Those numbers come from the speed of light in glass and cannot be improved by any amount of money. Light travels about 200,000 kilometres per second in fibre, so 1,000 km of fibre costs about 5 milliseconds one way, before any switching delay.
6. A region failure, in practice, is rarely the building burning. It is far more often a software or configuration fault in a service that everything else in the region depends on, such as identity, DNS or the metadata store.
7. When that happens, machines that are already running usually keep running, but you cannot start new ones, cannot log in, and cannot change anything.

■ 43.3.5 TECHNICAL – the engineer’s version

1. Current published footprints, checked in August 2026. AWS states 123 availability zones across 39 geographic regions, with plans announced for the Kingdom of Saudi Arabia and Chile. Microsoft states over 70 Azure regions. Google states 43 regions and 130 zones.
2. AWS defines an availability zone as one or more discrete datacentres with redundant power, networking and connectivity, physically separated by a meaningful distance, up to 100 km apart, with single-digit millisecond latency between them.
3. Azure calls the equivalent an availability zone too, and pairs most regions into region pairs for platform-managed geo-replication. You cannot choose your pair.
4. Google Cloud calls them zones, and a zone is a deployment area within a region, isolated for failure purposes.
5. The India footprint, with names as the providers publish them:

Provider	Region name	Live from
AWS	Mumbai, ap-south-1	June 2016
AWS	Hyderabad, ap-south-2	21 Nov 2022
Azure	Central, South, West India	Sept 2015
Azure	India South Central	6 Aug 2026
Google	Mumbai, asia-south1	Nov 2017
Google	Delhi NCR, asia-south2	15 July 2021

6. Azure also offers Jio India West and Jio India Central, operated in partnership with Reliance Jio. Azure’s three 2015 regions are in Pune, Chennai and Mumbai; the 2026 India South Central region is in Hyderabad and opened with three availability zones.
7. AWS announced an investment of 4.4 billion US dollars in India by 2030 at the Hyderabad launch. Microsoft’s stated India commitment reached 20.5 billion US dollars by 2026, combining announcements from January 2025 and December 2025.
8. Data residency is a legal question, not a technical one. In India the relevant instruments are the Digital Personal Data Protection Act, 2023, and the Reserve Bank of India’s April 2018 directive requiring payment system data to be stored in India.
9. In the European Union it is the General Data Protection Regulation of 2016, applied from May 2018, plus sector rules and sovereign cloud offerings.
10. Choosing a region therefore has three inputs: latency to your users, price, and law. They frequently disagree.
11. The honest note on multi-region. Marketing implies you tick a box. The reality is that you must solve write conflicts, replication lag, failover orchestration, DNS behaviour under partial failure, cost of duplicated capacity, and testing.
12. Almost nobody tests region failover under load. A failover path that has never been exercised is a hypothesis, not a capability.
13. Real example to anchor this. On 20 October 2025 AWS suffered a major disruption in us-east-1, caused by a latent race condition in the automated DNS management of DynamoDB. The trigger occurred around 06:49 UTC, DNS was restored by 09:25 UTC, and full recovery of dependent systems such as EC2 instance launches continued until about 20:50 UTC the same day, with some Redshift work finishing the next morning.
14. Many companies that believed they were multi-region discovered that their identity provider, their build system or their DNS was single-region.

15. Commands to inspect this: `aws ec2 describe-availability-zones --region ap-south-1` shows both the name and the stable zone ID.

■ 43.3.6 WORDS – remember these

1. Region — a city-sized place where the provider has capacity — an independent deployment area with its own service catalogue, pricing and endpoints.
2. Availability zone — one building group with its own power — an isolated failure domain within a region, single-digit millisecond latency to peers.
3. Failure domain — the boundary damage should not cross — the blast radius of a single correlated fault.
4. Edge location — a small cache near users — a point of presence for content delivery and connection termination, not general compute.
5. Data residency — the rule that data must stay in a country — a legal obligation on storage location, distinct from encryption or access control.
6. Region pair — Azure's fixed partner region — a Microsoft-assigned pairing used for platform geo-replication and staged updates.

43.4 Virtualization, the technology that made cloud possible

■ 43.4.1 PLAIN – in simple words

1. One physical computer used to run one operating system, and that was that.
2. Most of the time it was mostly idle, waiting for something to do.
3. Virtualization is a trick that lets one physical computer pretend to be many separate computers at once.
4. The program that does the pretending is called a **hypervisor**.
5. It sits between the real hardware and the pretend computers, and it hands out slices of processor, memory, disk and network.
6. Each pretend computer is called a **virtual machine**. It boots its own operating system and believes it is alone.
7. It is not alone. Ten or forty of its neighbours are on the same metal, completely unaware of each other.
8. This is what made renting computers by the hour possible. Without it, giving a customer a machine would mean physically plugging one in.
9. With it, giving a customer a machine means writing a few numbers into a table and starting a process.
10. It also lets the provider move a running customer off a server that needs repair, without switching that customer off. That is called live migration.

■ 43.4.2 PLAIN – a picture in your head

1. Think of a large old house converted into flats.
2. The house is the physical server. The flats are the virtual machines.
3. Each family has its own front door, own kitchen, own furniture, and never sees the others.
4. There is one water main, one electricity supply and one roof, shared. A caretaker, the hypervisor, splits them fairly and stops one family from flooding another.
5. If one family plays loud music, the others may hear it a little. That is resource contention, the noisy neighbour problem.
6. If the caretaker needs to fix the roof over one flat, a very good caretaker can move the whole family, mid-dinner, to an identical flat next door, so fast they barely notice. That is live migration.

Where this comparison breaks: a family in a flat knows it is in a flat. A well built virtual machine genuinely cannot tell, by any ordinary means, that it is virtual. That indistinguishability is a formal design goal, stated by Gerald Popek and Robert Goldberg in their 1974 paper, and it is stronger than any housing analogy suggests. Also, the caretaker in this story has absolute power: the hypervisor can read every byte of every flat, which is why the trust model of the provider matters so much.

■ 43.4.3 PLAIN – a worked example

1. Take a physical server with 2 processors of 64 cores each, so 128 physical cores, plus 1,024 gigabytes of memory.
2. With hyper-threading on, the operating system sees 256 logical processors.
3. You want to sell virtual machines with 4 virtual processors and 16 gigabytes of memory each.
4. On memory alone, 1,024 divided by 16 gives 64 virtual machines, minus about 5 per cent kept for the hypervisor itself. Call it 60.
5. On processors, 60 virtual machines x 4 virtual processors = 240 virtual processors against 256 logical ones. That is roughly 1:1, no oversubscription.
6. If instead you sell to customers whose machines are usually idle, you might place 120 virtual machines, giving 480 virtual processors on 256 logical ones, an oversubscription ratio of nearly 2:1.
7. That is a business decision, not a technical one, and it is exactly why cheap virtual servers feel inconsistent and expensive ones do not.

Setting	Ratio	Effect on tenant
No oversubscription	1:1	Steady, predictable
Light, 2:1	2:1	Usually fine, sometimes slow
Aggressive, 8:1	8:1	Frequent stealing of time

8. You can measure this from inside a Linux guest. Run `top` and look at the `st` column, short for steal time. It is the percentage of time your virtual processor was ready to run but the hypervisor gave the physical core to somebody else. Anything consistently above 5 is a crowded host.

■ 43.4.4 PLAIN – what is really happening inside

1. A processor has at least two privilege levels: a privileged one for the operating system and an unprivileged one for applications.
2. Normally the operating system sits in the privileged level and controls the hardware directly.
3. Under virtualization, the hypervisor takes the privileged level, and the guest operating system is pushed down a level, even though it still thinks it is privileged.
4. When the guest executes an instruction that only a truly privileged program may run, the processor stops and hands control to the hypervisor. This is called a **trap**.
5. The hypervisor looks at what the guest was trying to do, does something safe and equivalent, and resumes the guest.
6. Memory is handled with two levels of translation. The guest maps its own pages as usual; the hardware then maps those again to real physical pages, using a second table the hypervisor controls.
7. Disks are usually just large files on the host, or slices of a network storage system. A write inside the guest becomes a write to that file.
8. Network cards are emulated or, better, partly real: modern cards can present many independent copies of themselves, and the hypervisor gives one copy directly to each guest.

9. Live migration works by copying memory pages to the destination host while the guest keeps running, repeatedly re-copying pages that changed, until the set of changed pages is small enough to copy in a brief pause.
10. That final pause is typically well under a second, and the guest's network connections survive because the address moves with it.

■ 43.4.5 TECHNICAL – the engineer's version

1. Gerald Popek and Robert Goldberg, in Formal Requirements for Virtualizable Third Generation Architectures, Communications of the ACM, July 1974, gave three requirements: equivalence, resource control and efficiency.
2. Their theorem: an architecture is classically virtualizable if the set of sensitive instructions is a subset of the privileged instructions.
3. x86 failed that test. John Robin and Cynthia Irvine identified 17 problematic instructions in a 2000 USENIX Security paper. Instructions such as P0PF silently did the wrong thing instead of trapping.
4. Two workarounds followed. VMware, founded in 1998, shipped binary translation: rewrite the guest's privileged instruction stream on the fly.
5. Xen, from the University of Cambridge, presented at SOSP in 2003, shipped **paravirtualization**: modify the guest kernel so it calls the hypervisor deliberately, through hypercalls, instead of executing offending instructions. Faster, but needs a modified guest.
6. Hardware assistance ended the argument. Intel VT-x shipped in November 2005; AMD-V, code-named Pacifica, shipped in May 2006. Both add a new guest mode, so an unmodified guest kernel can run at its expected privilege level and trap cleanly to the hypervisor.
7. Memory virtualization was still expensive until second level address translation arrived: AMD Nested Page Tables in Barcelona in 2007, Intel Extended Page Tables in Nehalem in 2008. Before that, hypervisors maintained shadow page tables in software.
8. Device passthrough needs an IOMMU: Intel VT-d and AMD-Vi. PCI-SIG's Single Root I/O Virtualization specification, published 2007, lets one physical card present many virtual functions, each assignable to one guest.

Hypervisor type	Runs on	Examples
Type 1, bare metal	The hardware	ESXi, Xen, Hyper-V, KVM
Type 2, hosted	An operating system	VirtualBox, Workstation

9. The type 1 versus type 2 split is a useful teaching device and a slightly leaky one. KVM, merged into Linux 2.6.20 in February 2007, turns the Linux kernel itself into a type 1 hypervisor while Linux remains a normal operating system. Experts differ on which box it belongs in.
10. From the host's point of view a KVM virtual machine is an ordinary process. You can see it in `ps`, one thread per virtual processor, its guest memory is an anonymous mapping, and you can kill it with `kill`.
11. Live migration in QEMU/KVM is iterative pre-copy: transfer all pages, then repeatedly transfer the pages dirtied during the previous pass, then stop the guest, transfer the remainder and the device state, and resume on the target. Typical stop time is tens to a few hundred milliseconds.
12. The **hypervisor tax** is the fraction of a machine consumed by virtualization rather than by customers. Werner Vogels has written that on older AWS designs this was around 30 per cent of the resources.

13. AWS attacked it with hardware. The path: C3 in 2013 offloaded network processing, C4 in 2014 offloaded storage, Amazon acquired the Israeli chip company Annapurna Labs in early 2015, and the full **Nitro System** shipped with C5 instances in 2017.
14. Nitro has three parts: Nitro Cards, which are dedicated hardware running VPC networking, EBS storage and instance storage; the Nitro Security Chip, which verifies firmware; and the Nitro Hypervisor, a thin KVM-based component that now mainly assigns memory and CPU.
15. Because almost nothing is left in software, AWS can also sell `.metal` instances, where a customer gets the whole physical server with no hypervisor at all, yet still gets normal EBS volumes and VPC networking.
16. Microsoft's equivalent story runs through programmable hardware. The Catapult project put FPGAs in Azure servers from 2015, Accelerated Networking used those FPGA-based SmartNICs to move virtual switching off the CPU, and Azure Boost, announced in 2023, offloads storage and networking to a dedicated card in the same spirit as Nitro.
17. Observation commands: `lscpu` shows the hypervisor vendor line inside a guest; `systemd-detect-virt` names the hypervisor; `dmidecode -s` `system-manufacturer` often reveals it; `virsh list` and `virsh domstats` inspect KVM guests from the host.

■ 43.4.6 WORDS – remember these

1. Hypervisor — the program that splits one computer into many — a virtual machine monitor providing equivalence, resource control and efficiency.
2. Type 1 versus type 2 — running on bare metal versus on top of an existing operating system — native versus hosted VMM.
3. Paravirtualization — the guest knows it is a guest and cooperates — replacing sensitive instructions with explicit hypercalls, as in Xen.
4. VT-x and AMD-V — processor features that make the trick cheap — hardware virtualization extensions adding a distinct guest execution mode, 2005 and 2006.
5. Oversubscription — selling more slices than you physically have — allocating virtual resources beyond physical capacity, relying on idle time.
6. Steal time — time your machine was ready but not scheduled — the `st` counter in Linux CPU accounting, the direct measure of host contention.
7. Live migration — moving a running machine without switching it off — iterative pre-copy of memory and device state to another host.
8. Nitro — AWS's offload hardware — dedicated cards and a minimal hypervisor that remove virtualization overhead and enable bare-metal instances, from 2017.

43.5 Containers

■ 43.5.1 PLAIN – in simple words

1. A virtual machine is a whole pretend computer, with its own operating system inside. That costs memory and takes tens of seconds to start.
2. Most of the time you did not want a computer. You wanted to run one program, with the exact files and libraries it expects.
3. A **container** gives you that. It is one ordinary program, running on the normal operating system, but wrapped so that it can only see its own files, its own processes and its own network.
4. Say this clearly, because almost every beginner gets it wrong: a container is not a small virtual machine. There is no second operating system inside it.

5. From the host's point of view it is just a process, visible in the process list, killable, schedulable, like any other.
6. The wrapping is done by features built into the Linux kernel. The container asks for a private view of the world, and the kernel gives it one.
7. Because there is nothing to boot, a container starts in tens of milliseconds instead of tens of seconds.
8. Because there is no second operating system, it uses megabytes of extra memory instead of hundreds of megabytes.
9. The other half of the idea is the **image**: a frozen, shareable copy of all the files the program needs, built once and run anywhere.
10. That is why containers solved the oldest complaint in software: "it works on my machine". Now the machine travels with the program.
11. The trade is isolation. Virtual machines are separated by hardware enforcement. Containers are separated by kernel bookkeeping, which is thinner, and a kernel bug can cross it.

■ 43.5.2 PLAIN – a picture in your head

1. Imagine a big office building with one security system, one power supply and one set of stairs. That is the operating system kernel.
2. A virtual machine is like building a whole separate house in the car park: its own foundations, its own wiring, its own everything.
3. A container is like giving one team a locked room inside the existing building, plus a rule at reception that they may not ask about any other team, plus a cap on how much electricity and how many desks they may use.
4. The team genuinely cannot see the other teams. Ask them who else is in the building and they will answer, honestly, "nobody".
5. Setting up a room takes minutes. Building a house in the car park takes months.
6. But the room is inside a building that somebody else controls. If the building's fire alarm has a flaw, everybody in it is affected.

Where this comparison breaks: the locked room suggests a physical wall. There is no wall. There is only the receptionist consistently refusing to answer certain questions. If you find a way to make the receptionist answer, you are out. That is exactly what a container escape is, and it is why you do not run untrusted code in a plain container without further sandboxing.

■ 43.5.3 PLAIN – a worked example

1. Here is a real Dockerfile for a small Python web service, with every line explained afterwards.

```
FROM python:3.12-slim
WORKDIR /app
COPY requirements.txt .
RUN pip install --no-cache-dir -r requirements.txt
COPY . .
RUN useradd -m appuser && chown -R appuser /app
USER appuser
EXPOSE 8000
ENV PORT=8000
CMD ["gunicorn", "-b", "0.0.0.0:8000", "app:application"]
```

2. FROM python:3.12-slim starts from an existing image that already contains a minimal Linux userland and Python 3.12. You are not building from nothing.
3. WORKDIR /app creates and enters a directory. Later commands run there.
4. COPY requirements.txt . copies just the list of dependencies in first.

5. `RUN pip install ...` installs those dependencies. Because this is a separate layer, and because only the requirements file was copied so far, this expensive step is reused from cache whenever your source changes but your dependency list does not. This ordering is the single most valuable trick in the file.
6. `COPY . .` now copies your actual source code.
7. `RUN useradd ...` creates a non-root user and gives it ownership.
8. `USER appuser` means every later instruction, and the running container, operate as that user. Running as root inside a container is a common and bad default.
9. `EXPOSE 8000` is documentation plus metadata. It does not open a port by itself.
10. `ENV PORT=8000` sets an environment variable inside the image.
11. `CMD [...]` is the command run when the container starts. The list form avoids a shell, so signals reach your process directly.
12. The commands to build and run it:

```
docker build -t festival-site:1.4 .
docker run -d --name web -p 8080:8000 \
  --memory 512m --cpus 1.5 festival-site:1.4
docker ps
docker logs -f web
docker exec -it web /bin/sh
docker stop web && docker rm web
```

13. `-p 8080:8000` maps port 8080 on the host to 8000 in the container.
14. `--memory 512m --cpus 1.5` are the limits. Without them, one container can consume the whole machine.

■ 43.5.4 PLAIN - what is really happening inside

1. When you run a container, the runtime asks the Linux kernel to start a process with a private view of six or seven kinds of thing. Each private view is called a **namespace**.
2. The PID namespace gives the process its own process numbering. The first process inside sees itself as PID 1 and cannot see the host's processes.
3. The network namespace gives it its own network interfaces, its own routing table and its own firewall rules. Usually a virtual cable is created, one end inside, one end on a bridge in the host.
4. The mount namespace gives it its own filesystem tree, so `/` inside is not `/` outside.
5. The user namespace lets an identity that is root inside map to an ordinary unprivileged identity outside.
6. The IPC namespace separates shared memory and message queues. The UTS namespace lets the container have its own hostname.
7. Separately, **cgroups** put ceilings on what the process may consume: so much memory, so much processor time, so much disk bandwidth. If it exceeds the memory ceiling, the kernel kills it.
8. The filesystem is assembled from stacked read-only layers plus one writable layer on top. Reads fall through the stack to the first layer that has the file. Writes go to the top layer only, copying the file up first.
9. Because the read-only layers are shared, ten containers from the same image store one copy of the common files, not ten.
10. The image itself is just those layers plus a small JSON document describing the command, environment, user and layer order.
11. A **registry** is a web service that stores and serves those layers and documents, addressed by content hash.

■ 43.5.5 TECHNICAL – the engineer’s version

1. The idea is old. chroot appeared in Version 7 Unix in 1979: change the apparent root directory of a process. It isolates the filesystem view and nothing else, and it was never a security boundary.
2. FreeBSD jails, by Poul-Henning Kamp, arrived in FreeBSD 4.0 in March 2000, adding process, network and user isolation to the chroot idea.
3. Solaris Zones shipped in Solaris 10 in 2005, with resource controls and a full virtualized environment per zone.
4. On Linux the pieces arrived separately. The mount namespace landed in kernel 2.4.19 in 2002. Process containers, developed at Google by Paul Menage and Rohit Seth, were renamed control groups and merged in kernel 2.6.24 in January 2008. The user namespace was completed in kernel 3.8 in 2013.
5. LXC, released in 2008, was the first tool to assemble those pieces into something usable. It required real Linux skill.
6. Docker changed the packaging, not the kernel. Solomon Hykes demonstrated it at PyCon in Santa Clara and it was open sourced in March 2013, out of a company then called dotCloud, renamed Docker Inc. later that year.
7. Docker’s contribution was the image format, the layer cache, the Dockerfile and a public registry: a developer workflow, not an isolation mechanism. Early versions used LXC underneath, replaced by its own libcontainer in version 0.9 in 2014.
8. Standardization followed. The **Open Container Initiative** was founded in June 2015 under the Linux Foundation, by Docker, CoreOS and others. Its runtime and image specifications reached version 1.0 in July 2017, and the distribution specification followed in 2021.
9. runc is the OCI reference runtime. containerd and CRI-O are the higher level runtimes that Kubernetes actually calls. Docker Engine today is a developer-facing layer over containerd.
10. Namespaces in the kernel, with their clone flags:

Namespace	Isolates	Flag
PID	Process numbering	CLONE_NEWPID
Network	Interfaces, routes	CLONE_NEWNET
Mount	Filesystem tree	CLONE_NEWNS
User	UID and GID mapping	CLONE_NEWUSER
IPC	Shared memory, queues	CLONE_NEWIPC
UTS	Hostname, domain	CLONE_NEWUTS

11. There are also cgroup and time namespaces, added later. cgroup v2, the unified hierarchy, is the current standard on modern distributions.
12. Overlay filesystems: overlayfs was merged in kernel 3.18 in 2014 and is the default storage driver. It presents a merged view of lower read-only directories and one upper writable directory, with copy-up on first write.
13. Image layers are content-addressed by SHA-256 digest. The image manifest lists layer digests; the config blob holds the command, environment and history. Pulling an image you already partly have transfers only the missing digests.
14. Additional hardening beyond namespaces and cgroups: seccomp-bpf to restrict system calls, AppArmor or SELinux for mandatory access control, dropping Linux capabilities, and read-only root filesystems.
15. For untrusted workloads, use a stronger boundary: gVisor, which intercepts system calls in userspace, or Kata Containers and AWS Firecracker, which put a genuine lightweight virtual ma-

chine around each container. Firecracker, open sourced by AWS in 2018, boots a micro virtual machine in about 125 milliseconds and is what runs AWS Lambda and Fargate.

16. Inspection commands: `lsns` lists namespaces, `nsenter` enters one, `systemd-cgls` and `systemd-cgtop` show cgroup trees, `docker image history` shows the layers and their sizes, `crictl ps` lists containers on a Kubernetes node.

■ 43.5.6 WORDS – remember these

1. Container — an isolated process with its own files and limits — a process group running under restricting namespaces and cgroups on a shared kernel.
2. Namespace — a private view of one kind of system resource — a kernel mechanism partitioning PID, network, mount, user, IPC, UTS and cgroup views.
3. cgroup — a ceiling on how much a process may consume — control group hierarchy enforcing CPU, memory and I/O limits, cgroup v2 unified.
4. Image — a frozen copy of everything the program needs — an ordered set of content-addressed layers plus a config manifest, per the OCI image spec.
5. Layer — one saved change on top of the previous ones — a tar archive of filesystem differences, shared and cached by digest.
6. Registry — the shop where images live — an OCI distribution-spec service storing manifests and blobs, such as Docker Hub or ECR.
7. OCI — the agreed rules so tools interoperate — the Open Container Initiative runtime, image and distribution specifications, founded June 2015.
8. Container escape — breaking out into the host — exploitation of a kernel or configuration flaw to cross the namespace boundary.

43.6 Kubernetes and orchestration

■ 43.6.1 PLAIN – in simple words

1. Containers are easy to run one at a time on your laptop.
2. Now imagine 400 of them, across 30 machines, each needing to find the others, restart when they die, and move when a machine is taken away.
3. Doing that by hand is impossible. You need a program that does it for you. That program is called an **orchestrator**.
4. **Kubernetes** is the one that won. The name is Greek for helmsman, and it is often shortened to K8s, because there are eight letters between K and s.
5. The idea at its heart is simple and worth memorizing: you describe what you want, and the system continuously works to make reality match.
6. You do not say “start three copies”. You say “there should be three copies”.
7. If one dies at 3am, nobody is paged, because nothing has been violated except temporarily. The system notices the gap and starts another.
8. If you edit the number to five, the system notices the gap and starts two more. The same machinery handles both cases.
9. This is called **declarative reconciliation**: state the desired end, let a control loop close the difference, forever.
10. Everything else in Kubernetes is detail on top of that one idea.

■ 43.6.2 PLAIN – a picture in your head

1. Think of a thermostat on a wall.
2. You do not tell the heater to switch on for eleven minutes. You set 22 degrees.
3. The thermostat measures, compares with your setting, and acts. Then it does it again, forever.
4. Open a window and the temperature drops; the thermostat responds without being told about the window.
5. Kubernetes is a building full of thermostats, one for each kind of thing.
6. One watches “how many copies of this program are running” against “how many should be”. Another watches “which machines are alive”. Another watches “what traffic goes where”.
7. Each loop is small, dull and independent. The intelligence is in the fact that they never stop running.

Where this comparison breaks: a thermostat has one input and one output. Kubernetes controllers act on each other’s outputs, so an error can propagate. A wrong setting does not sit still and look wrong; it is enthusiastically and repeatedly enforced across your entire cluster in seconds. That is the same property that makes it powerful and makes mistakes fast.

■ 43.6.3 PLAIN – a worked example

1. Here is a minimal but real pair of Kubernetes objects.

```

apiVersion: apps/v1
kind: Deployment
metadata:
  name: festival-web
spec:
  replicas: 3
  selector:
    matchLabels:
      app: festival-web
  template:
    metadata:
      labels:
        app: festival-web
    spec:
      containers:
      - name: web
        image: registry.example.com/festival-site:1.4
        ports:
        - containerPort: 8000
        resources:
          requests:
            cpu: "250m"
            memory: "256Mi"
          limits:
            memory: "512Mi"
        readinessProbe:
          httpGet:
            path: /healthz
            port: 8000
---
apiVersion: v1
kind: Service
metadata:
  name: festival-web
spec:

```

```

selector:
  app: festival-web
ports:
- port: 80
  targetPort: 8000

```

2. `kind: Deployment` says this is a managed set of identical copies.
3. `replicas: 3` is the desired state. This one number is the whole contract.
4. `selector.matchLabels` says which pods this deployment considers its own. The labels in the template must match, or nothing works.
5. `image:` names the exact image, including a version tag. Using `latest` here is the classic mistake, because two nodes can then run different code.
6. `requests` is what the scheduler uses to decide where the pod fits. `limits` is what the kernel enforces at runtime.
7. Note there is a memory limit but no CPU limit. That is a deliberate and widely recommended pattern: CPU throttling hurts latency, while unlimited memory risks killing the node.
8. `readinessProbe` tells Kubernetes when this copy may receive traffic. Without it, traffic arrives before the program is ready and users see errors during every deployment.
9. The Service gives the three copies one stable internal name and one stable internal address, and spreads connections across whichever copies are ready.
10. Apply and observe:

```

kubectl apply -f festival.yaml
kubectl get deploy,rs,pods -l app=festival-web
kubectl describe pod festival-web-6c9f7d8b4-x2ktr
kubectl logs -f deploy/festival-web
kubectl rollout status deploy/festival-web
kubectl rollout undo deploy/festival-web

```

■ 43.6.4 PLAIN - what is really happening inside

1. `kubectl apply` sends your document to one program, the API server, which validates it and writes it into a database.
2. Nothing has run yet. All that exists is a written wish.
3. The deployment controller notices a Deployment with no matching ReplicaSet and creates one.
4. The ReplicaSet controller notices it should have three pods and has zero, so it creates three pod records. Still nothing is running.
5. The scheduler notices three pods with no node assigned. For each, it filters nodes that could fit, scores the survivors, picks the best, and writes the node name into the pod record.
6. On that node, an agent called the kubelet is watching for pods assigned to it. It sees one, pulls the image, and asks the container runtime to start it.
7. The kubelet then reports status back: starting, running, ready, or failed.
8. The endpoints controller notices a ready pod matching a Service's label selector, and adds its address to that Service's endpoint list.
9. On every node, a component programs the local packet rules so that traffic to the Service address is redirected to one of the current endpoint addresses.
10. If a pod dies, the kubelet reports it, the ReplicaSet controller sees two where three should be, and creates one more. The loop closes.
11. Nobody issued a command. Every step was a controller observing a difference and reducing it.

■ 43.6.5 TECHNICAL – the engineer’s version

1. Kubernetes descends from Borg, Google’s internal cluster manager, described publicly in the 2015 EuroSys paper Large-scale cluster management at Google with Borg, and from its successor experiment Omega.
2. The first Kubernetes commit was pushed to GitHub on 6 June 2014: 250 files and 47,501 lines of Go, shell and Markdown. Joe Beda, Brendan Burns and Craig McLuckie are the usually named originators, with Borg engineers including Brian Grant and Tim Hockin joining early.
3. Version 1.0 was released in July 2015, and Google donated the project to the newly formed Cloud Native Computing Foundation under the Linux Foundation at the same time. That donation is the reason competitors adopted it.
4. Core objects you must know:

Object	What it is for
Pod	Co-located containers, one unit
ReplicaSet	Keeps N identical pods up
Deployment	Rolling updates of ReplicaSets
Service	Stable name and virtual IP
Ingress	HTTP routing from outside
ConfigMap	Non-secret configuration data
Secret	Base64-encoded sensitive data
Namespace	A naming and policy boundary
Node	One worker machine

5. A pod is the smallest schedulable unit. Containers in a pod share a network namespace, so they reach each other on `localhost`, and can share volumes.
6. Control plane components: the API server, the only component that talks to the datastore; the scheduler, which assigns pods to nodes; the controller manager, which runs the built-in control loops; and `etcd`, a distributed key-value store using the Raft consensus algorithm.
7. On each worker: the kubelet, which owns pod lifecycle on that node, a network proxy component, and a container runtime speaking the Container Runtime Interface, usually `containerd` or `CRI-O`.
8. Be honest about Secrets. By default they are base64-encoded, not encrypted, in `etcd`. Encryption at rest must be enabled explicitly, and anyone with read access to the namespace can read them.
9. Ingress is being superseded. The Gateway API reached general availability for its core resources in October 2023 and is the direction of travel; Ingress remains extremely common and is not going away soon.
10. Scale limits, from the official documentation: no more than 5,000 nodes, 150,000 pods and 300,000 containers in a single cluster, with at most 110 pods per node.
11. Managed offerings remove the control plane work but not the concepts: EKS on AWS from June 2018, AKS on Azure from June 2018, and GKE on Google Cloud from 2015, which was the first.
12. Now the honest section, which matters more than the object list.
13. Most teams do not need Kubernetes. This is not a fashionable opinion; it is what the cost structure says.
14. Kubernetes solves problems that appear at a certain size: many services, many teams, high change rate, bin-packing pressure across many machines, and a genuine need for self-healing across node failures.

15. Below that size it adds a permanent, non-trivial tax: cluster upgrades every few months, a networking plugin to understand, ingress controllers, certificate rotation, RBAC, admission controllers, storage classes, and a new class of failure modes nobody on the team has seen before.
16. A useful test with three questions. Do you run more than about ten distinct services? Do you have someone whose job includes the platform? Would a single machine restarting cause a real outage today?
17. If the answer to all three is no, a managed container service such as ECS, Cloud Run or App Service, or even two virtual machines behind a load balancer, will serve you better and cost less in time.
18. Where experts disagree: some argue the standard interface is worth the tax even for small teams, because hiring and tooling are common. Others argue that complexity you do not need is complexity that will page you at 3am. Both are stated in good faith and depend on team size and turnover.

■ 43.6.6 WORDS - remember these

1. Orchestrator — the program that runs your containers for you — a cluster scheduler and lifecycle manager across many hosts.
2. Pod — the smallest thing Kubernetes runs — one or more containers sharing a network namespace and storage volumes, scheduled as a unit.
3. Deployment — the object that keeps N copies of your app alive — a controller managing ReplicaSets to provide declarative rolling updates.
4. Reconciliation — repeatedly closing the gap between wish and reality — a level-triggered control loop comparing desired and observed state.
5. etcd — the cluster's memory — a strongly consistent distributed key-value store using Raft, the only stateful control plane component.
6. kubelet — the agent on each machine — the node-level daemon that starts pods assigned to it and reports their status.
7. Service — a stable name in front of moving copies — a virtual IP and DNS name load-balancing to the current ready endpoints.

43.7 The Bezos API mandate

■ 43.7.1 PLAIN - in simple words

1. Around 2002, Jeff Bezos sent an internal message to everyone building software at Amazon.
2. It said, in effect: every team must publish its work as a service that other teams call over the network, and no team may reach into another team's data any other way.
3. That sounds like a boring technical rule. It was one of the most consequential management decisions in the history of the industry.
4. Before it, teams shared databases and linked directly to each other's code. That is fast to write and impossible to change later.
5. After it, the only way to use another team's work was to call its published interface, over the network, like an outsider.
6. And the last rule was the sharp one: build every interface as if a stranger outside the company would use it.
7. Nobody was selling anything to outsiders yet. But once every internal service was already built for outsiders, selling it later was a small step rather than a rewrite.

8. That is the link between the memo and AWS. AWS is what you get when a company spends four years turning itself into a set of public-quality services and then notices it can sell them.
9. Amazon never published the memo. What everyone quotes is one former employee's recollection, written down in 2011.

■ 43.7.2 PLAIN – a picture in your head

1. Think of a large hospital where every department shares one giant paper filing cabinet.
2. Radiology reaches into the pharmacy's drawer to check a prescription. Pharmacy reaches into billing's drawer. Everyone rummages everywhere.
3. It works, and it is fast, right up until one department reorganizes its drawer. Then four other departments break, and nobody knows who or why.
4. Now the director issues a rule: no department may open another department's drawer. If you need something, you fill in that department's request form and they answer it.
5. At first this is slower and everybody hates it. Forms take longer than rummaging.
6. But now pharmacy can completely redesign its drawer over a weekend, and nobody else notices, because the form did not change.
7. And one day the hospital realizes that since every department already answers formal requests, it can answer requests from other hospitals too, for a fee.

Where this comparison breaks: a paper form is slow but reliable. A network call can be slow, can fail halfway, can succeed while appearing to fail, and can arrive twice. The hospital analogy makes the mandate look like pure gain. The real version bought flexibility with a permanent bill in latency and in failure handling, and that bill never stops being paid.

■ 43.7.3 PLAIN – a worked example

1. Here is the mandate as it is publicly reported. The source is a long post by Steve Yegge, an engineer who worked at Amazon for about six years and then at Google. He wrote it in October 2011 as an internal Google memo and posted it publicly by accident.
2. His introduction is "His Big Mandate went something along these lines". The rules, quoted:
3. One. "All teams will henceforth expose their data and functionality through service interfaces."
4. Two. "Teams must communicate with each other through these interfaces."
5. Three. "There will be no other form of interprocess communication allowed: no direct linking, no direct reads of another team's data store, no shared-memory model, no back-doors whatsoever. The only communication allowed is via service interface calls over the network."
6. Four. "It doesn't matter what technology they use. HTTP, Corba, Pubsub, custom protocols – doesn't matter."
7. Five. "All service interfaces, without exception, must be designed from the ground up to be externalizable. That is to say, the team must plan and design to be able to expose the interface to developers in the outside world. No exceptions."
8. Then the closing line: "Anyone who doesn't do this will be fired."
9. The honest version: in Yegge's original post this is a list of seven items, not five plus a closing line. Item six is the firing line, and item seven is a one-line pleasantry, which he immediately identifies as his own joke. The five substantive rules plus the firing line is the accurate summary.
10. Yegge also wrote that item six "was quite real, so people went to work". He was recalling, not quoting a document. Amazon has never released the memo, so the wording is a recollection and should always be described that way.
11. Note what rule four is not doing. It does not pick a technology. That is deliberate and correct: the mandate is about boundaries, not protocols.

■ 43.7.4 PLAIN – what is really happening inside

1. Follow what the rule forces, step by step. This is the part that matters.
2. Once teams may only call each other over the network, they must first be able to find each other. So somebody has to build a service registry, and the registry is itself a service.
3. Once hundreds of services call each other, any team can accidentally flood another. Yegge's words: "every single one of your peer teams suddenly becomes a potential DOS attacker". So quotas and throttling become mandatory everywhere, not optional.
4. Once a request crosses twenty services, an alarm has to reach the right team. Yegge again: a ticket "might bounce through 20 service calls before the real owner is identified", and at fifteen minutes per bounce that is hours. So you must build ownership metadata and automated pager routing.
5. Once you cannot see inside another team's code, "monitoring and QA are the same thing". A service that answers "I am fine" may have nothing working except the part that says "I am fine". So health checks must exercise real behaviour, and at that point monitoring has become automated testing.
6. Once debugging spans teams, it "is basically impossible unless there is a universal standard way to run every service in a debuggable sandbox". So you must build sandboxes and standardized local environments.
7. Look at that list again: discovery, quotas, paging, deep health checking, sandboxes. Every one of those is a component of a public cloud platform.
8. Amazon did not set out to build platform tooling. The mandate made it unavoidable, and four years later they had it.

■ 43.7.5 TECHNICAL – the engineer's version

1. Organizational consequence one: the **two-pizza team**. Bezos's stated rule was that a team should be small enough to be fed by two pizzas, roughly six to ten people. The number is not the point; the bound on communication paths is.
2. Organizational consequence two: **you build it, you run it**. Werner Vogels, Amazon's Chief Technology Officer, stated it in an ACM Queue interview with Jim Gray in 2006. The team that writes a service also operates it and carries its pager.
3. That closes a loop. If the author of the 3am page is also the person woken by it, quality arguments stop needing management.
4. Organizational consequence three: **Conway's law**. Melvin Conway wrote in *How Do Committees Invent?*, published in *Datamation* in April 1968, that organizations produce designs which copy their own communication structures.
5. The mandate is Conway's law used deliberately. Change the communication structure, and the architecture follows. This is sometimes called the inverse Conway manoeuvre.
6. Now the costs, stated plainly, because the reader is owed them.
7. Latency. An in-process function call is on the order of nanoseconds. A call to another service in the same datacentre is on the order of 0.5 to 2 milliseconds. That is a factor of roughly a million.

Call type	Typical latency
Function call in process	1 to 100 ns
Same-host loopback call	50 to 200 us
Same-AZ service call	0.5 to 2 ms
Cross-region call	50 to 250 ms

8. Failure semantics. A local call either returns or throws. A network call can also time out with the

work completed, be retried and applied twice, or succeed with the response lost. Every service boundary therefore needs idempotency keys, retries with backoff, timeouts and circuit breakers.

9. Data integrity. You can no longer wrap two teams' updates in one database transaction. You are pushed into eventual consistency and compensating actions.
10. Operational cost. Each service needs its own build, deployment, monitoring, on-call rota, dependency updates and security patching.
11. The most important honest point in this chapter: most companies that copied the microservice structure did not copy the mandate's discipline.
12. The mandate had four properties that copies usually lack. It was absolute, with no exceptions. It was enforced from the top. It required interfaces to be externalizable, which forces documentation, versioning and stability. And it was accompanied by real investment in the platform tooling that the consequences demanded.
13. Split a system into thirty services without discovery, quotas, tracing, ownership routing and sand-boxes, and you have not built a service-oriented architecture. You have built a distributed monolith, which has all the latency and failure modes of distribution and none of the independence.
14. Where experts disagree: some argue the mandate is a timeless engineering principle, others that it was a response to a specific scale and coupling crisis at Amazon in 2001 and 2002, and that applying it to a twelve-person company is cargo cult. The second view is the majority among practitioners today.

■ 43.7.6 WORDS – remember these

1. API mandate — the 2002 rule that teams talk only through published interfaces — an organization-wide prohibition on any interprocess communication other than service calls.
2. Externalizable — built as if a stranger will use it — designed with the documentation, versioning and stability required for third-party exposure.
3. Two-pizza team — a team small enough to feed with two pizzas — an organizational unit sized to bound internal communication paths.
4. You build it, you run it — the authors carry the pager — development teams own production operation of their own services.
5. Conway's law — you ship your org chart — systems mirror the communication structure of the organizations that design them, Conway 1968.
6. Distributed monolith — services that must all deploy together — a system with the costs of distribution and the coupling of a monolith.

43.8 How AWS actually started

■ 43.8.1 PLAIN – in simple words

1. By 2000 Amazon was a large online shop with a serious internal problem.
2. Every new project spent months on the same groundwork: getting machines, setting up databases, storage, networking and monitoring.
3. Teams were reinventing the same plumbing over and over, and waiting on each other to do it.
4. The API mandate had already forced them to expose everything as a service. The next thought was obvious: make the infrastructure itself a service.
5. In 2003, engineers wrote a proposal describing computing capacity offered as a service, so that any team could ask for a server through an interface.
6. In parallel, a senior manager wrote a proposal arguing that this could be a business, sold to the outside world.

7. Amazon approved both. Development of the compute service was set up in Cape Town, South Africa, of all places, because the engineer leading it wanted to move home.
8. The public services arrived in 2006: storage in March, and rentable computers in August.
9. It was not a side project selling leftovers. It was a deliberate new business with its own staffing plan.

■ 43.8.2 PLAIN – a picture in your head

1. Imagine a large restaurant chain that keeps building its own kitchens.
2. Every new branch designs plumbing, gas, extraction and cold storage from scratch, badly, and slowly.
3. Head office finally standardizes: one kitchen design, ordered as a kit, ready in a week.
4. Branches stop thinking about plumbing and start thinking about food. Opening a branch goes from a year to a month.
5. Then somebody points out that other restaurant chains have the same problem, and that the kit could be sold.
6. The kit business becomes larger and far more profitable than the original restaurants.

Where this comparison breaks: a kitchen kit is a product you build once and ship. AWS had to be operated forever, at growing scale, for customers who could leave. Also, the myth this analogy tempts you into is that head office sold its spare kitchens. It did not. It designed and built a product from scratch, then sold it, which is a completely different thing.

■ 43.8.3 PLAIN – a worked example

1. The dates, in order, from public records.
2. July 2002: Amazon launches Amazon.com Web Services, a free interface letting affiliates pull product data. This is where the name comes from. It is not cloud computing.
3. 2003: Chris Pinkham and Benjamin Black write a short internal paper proposing standardized, automated infrastructure delivered as a service, and noting that virtual servers could be sold.
4. 2003: Andy Jassy, who had joined Amazon in 1997 and become Bezos's technical assistant in 2001, writes a separate proposal for the business, including a plan for the first 57 hires. It is approved by the senior team.
5. 2004: Pinkham moves to Cape Town and opens a development centre there to build the compute service.
6. 3 November 2004: Simple Queue Service launches in beta. Chronologically this is the first thing recognizably cloud.
7. 14 March 2006: Simple Storage Service, S3, launches generally available, at 15 US cents per gigabyte-month.
8. 25 August 2006: Elastic Compute Cloud, EC2, launches in limited beta. One instance size only, 1.7 GHz, 1.75 GB of memory, 160 GB of local disk, at 10 US cents per hour. It reached general availability in October 2008.
9. From 10 cents an hour in 2006 to 128.7 billion US dollars of revenue in 2025 is the whole arc.

■ 43.8.4 PLAIN – what is really happening inside

1. Why Amazon and not IBM, Microsoft, Sun or a telephone company.
2. First, Amazon already had to run huge, spiky, low-margin infrastructure, and was already good at it out of necessity.
3. Second, the API mandate had already forced internal services to be built for external use. The hard organizational work was done before the product was conceived.

4. Third, retail is a low-margin business, so Amazon's culture was to treat infrastructure cost as an enemy. A company used to 3 per cent margins prices very differently from one used to 60 per cent margins.
5. Fourth, nobody else wanted the customers. In 2006 the buyers were startups with no money. Established vendors sold to enterprises with purchase orders and salespeople, and a self-service credit-card product looked like a toy.
6. Fifth, Amazon was willing to be unprofitable for years and did not have to protect an existing licence business. Microsoft and others did.
7. Now correct the myth. The popular story is that AWS was built to rent out servers left idle after the Christmas shopping peak.
8. It is false. Werner Vogels, Amazon's Chief Technology Officer, publicly rejected it in 2011, and Andy Jassy has repeated the correction many times.
9. The mechanics also do not work. Retail's peak is Q4, exactly when external customers would need capacity most, so you would have to evict them at the worst moment. And AWS ran on different hardware, in different facilities, with different software, from the start.
10. The kernel of truth is smaller and duller: Amazon's own experience of running infrastructure badly and expensively is what taught it what the product should be.

■ 43.8.5 TECHNICAL - the engineer's version

1. The service launch timeline, with dates as published:

Year	Service	Date
2004	SQS beta	3 Nov 2004
2006	S3	14 Mar 2006
2006	EC2 beta	25 Aug 2006
2007	SimpleDB beta	14 Dec 2007
2008	EBS	20 Aug 2008
2008	CloudFront	18 Nov 2008
2009	ELB, CloudWatch	18 May 2009
2009	VPC	25 Aug 2009
2009	RDS	26 Oct 2009
2010	Route 53	5 Dec 2010
2012	DynamoDB	19 Jan 2012
2012	Redshift	28 Nov 2012
2014	Lambda, ECS	13 Nov 2014
2017	Fargate, Nitro C5	Nov 2017
2018	EKS general availability	June 2018

2. Read the order. Storage, then compute, then block storage, then content delivery, then load balancing and monitoring, then networking, then managed databases. Each launch is a response to what the previous one made painful.
3. VPC arriving three years after EC2 is the most instructive gap. The original EC2 put every instance on a flat shared network with a public address, which enterprises would not accept.
4. Financially, AWS was reported separately for the first time in Amazon's first quarter 2015 results, revealing a business with roughly 5 billion US dollars of annualized revenue that was already profitable. That disclosure repriced Amazon's stock and forced competitors to respond.

5. Current figures, from company filings. Full year 2025 AWS net sales were 128,725 million US dollars, with segment operating income of 45,606 million, an operating margin near 35 per cent, against total Amazon net sales of 716,924 million.
6. In the quarter ending June 2026, AWS reported 42.2 billion US dollars, growth of about 37 per cent, and operating income of 16.6 billion, which Amazon's chief executive described as the fastest growth in eighteen quarters.
7. Reference customer for scale: Netflix began moving to AWS in 2008 after a database corruption incident halted DVD shipping for three days, and completed the shutdown of its last own-datacentre systems in January 2016. It took seven years, and Netflix is a well-resourced engineering organization.
8. Where sources disagree. Some accounts credit the 2003 Pinkham and Black paper as the origin of AWS; others credit Jassy's business proposal; Black himself has written that theirs was one of several parallel efforts. The honest summary is that both existed in 2003 and both mattered.

■ 43.8.6 WORDS – remember these

1. AWS — Amazon's cloud business — Amazon Web Services, launched publicly 2006, 128.7 billion US dollars of net sales in 2025.
2. EC2 — rentable computers by the hour — Elastic Compute Cloud, virtual machines billed per second with a 60 second minimum, beta August 2006.
3. S3 — a place to put files, reached over the web — Simple Storage Service, object storage launched 14 March 2006, the first generally available service.
4. SQS — a queue you do not have to run — Simple Queue Service, beta November 2004, chronologically the first AWS service.
5. Two-pizza origin — small teams owning services — the organizational precondition that let Amazon staff many independent services at once.
6. Spare capacity myth — the false story that AWS resold leftover retail servers — publicly denied by Amazon's CTO in 2011 and contradicted by the timeline.

43.9 The AWS services you actually need to know

■ 43.9.1 PLAIN – in simple words

1. AWS advertises more than 200 services. You will use about eighteen.
2. Here is each one, in a sentence, as the problem it solves.
3. EC2: I need a computer. Rent a virtual machine by the second.
4. S3: I need somewhere to put files that never fills up. Store objects by name, reached over the web.
5. EBS: my rented computer needs a hard disk that survives a reboot. Attach a network-backed disk to one machine.
6. VPC: I need my machines on a private network of my own design, not on the open internet.
7. Route 53: I need names to turn into addresses, and I need to steer traffic. This is DNS, run for you.
8. RDS: I need a normal database, but I do not want to install, patch, back up or fail it over myself.
9. DynamoDB: I need a store that never slows down as it grows, and I can live with looking things up only by key.
10. Lambda: I need to run a small piece of code when something happens, and I do not want a server sitting there waiting.
11. IAM: I need to say exactly who may do what. This is the permission system, and it applies to every other service.
12. CloudFront: my users are far away and my files are large. Keep copies near them.

13. ELB and ALB: I have several machines and one address. Spread the traffic and skip the dead ones.
14. SQS: I need to hand work to something else without waiting for it, and without losing it if the other side is down.
15. SNS: I need to tell many interested parties that something happened.
16. ECS: I have containers and I want them run for me, simply.
17. EKS: I have containers and I want Kubernetes, without operating the control plane myself.
18. CloudWatch: I need to see what is happening. Logs, numbers and alarms.
19. CloudFormation: I want my whole setup written down as a file, so it can be rebuilt exactly.
20. Secrets Manager: I need to keep passwords somewhere that is not the source code.

■ 43.9.2 PLAIN – a picture in your head

1. Think of building a shop in a market town.
2. EC2 is renting the shop unit. EBS is the storeroom attached to your unit. S3 is the town warehouse where anyone with a key can drop off boxes.
3. VPC is the private courtyard you rent, with your own gate and your own path layout. Route 53 is the street sign that tells people where your shop is.
4. ELB is the doorman who splits an arriving crowd between your three counters and stops sending people to the one that has closed.
5. RDS is a bookkeeper the market provides, who keeps your ledger, backs it up nightly and covers for himself when ill.
6. SQS is the in-tray by the back door. Deliveries go in whether you are ready or not, and you take them at your pace.
7. IAM is the master key system: who may open which door, when, from where.
8. CloudWatch is the set of meters and the alarm bell. CloudFormation is the architect's drawing from which the whole shop could be rebuilt.

Where this comparison breaks: in a market town you rent one unit and that is the bill. Here, almost every one of these has three or four separate meters running at once, and the doorman charges by the crowd as well as by the hour.

■ 43.9.3 PLAIN – a worked example

1. A three-tier web application, in AWS parts, in the order you would create them.
2. VPC with six subnets across two availability zones: two public, two private for applications, two private for the database.
3. An Application Load Balancer in the public subnets, holding the TLS certificate.
4. An Auto Scaling group of EC2 instances in the private application subnets, each with a gp3 EBS root volume.
5. RDS for PostgreSQL in the database subnets, with a standby in the second availability zone.
6. S3 for user uploads, with CloudFront in front of it for delivery.
7. Route 53 holding the hosted zone and an alias record pointing at the load balancer.
8. IAM roles attached to the instances so that no access key is ever written to disk.
9. Secrets Manager holding the database password, fetched at startup.
10. CloudWatch collecting logs and metrics, with alarms on error rate and database CPU.
11. CloudFormation or Terraform describing all of the above in one repository.

■ 43.9.4 PLAIN – what is really happening inside

1. Every one of these is reached the same way: an HTTPS request to a region-specific endpoint, signed with a key derived from your credentials.

2. That signature scheme is called Signature Version 4. It hashes the request, the date, the region and the service name, so a signature stolen for one region and service is useless elsewhere.
3. The AWS console, the aws command line tool and every language SDK all do exactly this. There is no private channel.
4. Services are separated into control plane operations, which create and modify resources, and data plane operations, which use them.
5. That split matters during outages. A control plane failure stops you creating new things while existing things keep serving.
6. Almost every service integrates with two others by default: IAM decides whether the call is allowed, and CloudTrail records that it happened.

■ 43.9.5 TECHNICAL – the engineer’s version

1. Equivalents across the three large providers. Names are current as of August 2026; providers rename services often, so check before quoting.

AWS	Azure	Google Cloud
EC2	Virtual Machines	Compute Engine
S3	Blob Storage	Cloud Storage
EBS	Managed Disks	Persistent Disk
VPC	Virtual Network	VPC
Route 53	Azure DNS	Cloud DNS
RDS	Azure SQL, Flexible	Cloud SQL
DynamoDB	Cosmos DB	Firestore, Bigtable
Lambda	Azure Functions	Cloud Run functions
IAM	Entra ID plus RBAC	Cloud IAM
CloudFront	Azure Front Door	Cloud CDN
ALB	Application Gateway	Cloud Load Balancing
SQS	Storage or Service Bus	Pub/Sub
SNS	Event Grid	Pub/Sub
ECS	Container Apps	Cloud Run
EKS	AKS	GKE
CloudWatch	Azure Monitor	Cloud Monitoring
CloudFormation	ARM, Bicep	Deployment Manager
Secrets Manager	Key Vault	Secret Manager

2. The mapping is approximate on purpose. DynamoDB and Cosmos DB have different consistency models. SQS is a queue with one consumer per message; Pub/Sub is a topic with fan-out, so it maps to both SQS and SNS.
3. Durability and availability commitments, as published in the service level agreements: S3 Standard is designed for 99.99999999 per cent durability, eleven nines, with a 99.9 per cent availability service level agreement.
4. Eleven nines means that for ten million objects you would statistically expect to lose one object every ten thousand years. It is a design target derived from redundancy, not a measured result.
5. EC2 offers a 99.99 per cent regional service level agreement when instances are spread across two or more availability zones, and 99.5 per cent for a single instance with certain storage configurations.

6. Storage duplication: S3 Standard stores objects redundantly across at least three availability zones. S3 One Zone-IA deliberately does not, which is why it is cheaper and why you must not use it for anything irreplaceable.
7. Service quotas are real and will surprise you: default limits such as 5 VPCs per region, 5 Elastic IP addresses per region, and per-instance-family vCPU limits are common causes of failed deployments. Check `aws service-quotas list-service-quotas`.
8. Useful commands: `aws sts get-caller-identity` answers “who am I”, which is the first thing to run when something is denied; `aws configure list` shows which credentials and region are in effect.

■ 43.9.6 WORDS - remember these

1. EC2 — a rented computer — Elastic Compute Cloud instances, billed per second with a 60 second minimum, in families tuned for compute, memory or storage.
2. S3 — files stored by name on the web — object storage with eleven nines design durability and a flat key namespace per bucket.
3. EBS — a disk for one machine — network-attached block storage, gp3 by default, snapshottable, tied to one availability zone.
4. VPC — your own private network in the cloud — a logically isolated virtual network with your own address ranges, subnets and route tables.
5. IAM — the rules about who may do what — Identity and Access Management, evaluating identity and resource policies on every API call.
6. Lambda — run code without a server — a function-as-a-service runtime billed per millisecond of execution and per request.
7. Signature Version 4 — how a request proves it is really you — the AWS request signing scheme scoped to date, region and service.

43.10 Azure, Google Cloud and the rest

■ 43.10.1 PLAIN - in simple words

1. Microsoft announced its cloud, then called Windows Azure, in October 2008, and opened it for paying customers on 1 February 2010.
2. Its first version made a bet that turned out to be wrong. It offered a platform: you gave it your application, it ran it, and you never saw a machine.
3. That was elegant, but customers did not want elegant. They wanted to move the servers they already had, unchanged.
4. So Microsoft turned around and added plain virtual machines, and then Linux, and then everything else. It renamed itself Microsoft Azure in 2014 to signal that it was no longer a Windows product.
5. That late start cost Microsoft the developer-first market, which AWS held.
6. But Microsoft had something AWS did not: it was already inside almost every large company on earth, selling Windows, Office and, crucially, the identity system that decides who employees are.
7. So Azure won the enterprise from the inside. If your staff already log in with a Microsoft account, the cloud that understands that account has an enormous advantage.
8. Google Cloud started earlier in one narrow sense and later in every other. It is respected for containers, networking and data analysis, and is a clear third by revenue.
9. Below the big three there is a real second tier, and for many small projects it is cheaper and simpler.

■ 43.10.2 PLAIN – a picture in your head

1. Imagine three shops selling building materials.
2. The first, AWS, opened years earlier, stocks absolutely everything, and its staff assume you are a professional builder. The catalogue is enormous and the labels are terse.
3. The second, Azure, is owned by the company that already supplied the doors, locks and keys for every office in town. It says: your existing keys work here, and we will send someone to your site.
4. The third, Google Cloud, is run by engineers who built the largest structures in the world for themselves, and now sell the tools. The tools are excellent. The shop assistants are fewer.
5. Around the corner are small shops selling four or five items at half the price, with a printed price list you can understand in a minute.

Where this comparison breaks: building materials are interchangeable between shops. Cloud services are not. Once your identity, your networking and your managed databases are with one provider, moving is a project measured in quarters, not an afternoon of carrying bricks.

■ 43.10.3 PLAIN – a worked example

1. Azure's naming conventions are worth learning, because they are consistent and they differ from AWS.
2. Everything lives in a **resource group**, which is a folder for related resources with a shared lifecycle. AWS has no exact equivalent; the closest habits are tags and stacks.
3. Above resource groups sit subscriptions, which are the billing boundary, and above those, management groups, which apply policy.
4. Identity is not per subscription. It comes from a **tenant** in Entra ID, which can span many subscriptions.
5. So the Azure hierarchy reads: tenant, management group, subscription, resource group, resource.
6. In AWS the hierarchy reads: organization, organizational unit, account, resource. There is no resource group layer, which is why AWS practitioners use separate accounts for separation far more aggressively.
7. Creating a machine, side by side:

```
# Azure
az group create -n festival-rg -l centralindia
az vm create -g festival-rg -n web1 \
  --image Ubuntu2404 --size Standard_B2s \
  --admin-username azureuser --generate-ssh-keys

# AWS
aws ec2 run-instances --image-id ami-0abcd1234 \
  --instance-type t3.medium --key-name mykey \
  --subnet-id subnet-0123456789abcdef0
```

■ 43.10.4 PLAIN – what is really happening inside

1. The reason Entra ID is described as Microsoft's real moat is worth understanding mechanically.
2. Most large organizations authenticate employees against Active Directory, a system Microsoft shipped in Windows 2000. It holds users, groups, machines and policies.
3. Entra ID, which was called Azure Active Directory until Microsoft renamed it on 11 July 2023, is the cloud version. It issues tokens for web applications using OAuth 2.0 and OpenID Connect.
4. Once employees sign in to Microsoft 365 with Entra ID, the same identity can authorize Azure resources, third-party software and internal applications.

5. That means the decision “which cloud” is partly already made by a decision taken years earlier about email and file sharing.
6. Switching cost is therefore not mainly about servers. It is about identity, group membership, conditional access rules and hundreds of application integrations.
7. Hybrid follows from the same fact. Azure Arc, Azure Stack and ExpressRoute exist so that machines in a company’s own building appear in the same management and identity plane as machines in Azure.

■ 43.10.5 TECHNICAL – the engineer’s version

1. Azure timeline. Announced at the Professional Developers Conference on 27 October 2008 by Ray Ozzie, under the internal codename Red Dog, led by Dave Cutler, the architect of Windows NT.
2. Commercially available 1 February 2010, initially as a platform service with web roles and worker roles, Blob storage, SQL Azure and Service Bus.
3. Infrastructure services, meaning ordinary virtual machines, entered preview in June 2012 and reached general availability in April 2013. Renamed from Windows Azure to Microsoft Azure on 25 March 2014.
4. Position today: Azure passed 100 billion US dollars of annual revenue in Microsoft’s fiscal year 2026, growing 41 per cent from 75 billion in fiscal 2025. Microsoft states over 70 Azure regions.
5. Google Cloud timeline. App Engine, a platform service, previewed 7 April 2008. Compute Engine was announced at Google I/O on 28 June 2012 in limited preview, opened broadly in May 2013 and reached general availability in December 2013. Google Kubernetes Engine launched in 2015, the first managed Kubernetes service.
6. Google Cloud’s strengths are concentrated: Kubernetes, since it wrote it; networking, since it owns an unusually large private backbone; and data analytics, where BigQuery separates storage from compute and is genuinely ahead. Revenue was 17.664 billion US dollars in the December 2025 quarter, up 48 per cent.

Provider	Regions	Recent revenue
AWS	39, 123 AZs	128.7 bn, FY2025
Azure	Over 70	Over 100 bn, FY2026
Google Cloud	43, 130 zones	17.7 bn, Q4 2025

7. The rest of the field, briefly and honestly. Oracle Cloud Infrastructure competes on database licensing terms and, since 2024, on large AI compute contracts. IBM Cloud is strongest in regulated industries and mainframe adjacency. Alibaba Cloud leads in China and much of South East Asia.
8. DigitalOcean, Hetzner and OVHcloud sell simple virtual servers at a fraction of hyperscaler list prices, with flat pricing and generous or unmetered traffic. For a small production workload the difference can be five to ten times.
9. Cloudflare is a different shape: a network-first provider whose Workers run code at edge locations and whose R2 object storage charges no egress fee, which is a direct attack on the industry’s most disliked charge.
10. The trade is real. The second tier gives you fewer managed services, fewer compliance certifications, smaller regional footprints and less depth of support. For a database-plus-web-server application, that often does not matter. For a regulated enterprise, it does.

■ 43.10.6 WORDS – remember these

1. Azure — Microsoft's cloud — announced October 2008, commercially available 1 February 2010, over 100 billion US dollars in fiscal 2026.
2. Entra ID — the Microsoft login your company already uses — the cloud identity service formerly named Azure Active Directory, renamed 11 July 2023.
3. Resource group — an Azure folder for related things — a management and lifecycle boundary containing resources within one subscription.
4. Hybrid cloud — some machines yours, some rented, managed together — a deployment model joining on-premises infrastructure with public cloud under one control and identity plane.
5. Hyperscaler — one of the very large providers — an operator running global fleets at a scale where custom hardware and custom networks are economic.
6. Egress-free storage — object storage with no charge to read data out — Cloudflare R2's pricing model, contrasted with per-gigabyte egress charges.

43.11 The service models: IaaS, PaaS, SaaS and FaaS

■ 43.11.1 PLAIN – in simple words

1. The models differ in one thing only: where the line is drawn between what you look after and what the provider looks after.
2. **IaaS**, infrastructure as a service. You rent machines, disks and networks. You install and patch the operating system, the runtime and your code. You have the most control and the most work.
3. **PaaS**, platform as a service. You give the provider your code. It provides the operating system, the runtime, scaling and deployment. You lose some control and most of the work.
4. **SaaS**, software as a service. You do not write anything. You use finished software over the web and configure it. Gmail, Salesforce, Zoom.
5. **FaaS**, function as a service, also called serverless. You give the provider one function. It runs it only when something triggers it, and charges only for the milliseconds it runs.
6. These are not four products. They are four points on one line, and the line is "how much of the stack do I own".
7. Nothing forces you to pick one. Real systems mix all four, usually without anybody deciding to.

■ 43.11.2 PLAIN – a picture in your head

1. The standard analogy is pizza as a service, and it is genuinely useful.
2. Made at home: you buy flour, cheese, an oven, gas and a table. That is owning your own servers.
3. Take and bake: you buy a ready pizza and use your own oven, gas and table. That is infrastructure as a service.
4. Delivered: someone else makes and cooks it; you supply the table, the drinks and the dining room. That is platform as a service.
5. Dining out: you supply nothing but yourself and money. That is software as a service.

Where this comparison breaks, and it breaks in three specific places. First, it suggests you own less as you move along, when in fact you still own all the important things: your data, your access rules and your legal obligations. Second, pizza has one dimension of choice. Cloud stacks let you take the oven from one supplier and the dough from another, which the analogy cannot express. Third, and worst, the analogy implies dining out costs the most. In cloud pricing the fully managed option is often the cheapest at small scale and the most expensive at large scale, and the crossover is the whole argument.

■ 43.11.3 PLAIN – a worked example

1. The same task, a small web application, at each level.
2. IaaS: launch an EC2 instance, install Ubuntu updates, install Python, install a web server, write a service unit file, configure log rotation, set up certificate renewal, and repeat all of it when you scale out.
3. PaaS: push your code to Azure App Service or Google Cloud Run. It builds a container, runs it, terminates TLS, scales copies with traffic, and rolls back if health checks fail.
4. FaaS: write one function that handles one request, register it against an HTTP trigger, and let the provider create and destroy execution environments as demand moves.
5. SaaS: realize you were building a form-and-spreadsheet tool and buy one.

Layer	IaaS	PaaS
Application code	You	You
Runtime, libraries	You	Provider
Operating system	You	Provider
Virtualization	Provider	Provider
Servers, network	Provider	Provider

■ 43.11.4 PLAIN – what is really happening inside

1. The important consequence of the split is not convenience. It is who is accountable when something goes wrong.
2. This is formalized as the **shared responsibility model**, and every major provider publishes a version of it.
3. The provider is responsible for security **of** the cloud: the buildings, the hardware, the hypervisor, the physical network, and the managed service software itself.
4. The customer is responsible for security **in** the cloud: operating system patching where applicable, network rules, identity and permissions, data encryption choices, and application code.
5. The line moves with the model. On IaaS you patch the guest operating system. On PaaS the provider does. On SaaS almost everything technical is theirs.
6. One thing never moves. Access control and data classification are always yours, in every model, without exception.
7. This is why almost every publicized cloud breach is a customer-side misconfiguration rather than a provider failure: a storage bucket made public, a permission granted too widely, a key committed to a repository.

■ 43.11.5 TECHNICAL – the engineer's version

1. The definitions are standardized in NIST SP 800-145, September 2011, which defines IaaS, PaaS and SaaS. FaaS post-dates it and is generally treated as a specialization of PaaS.
2. Responsibility split, stated as the providers state it:

Concern	IaaS	PaaS	SaaS
Data and access	You	You	You
Application code	You	You	Provider
Runtime, middleware	You	Provider	Provider
Guest OS patching	You	Provider	Provider
Host and hardware	Provider	Provider	Provider

Concern	IaaS	PaaS	SaaS

- Encryption responsibilities are subtler than the table suggests. Providers supply encryption at rest by default in most storage services, but key custody is a choice: provider-managed keys, customer-managed keys in a key management service, or customer-supplied keys held outside entirely.
- Compliance is inherited, not transferred. A provider's ISO/IEC 27001 or SOC 2 report covers their controls. Your auditor still tests yours. The document that connects the two is the provider's customer responsibility matrix.
- Service level agreements are financial instruments, not promises of uptime. A 99.99 per cent monthly agreement permits about 4 minutes 23 seconds of downtime per month, and the remedy for breach is typically a service credit of 10 to 100 per cent of that service's fee. It does not compensate your business loss.
- Availability arithmetic that engineers get wrong: dependencies multiply. A system depending on four independent components each at 99.9 per cent has a theoretical availability of 0.999 to the fourth power, which is 99.6 per cent, or about three hours per month.

■ 43.11.6 WORDS - remember these

- IaaS — renting raw machines — infrastructure as a service, where the tenant manages the guest operating system and everything above it.
- PaaS — hand over code, get a running service — platform as a service, provider-managed runtime, scaling and deployment.
- SaaS — finished software you just use — software as a service, delivered multi-tenant over the network, configured not coded.
- FaaS — one function, run on demand — function as a service, event-triggered, billed per invocation and per millisecond.
- Shared responsibility — who is to blame for what — the provider secures the cloud, the customer secures what they put in it.
- Service level agreement — the promised uptime and the refund if missed — a contractual availability target with service credits as the sole remedy.

43.12 Serverless, properly

■ 43.12.1 PLAIN - in simple words

- Serverless does not mean there are no servers. There are servers. You do not see them, name them, patch them or pay for them when idle.
- A better name would have been "someone else's servers, allocated per request". That name lost.
- You upload a function: a piece of code with one entry point.
- You attach a **trigger**: an HTTP request, a file appearing in storage, a message in a queue, a database change, a timer.
- When the trigger fires, the provider finds or creates an execution environment, runs your function, and returns the result.
- You are billed for the milliseconds it ran and the memory it was given. Between events the cost is zero.
- If a thousand events arrive at once, a thousand copies run at once. You did not configure that.
- The catch is that each run starts with no memory of any previous run. Nothing you leave in a variable can be relied on next time.

9. The other catch is that the very first run after a pause is slower, because the environment has to be created. That is the **cold start**.

■ 43.12.2 PLAIN – a picture in your head

1. Think of a hotel meeting room you can book by the minute.
2. Ordinary servers are like renting an office all year: it is yours, your things are on the desk, and you pay in August when nobody is there.
3. Serverless is like walking to reception, being handed an empty room in seconds, using it for ninety seconds, and leaving.
4. The room is always empty when you arrive. Anything you left last time is gone.
5. Most of the time a cleaned room is already waiting and you walk straight in. That is a warm start.
6. Occasionally none is ready, and staff must prepare one while you wait. That is a cold start.
7. If two hundred of your colleagues arrive at once, reception opens two hundred rooms, and you get one bill for two hundred short bookings.

Where this comparison breaks: a hotel has a fixed number of rooms and will eventually say no. Serverless platforms feel unlimited but have concurrency quotas, and hitting one produces throttling errors rather than a polite refusal. Also, in a hotel you pay per room. Here you pay per room multiplied by its size, so a function given four times the memory costs four times as much per second, even when it does not use the memory.

■ 43.12.3 PLAIN – a worked example

1. A real AWS Lambda function in Python, triggered when an image is uploaded to S3, which records the upload in DynamoDB.

```
import os, json, boto3, urllib.parse

ddb = boto3.resource("dynamodb")
table = ddb.Table(os.environ["TABLE_NAME"])

def handler(event, context):
    for record in event["Records"]:
        bucket = record["s3"]["bucket"]["name"]
        key = urllib.parse.unquote_plus(
            record["s3"]["object"]["key"])
        size = record["s3"]["object"]["size"]
        table.put_item(Item={
            "pk": f"{bucket}/{key}",
            "size": size,
            "eventTime": record["eventTime"],
        })
    return {"statusCode": 200,
            "body": json.dumps({"ok": len(event["Records"])))}
```

2. The two lines creating ddb and table are outside the handler on purpose. Code outside the handler runs once per execution environment, not once per event, so the connection is reused across warm invocations.
3. event describes what happened. context carries the request id and the remaining time in milliseconds.
4. unquote_plus is not decoration. S3 event keys are URL-encoded, and spaces arrive as plus signs. Forgetting this is one of the most common real bugs.

5. The function returns; the environment is kept warm for a while in case another event arrives; eventually it is destroyed.
6. Now the cost. Suppose 2 million invocations a month, 200 milliseconds each, at 512 MB.
7. Compute: $2,000,000 \times 0.2 \text{ s} \times 0.5 \text{ GB} = 200,000 \text{ GB-seconds}$. At 0.0000166667 US dollars per GB-second that is 3.33 US dollars.
8. Requests: 2,000,000 at 0.20 US dollars per million is 0.40 US dollars.
9. Total about 3.73 US dollars per month, before the free allowance of one million requests and 400,000 GB-seconds, which would cover most of it.
10. A single small EC2 instance running all month costs about 30 US dollars. For this workload serverless is roughly ten times cheaper.

■ 43.12.4 PLAIN – what is really happening inside

1. A cold start has four phases. The platform first downloads your code package.
2. It then creates an isolated execution environment. On AWS this is a Firecracker micro virtual machine, which boots in roughly 125 milliseconds.
3. It then starts the language runtime: interpreter, virtual machine or process.
4. Finally it runs your initialization code, the part outside the handler, and only then calls your handler.
5. After the handler returns, the environment is frozen rather than destroyed. A later event thaws it, and only the handler runs. That is a warm start, typically a few milliseconds of overhead.
6. Environments are frozen for some minutes and then reclaimed. The exact time is not documented and has changed over the years.
7. This is why state is unreliable. A warm environment keeps its variables, so caching sometimes appears to work, which is more dangerous than if it never worked.
8. Concurrency is not threads. Each concurrent event gets its own environment, so your function does not need to be thread-safe, but it also cannot share memory with its siblings.

■ 43.12.5 TECHNICAL – the engineer's version

1. AWS Lambda launched 13 November 2014, the first mainstream function service. Google Cloud Functions followed in 2016, Azure Functions in 2016.
2. Current published limits for Lambda: memory from 128 MB to 10,240 MB in 1 MB steps; maximum execution time 15 minutes; deployment package 50 MB zipped direct upload, 250 MB unzipped, or up to 10 GB as a container image; request and response payload 6 MB synchronous, 256 KB asynchronous; /tmp from 512 MB to 10 GB.
3. CPU is not configured separately. It is allocated in proportion to memory, with roughly one full virtual CPU at about 1,769 MB. Raising memory to make a function faster is a legitimate and frequently profitable tactic.
4. Pricing, x86, at the time of writing: 0.20 US dollars per million requests and 0.0000166667 US dollars per GB-second, with an always-free tier of one million requests and 400,000 GB-seconds per month. Provisioned concurrency costs 0.0000041667 US dollars per GB-second on top.
5. Measured cold start durations at the median, from public benchmarking:

Runtime	Typical cold start
Rust	150 to 300 ms
Python 3.12	200 to 300 ms
Node.js 20	200 to 400 ms
C# .NET 8	500 to 1,500 ms

Runtime	Typical cold start
Java 17, no SnapStart	800 to 2,000 ms

6. Cold start frequency depends entirely on traffic shape. At sustained high traffic it is well under 1 per cent of invocations. At a handful of requests per hour, 30 to 50 per cent of invocations are cold.
7. Two mitigations exist. Provisioned concurrency keeps environments warm at a price. SnapStart, introduced for Java in 2022 and later extended, takes a snapshot of the initialized environment and restores from it, cutting multi-second Java starts to a few hundred milliseconds.
8. The VPC penalty is historical. Before 2019, attaching a Lambda to a VPC added 10 to 15 seconds to a cold start because an elastic network interface was created per environment. AWS re-engineered this with shared interfaces, and the penalty is now typically under 50 milliseconds. Beware of old advice.
9. When serverless is right: spiky or unpredictable traffic; event processing glue between services; scheduled jobs; low steady volume where a server would sit idle; teams with no operations capacity.
10. When serverless is a trap: sustained high throughput, where per-request pricing exceeds a reserved instance by a wide margin; workloads needing more than 15 minutes; anything needing large in-memory state or a warm cache; latency-critical paths where a cold start is unacceptable; heavy database use, because a thousand concurrent functions open a thousand connections and exhaust the database, which is what RDS Proxy exists to fix.
11. Note also the debugging cost. Local reproduction is imperfect, stack traces cross service boundaries, and understanding a failure requires distributed tracing rather than a debugger.
12. Vendor lock-in is strongest here. The function body is portable. The triggers, permissions, event shapes and surrounding services are not.

■ 43.12.6 WORDS – remember these

1. Serverless — you never see or pay for an idle machine — an execution model with per-invocation billing, automatic scaling and no capacity management.
2. Cold start — the slow first run — the latency of creating an execution environment, starting the runtime and running initialization code.
3. Warm start — reusing a paused environment — invocation of a thawed environment, adding only milliseconds of overhead.
4. Trigger — the thing that causes your code to run — an event source binding such as HTTP, object creation, queue message or schedule.
5. Concurrency limit — how many copies may run at once — an account or function quota beyond which invocations are throttled.
6. Provisioned concurrency — paying to keep some copies warm — pre-initialized environments billed continuously to eliminate cold starts.
7. Firecracker — the tiny virtual machine underneath — AWS’s open-source micro-VM monitor, booting in about 125 milliseconds, used by Lambda and Fargate.

43.13 Storage in the cloud

■ 43.13.1 PLAIN – in simple words

1. There are three kinds of cloud storage, and choosing the wrong one is a common and expensive mistake.
2. **Block storage** is a virtual hard disk. You attach it to one machine, and the machine puts a filesystem on it. It is fast and it belongs to one owner.
3. **File storage** is a shared drive. Many machines mount it at once and see the same folders. Slower, but shared.
4. **Object storage** is different in kind. There are no folders and no disk. You store a whole item under a name, and you get the whole item back by name, over the web.
5. Object storage cannot be partly edited. To change one byte you upload the whole object again.
6. In exchange it is cheap, effectively unlimited, and enormously durable.
7. Choose block for databases and operating system disks. Choose file when several machines genuinely need the same files. Choose object for uploads, backups, logs, images, video and anything a browser will download.
8. There is one more thing everyone learns painfully. Putting data in is usually free. Taking data out to the internet is not.

■ 43.13.2 PLAIN – a picture in your head

1. Block storage is a blank notebook on your desk. You can rub out one word on page 40 and write another. Only you have it.
2. File storage is a shared filing cabinet in the office. Several people open drawers at once, and there are rules about who may write.
3. Object storage is a left-luggage counter. You hand over a sealed bag and get a ticket. Later you show the ticket and get the whole bag back.
4. You cannot ask the counter to change one shirt inside the bag. You take the bag, change the shirt, and hand back a new bag.
5. The counter is astonishingly cheap and never runs out of shelves.
6. But it charges you a small fee every time you carry a bag out of the building.

Where this comparison breaks: a left-luggage counter has one shelf per bag. Object storage keeps several copies of your bag in several buildings, which is why it survives a fire and a notebook does not. Also, the counter here is reachable by anyone in the world with the right ticket, which is a security property the analogy hides and which has caused a great many public data leaks.

■ 43.13.3 PLAIN – a worked example

1. Real S3 list prices for the North Virginia region, August 2026, per gigabyte per month.

Storage class	Price per GB	Use for
Standard, first 50 TB	0.0230	Active data
Standard-IA	0.0125	Monthly access
One Zone-IA	0.0100	Recreatable data
Glacier Instant	0.0040	Quarterly access
Glacier Flexible	0.0036	Backups
Glacier Deep Archive	0.00099	Legal retention

2. Deep Archive is about 23 times cheaper than Standard. That is why lifecycle rules exist.

3. Requests cost separately: 0.005 US dollars per 1,000 PUT requests and 0.0004 per 1,000 GET requests in Standard. In Glacier Deep Archive a PUT costs 0.05 per 1,000, ten times more, because the class is designed for few, large objects.
4. Store 10 terabytes of logs. In Standard: $10,240 \text{ GB} \times 0.023 = 235.52$ US dollars per month. In Deep Archive: $10,240 \times 0.00099 = 10.14$ US dollars.
5. Now the trap. You want to download those 10 terabytes to your own datacentre.
6. Data transfer out to the internet is billed at 0.09 US dollars per gigabyte for the first 10 TB each month, after 100 GB free.
7. $10,240 \text{ GB} \times 0.09 = 921.60$ US dollars, minus the free 100 GB, so about 912 US dollars.
8. Read that again. Storing the data for a month cost 10 dollars. Reading it once cost 912. The exit costs 90 times the rent.
9. That asymmetry is the single most important commercial fact about cloud storage, and it is not an accident.

■ 43.13.4 PLAIN – what is really happening inside

1. When you PUT an object, the service splits it, computes checksums, and writes copies to storage nodes in at least three separate availability zones before it answers “done”.
2. That is why the write is slower than a local disk write and why the durability claim is so high.
3. Object names look like paths, but there are no directories. `2026/08/log.txt` is one flat key that happens to contain slashes, and the console draws fake folders from them.
4. A lifecycle policy is a background process the service runs on your bucket daily. It looks at object age and moves or deletes objects by rule.
5. Transitions are not free: each object moved costs a lifecycle transition request. Moving ten million tiny objects to Glacier can cost more than leaving them where they were.
6. Egress is metered at the edge of the provider’s network. Traffic to the internet is charged; traffic to another service inside the same region is usually free; traffic between availability zones or regions has its own smaller rate.

■ 43.13.5 TECHNICAL – the engineer’s version

1. Consistency. S3 offered eventual consistency for overwrites and deletes until 1 December 2020, when AWS made it strongly read-after-write consistent for all operations, at no extra cost and with no performance penalty. A great deal of published advice about “eventual consistency workarounds” predates that date and is now wrong.
2. Strong consistency here means a successful PUT is immediately visible to a subsequent GET or LIST from any client. It does not provide transactions across objects, and there is still no locking beyond conditional writes.
3. Performance figures: at least 3,500 PUT, COPY, POST or DELETE and 5,500 GET or HEAD requests per second per partitioned prefix, scaling by adding prefixes. Maximum object size 5 TB; maximum single PUT 5 GB; multipart upload required above that, with up to 10,000 parts.
4. Block storage on AWS is EBS: gp3 at 0.08 US dollars per GB-month with 3,000 IOPS and 125 MB/s included, extra IOPS at 0.005 each per month; io2 at 0.125 per GB-month plus 0.065 per provisioned IOPS. Snapshots cost 0.05 per GB-month standard, 0.0125 archived, and are incremental.
5. gp2, the older class, costs 0.10 per GB-month and ties performance to size at 3 IOPS per GB. gp3 is cheaper and decouples the two. Migrating gp2 volumes to gp3 is one of the easiest genuine savings in AWS.
6. File storage is EFS on AWS, Azure Files, or Filestore on Google Cloud. EFS speaks NFSv4.1 and costs several times more per gigabyte than EBS, so use it only when sharing is a real requirement.
7. Lifecycle policy, expressed in the JSON that the API actually takes:

```
{
  "Rules": [
    {
      "ID": "logs-tiering",
      "Filter": {"Prefix": "logs/"},
      "Status": "Enabled",
      "Transitions": [
        {"Days": 30, "StorageClass": "STANDARD_IA"},
        {"Days": 90, "StorageClass": "GLACIER"},
        {"Days": 365, "StorageClass": "DEEP_ARCHIVE"}
      ],
      "Expiration": {"Days": 2555}
    }
  ]
}
```

8. Minimum storage durations are billed even if you delete early: 30 days for Standard-IA and One Zone-IA, 90 days for Glacier Flexible, 180 days for Deep Archive. Standard-IA and One Zone-IA also bill a minimum object size of 128 KB, so tiering many small files can increase the bill.
9. Retrieval from Deep Archive takes up to 12 hours in standard mode and costs per gigabyte on top. It is an archive, not cold storage you can browse.
10. Egress pricing tiers for data out to the internet from US and EU regions: first 100 GB per month free across all services, then 0.09 US dollars per GB to 10 TB, 0.085 to 50 TB, 0.07 to 150 TB, and 0.05 above that. Cross-availability-zone traffic is 0.01 per GB in each direction, and NAT gateway processing adds 0.045 per GB on top of everything else.
11. Two changes have eroded the egress lock. From 5 March 2024 AWS offers free data transfer out for customers who are leaving AWS entirely, with 90 days to complete the move and a support request required; other major providers made similar announcements. And the European Union's Data Act, Regulation 2023/2854, requires switching charges including egress fees to be fully withdrawn from 12 January 2027.
12. Cloudflare R2 and several second-tier providers charge no egress at all, which is a deliberate competitive attack on this pricing model.

■ 43.13.6 WORDS - remember these

1. Object storage — whole items stored and fetched by name — a flat key-value store over HTTP, immutable per object, replicated across zones.
2. Block storage — a virtual hard disk for one machine — network-attached block device presented as raw sectors, formatted by the guest.
3. File storage — a shared network drive — a managed NFS or SMB filesystem mountable by many clients at once.
4. Storage class — how cheap and how slow — a tier trading price per gigabyte against retrieval time, minimum duration and request cost.
5. Lifecycle policy — automatic tiering and deletion by age — bucket rules that transition or expire objects on a daily background pass.
6. Egress — the charge for data leaving — per-gigabyte data transfer out to the internet, typically 0.09 US dollars per GB at the first tier.

43.14 Cloud networking

■ 43.14.1 PLAIN - in simple words

1. A VPC, virtual private cloud, is your own private network inside the provider's network. You choose the address range and the layout.
2. Inside it you create **subnets**, which are slices of that address range, each pinned to one availability zone.

3. A subnet is called **public** if its route table sends unknown traffic to an internet gateway, and **private** if it does not. That is the only difference.
4. An **internet gateway** lets traffic in and out. A **NAT gateway** lets private machines reach out to the internet while nothing can reach in.
5. **Security groups** are firewalls attached to individual machines. They allow traffic; they cannot deny it, and they remember connections.
6. **Network ACLs** are firewalls attached to whole subnets. They can allow and deny, and they remember nothing.
7. **Load balancers** sit in front of your machines and spread traffic. Layer 4 forwards connections without reading them. Layer 7 reads the request and can route by hostname or path.
8. **Private endpoints** let you reach a provider service without your traffic going over the internet at all.
9. **Peering** joins two networks. A **transit gateway** joins many, in a hub pattern, instead of one link per pair.

■ 43.14.2 PLAIN – a picture in your head

1. Think of a gated business park that you have rented and laid out.
2. The park boundary is the VPC. The address range is the numbering scheme for all the plots.
3. Subnets are the blocks of plots. Two blocks are in one part of the park and two in another, on separate power and water.
4. The main gate is the internet gateway.
5. A NAT gateway is a courier desk. Staff in the inner blocks can send parcels out through it and get replies, but nobody outside can address a parcel to them directly.
6. Security groups are the locks on each individual building's doors.
7. Network ACLs are the barriers at the entrance to each block, checking every vehicle in both directions with no memory of who came in.
8. A load balancer is the receptionist at the front, directing arrivals to whichever office is open.

Where this comparison breaks: in a real park a delivery van drives itself. Here, every packet's path is decided by a route table you wrote, and if no route matches, the packet is silently dropped. There is no lost-property office and no error message. Silence is the normal failure mode, which is why the first thing to check in any cloud networking problem is the route table.

■ 43.14.3 PLAIN – a worked example

1. A standard three-tier VPC, spread over two availability zones.

2. Address maths. $10.0.0.0/16$ gives 65,536 addresses. Each $/24$ gives 256, of which AWS reserves 5, leaving 251 usable.
3. Route table for the public subnets: $10.0.0.0/16$ local, $0.0.0.0/0$ to the internet gateway.
4. Route table for the application subnets: $10.0.0.0/16$ local, $0.0.0.0/0$ to the NAT gateway in the same availability zone.
5. Route table for the data subnets: $10.0.0.0/16$ local, and nothing else. The database cannot reach the internet at all, which is deliberate.
6. Security group chain: the load balancer group allows 443 from anywhere; the web group allows 8000 only from the load balancer's group; the database group allows 5432 only from the web group.
7. Referencing a group rather than an address range is the important habit. It keeps working when instances are replaced.
8. One NAT gateway per availability zone, not one shared, because a shared NAT gateway makes the other zone depend on the first, defeating the whole design.

■ 43.14.4 PLAIN – what is really happening inside

1. None of this is physical. There is no cable and no real router.
2. Every packet leaving an instance is intercepted by the host's virtualization hardware, which looks up your VPC's rules and rewrites the packet into an encapsulated form.
3. That encapsulated packet crosses the provider's physical network as ordinary traffic, is decapsulated at the destination host, and delivered.
4. Your route tables and security groups are entries in a distributed database that is pushed to every host that needs them.
5. On AWS this mapping work happens on the Nitro card, not on the CPU, which is why a security group costs almost nothing in performance.
6. Because rules are enforced at the source host, a denied packet never reaches the network. There is no device to log it, which is why denied traffic is invisible unless you enable flow logs.

■ 43.14.5 TECHNICAL – the engineer's version

1. Address planning uses RFC 1918 private ranges: $10.0.0.0/8$, $172.16.0.0/12$ and $192.168.0.0/16$. AWS VPC CIDR blocks may be $/16$ to $/28$. Overlapping ranges between VPCs make peering impossible later, so allocate deliberately from day one.
2. Security groups versus network ACLs, the exam question and the real one:

Property	Security group	Network ACL
Attaches to	Instance interface	Subnet
Rules	Allow only	Allow and deny
State	Stateful	Stateless
Evaluation	All rules, any match	Numbered, first match

3. **Stateful** means the return traffic of an allowed outbound connection is automatically permitted. **Stateless** means you must write both directions, including the ephemeral port range 1024 to 65535 for replies. This is the same distinction drawn in Chapter 34 for ordinary firewalls, and it is the most common source of network ACL mistakes.

4. Load balancers by layer. A network load balancer operates at layer 4, forwards TCP or UDP flows, preserves the client address, handles millions of connections per second and adds tens of microseconds. An application load balancer operates at layer 7, terminates TLS, understands HTTP, and can route by host header, path, method or header value, at the cost of about one millisecond and a more complex failure surface.
5. Private connectivity to services: gateway endpoints, which are route table entries for S3 and DynamoDB and are free; and interface endpoints, which are PrivateLink elastic network interfaces in your subnets, billed per hour and per gigabyte. Using a gateway endpoint for S3 removes both NAT gateway processing charges and the internet path.
6. VPC peering is one-to-one, non-transitive, and requires non-overlapping CIDR blocks. If A peers with B and B peers with C, A cannot reach C. That limitation is exactly why AWS Transit Gateway exists: a hub that all VPCs attach to, giving transitive routing, at a per-attachment hourly charge plus per-gigabyte processing.
7. Hybrid connectivity: site-to-site VPN over the internet using IPsec, typically 1.25 Gbps per tunnel and subject to internet variability; or Direct Connect, a dedicated physical circuit from 50 Mbps to 100 Gbps with predictable latency and lower egress rates. Azure calls the equivalent Express-Route; Google calls it Cloud Interconnect.
8. Observation: VPC Flow Logs record accepted and rejected flows to CloudWatch or S3. Reachability Analyzer traces a path through your configuration and tells you which rule blocked it, without sending a packet. `aws ec2 describe-route-tables` and `aws ec2 describe-security-groups` are the two commands most often needed at 3am.

■ 43.14.6 WORDS – remember these

1. VPC — your own private network in the provider — a logically isolated virtual network with tenant-defined CIDR, subnets and routing.
2. Subnet — a slice of that network in one zone — a CIDR range bound to a single availability zone with one associated route table.
3. Internet gateway — the way in and out — a horizontally scaled VPC component providing a route to and from the public internet.
4. NAT gateway — outbound only, for private machines — a managed network address translation service, billed hourly and per gigabyte.
5. Security group — a stateful allow-list on one machine — instance-level rules permitting traffic, with automatic return-path allowance.
6. Network ACL — a stateless filter on a whole subnet — numbered allow and deny rules evaluated in order, requiring explicit return rules.
7. Transit gateway — one hub instead of many pairwise links — a regional router providing transitive connectivity between many VPCs and on-premises networks.

43.15 Identity and access

■ 43.15.1 PLAIN – in simple words

1. Every action in a cloud account is an API call, and every API call is checked against rules before it runs.
2. The system holding those rules is identity and access management, IAM.
3. There are two kinds of actor. A **user** is a person with a long-lived password or key. A **role** is a set of permissions that anything can borrow temporarily.
4. A **policy** is a document listing which actions are allowed on which resources, and under which conditions.
5. The single most important habit is **least privilege**: grant exactly what is needed and nothing more, then review it.
6. The second most important habit is to stop using long-lived keys.
7. A long-lived key is a password that never expires, is often copied into a config file, and frequently ends up in a code repository.
8. A role gives out temporary credentials that expire in an hour. If they leak, the window is small.
9. Machines should never hold permanent keys. A server gets a role attached to it, and the credentials appear automatically and rotate themselves.

■ 43.15.2 PLAIN – a picture in your head

1. Think of a hospital again.
2. A user is a staff member with a permanent badge that opens certain doors.
3. A role is a coat hanging by the door of the operating theatre. Anyone authorized may put it on, and while wearing it they can do surgery.
4. The coat is returned. It cannot be taken home, and it stops working at the end of the shift.
5. A policy is the written list of which doors that coat opens.
6. Least privilege means the surgery coat does not also open the pharmacy safe, even though it would occasionally be convenient.
7. The commonest real-world failure is a coat that opens everything, made once during an emergency, and never taken out of circulation.

Where this comparison breaks: a coat is physical, so only one person wears it at a time. Temporary credentials can be copied and used from anywhere in the world until they expire. That is why conditions such as source address, multi-factor authentication and session duration matter as much as the permission list.

■ 43.15.3 PLAIN – a worked example

1. A policy allowing an application to read one bucket and nothing else.

```
{
  "Version": "2012-10-17",
  "Statement": [{
    "Sid": "ReadUploadsOnly",
    "Effect": "Allow",
    "Action": ["s3:GetObject", "s3:ListBucket"],
    "Resource": [
      "arn:aws:s3:::festival-uploads",
      "arn:aws:s3:::festival-uploads/*"],
    "Condition": {
      "Bool": {"aws:SecureTransport": "true"}
    }
  ]
}
```

```

    }
  }
}

```

2. Two resource lines are needed because `ListBucket` acts on the bucket and `GetObject` acts on objects inside it. Forgetting this is a daily support question.
3. The condition rejects any request that did not arrive over TLS.
4. Version is a fixed policy language date, not your version number. It must be 2012-10-17.
5. Attach this policy to a role, attach the role to the instance, and the application never sees a key.
6. Compare with the wildcard policy that people write when they are tired: `"Action": "s3:*", "Resource": "*"`. That grants delete on every bucket in the account, including the backups.

■ 43.15.4 PLAIN – what is really happening inside

1. Policy evaluation follows a fixed order, and knowing it saves hours.
2. Start from an implicit deny. Nothing is allowed by default.
3. Evaluate all applicable policies: identity policies on the caller, resource policies on the target, permission boundaries, service control policies from the organization, and session policies.
4. If any of them contains an explicit deny that matches, the answer is deny. Nothing can override an explicit deny.
5. Otherwise, if at least one allow matches and no boundary excludes it, the answer is allow.
6. Otherwise the answer is deny by default.
7. In one line: explicit deny beats allow, and allow beats the default deny.
8. Temporary credentials work through a token service. An entity calls “assume this role”, proving its own identity; the service checks the role’s trust policy; if satisfied it returns an access key, a secret key and a session token with an expiry.
9. On an EC2 instance a metadata service delivers those credentials to software on the machine and refreshes them before expiry. On Kubernetes, a service account token is exchanged for the same thing.

■ 43.15.5 TECHNICAL – the engineer’s version

1. Policy types and their interaction: identity-based policies attach to users, groups and roles; resource-based policies attach to buckets, queues and keys and can grant cross-account access without a role; permission boundaries cap the maximum a principal can be granted; service control policies cap an entire account within an organization; session policies narrow one session.
2. A principal’s effective permission is the intersection of all caps and the union of all grants, minus every explicit deny.
3. Instance metadata: IMDSv1 was a plain unauthenticated HTTP GET to 169.254.169.254. IMDSv2 requires a PUT to obtain a session token first and sets a low IP hop limit, which defeats the classic server-side request forgery path. AWS began defaulting new instances to IMDSv2 in 2024. Enforce it explicitly on older infrastructure.
4. That specific weakness produced the best-known cloud breach. In March 2019 an attacker exploited a server-side request forgery flaw in a misconfigured web application firewall at Capital One, reached the metadata service, obtained the credentials of an over-permissive role, and used them to list and copy S3 buckets containing roughly 106 million customer records. Regulators fined the bank 80 million US dollars in 2020 and a class action settled at 190 million.
5. Note that no AWS component failed. Every step used a documented feature. The failure was a firewall misconfiguration plus a role with far more S3 access than the application needed.
6. The two dominant causes of cloud compromise remain over-permissive policies and leaked long-lived keys. Keys leak through public repositories, container images, CI logs, browser bundles

and screenshots. Automated scanners find a newly committed AWS key in public GitHub within minutes.

7. Mitigations in order of value: use roles and short-lived credentials everywhere; federate human access through single sign-on so no human has an access key at all; enable multi-factor authentication on every account with console access; turn on GitHub push protection and secret scanning; set an organization-wide service control policy denying dangerous actions outright.
8. Right-sizing tools: IAM Access Analyzer generates a least-privilege policy from CloudTrail history; last-accessed data shows which services a principal has actually used; Access Advisor exposes the same for roles.
9. Naming, for cross-provider fluency. AWS uses roles and JSON policies. Azure uses Entra ID principals with role-based access control, where a role assignment binds a role definition to a scope. Google Cloud binds members to predefined or custom roles at a resource in the hierarchy, and its default Compute Engine service account is famously over-permissive and should be replaced.
10. Diagnostic commands: `aws sts get-caller-identity` to learn who you are; `aws iam simulate-principal-policy` to test a decision before deploying it; CloudTrail event history to find the exact denied call and its reason.

■ 43.15.6 WORDS – remember these

1. IAM — the rules about who may do what — identity and access management, evaluated on every API call against identity and resource policies.
2. Role — a borrowable set of permissions — an identity with no long-term credentials, assumed to obtain time-limited session credentials.
3. Policy — the document listing allowed actions — a JSON statement set of effect, action, resource and condition.
4. Least privilege — grant only what is needed — the principle of minimizing granted permissions to those actually exercised.
5. Explicit deny — a refusal nothing can override — the highest-precedence outcome in policy evaluation, above any allow.
6. Instance metadata service — where a machine gets its own credentials — the link-local endpoint at 169.254.169.254, hardened as IMDSv2.
7. Service control policy — an account-wide ceiling — an organization policy limiting the maximum permissions available in member accounts.

43.16 What cloud costs and how bills explode

■ 43.16.1 PLAIN – in simple words

1. A cloud bill is not one price. It is dozens of meters running at once.
2. The usual dimensions are: time a machine existed, storage held per month, number of requests, gigabytes moved, and per-hour charges for things that feel free, such as addresses and gateways.
3. Three ways to pay for compute. **On demand** is the list price, no commitment. **Reserved**, or savings plans, means promising one or three years of spending for a discount of roughly 30 to 72 per cent. **Spot** means using spare capacity at up to 90 per cent off, on the condition it can be taken away with two minutes' notice.
4. Bills explode for boring reasons, almost never exciting ones.
5. Something was left running. Somebody chose a machine ten times bigger than needed. Logs were kept forever. Data crossed a boundary that charges.
6. The free tier is genuinely useful and genuinely a trap: it hides which resources cost money until the day it expires.
7. The honest headline: at steady, predictable load, owning hardware is usually cheaper than renting it. Cloud wins on speed, elasticity and not needing a team, not on unit price.

■ 43.16.2 PLAIN – a picture in your head

1. Think of a mobile phone bill from before unlimited plans.
2. The handset rental is the machine. The data pack is the storage. Calls are requests. Roaming is egress.
3. Everyone understood the handset charge. Everyone was shocked by roaming.
4. Roaming had three properties that made it dangerous: it was per unit, it was invisible while it happened, and it was triggered by crossing a boundary nobody was thinking about.
5. Cloud egress and cross-zone traffic are exactly that. The boundary is invisible in your code and expensive in your bill.
6. And there is one extra hazard the phone bill did not have: your program can generate charges by itself, all night, with nobody watching.

Where this comparison breaks: a phone bill has a ceiling because a human can only talk so much. A misconfigured job can generate a five-figure bill in hours, and there is no hard spending limit you can set on the major clouds. Budgets alert you; they do not stop you.

■ 43.16.3 PLAIN – a worked example

1. A real monthly bill for a modest production application in North Virginia, using the list prices quoted earlier in this chapter. Two web servers across two zones, a managed database with a standby, a load balancer, storage and 500 GB of traffic to users.

Item	Calculation	USD
2 x t3.medium, 730 h	2x730x0.0416	60.74
2 x 30 GB gp3 root	60x0.08	4.80
RDS db.t4g.medium, MAZ	730x0.129	94.17
RDS storage 100 GB gp3	100x0.115	11.50
ALB, base + ~8 LCU	730x(0.0225+0.064)	63.15
NAT gateway, 1 zone	730x0.045	32.85
NAT data, 200 GB	200x0.045	9.00
S3 200 GB Standard	200x0.023	4.60

Item	Calculation	USD
Egress 500 GB, 100 free	400x0.09	36.00
Route 53 zone + queries	0.50 + ~0.40	0.90
Secrets Manager, 4	4x0.40	1.60
CloudWatch logs 20 GB	20x0.50	10.00
Total		329.31

- Now read the bill rather than the total. The two web servers, the thing everybody thinks of as “the cost”, are 18 per cent of it.
- The database costs more than the servers. The load balancer costs as much as the servers. The NAT gateway costs 42 dollars to forward packets.
- Egress of half a terabyte, which is a small website, costs more than the object storage holding everything.
- Savings available without changing the architecture: a one-year compute savings plan takes about 30 per cent off the EC2 and RDS lines, roughly 47 dollars. A gateway endpoint for S3 removes much of the NAT data charge. Log retention set to 14 days cuts CloudWatch.
- For comparison, a dedicated server of similar capability from a low-cost European host costs about 40 to 70 US dollars per month including generous traffic, but with no managed database, no standby, no load balancer and no support.

■ 43.16.4 PLAIN – what is really happening inside

- Every service writes usage records continuously, usually per hour, sometimes per second, into a billing pipeline.
- Those records land in a detailed usage report with one row per resource, per usage type, per hour. The monthly invoice is a summary of tens of millions of rows.
- This is why bills are hard to read: the invoice groups by service, but costs are caused by resources and by teams.
- Tags are the only mechanism that connects the two. An untagged resource is effectively anonymous spending.
- Charges accrue whether or not anything useful happens. A stopped EC2 instance still bills its EBS volume, its snapshots and its allocated public address.
- Since February 2024 AWS charges for every public IPv4 address, in use or not, at 0.005 US dollars per hour, about 3.60 per month each. Many organizations discovered hundreds of forgotten addresses.

■ 43.16.5 TECHNICAL – the engineer’s version

- Commitment mechanisms: Reserved Instances lock instance family and region; Savings Plans commit to a dollar per hour of spend and are more flexible. Discounts run roughly 30 to 40 per cent for one year with no upfront payment, and up to 72 per cent for three years paid fully in advance.
- Spot instances draw on spare capacity at typically 70 to 90 per cent off, with a two-minute interruption notice. Correct uses are stateless web tiers behind a load balancer, batch processing, continuous integration runners and fault-tolerant analytics. Incorrect uses are databases and anything holding state a customer cares about.
- Free tier changed materially on 15 July 2025. Accounts created from that date receive 100 US dollars of credit at sign-up and up to 100 more for completing activities, on a plan that ends after six months or when credits run out. The old twelve-month free tier applies only to accounts cre-

ated before that date. Always-free allowances, such as one million Lambda requests per month, continue under both schemes.

4. The classic explosion patterns, in the order they actually occur: a development environment left running over a holiday; log retention set to never expire; a NAT gateway processing data that should have used an endpoint; cross-availability-zone chatter between services that could have been zone-aware; oversized instances chosen from a template; unattached EBS volumes and old snapshots; and a recursive trigger, where a function writes to the bucket that triggers it.
5. **FinOps** is the discipline that grew up around this. The FinOps Foundation was formed in 2019 and moved under the Linux Foundation in 2020. Its model is three iterative phases: inform, meaning visibility and allocation; optimize, meaning rightsizing and commitments; and operate, meaning continuous governance.
6. Practical controls, in order of return on effort: mandatory cost allocation tags enforced by policy; AWS Budgets with alerts at 50, 80 and 100 per cent; automatic shutdown schedules for non-production; Compute Optimizer or equivalent for rightsizing; S3 lifecycle rules and log retention limits; gateway endpoints for S3 and DynamoDB; and one named person who reviews the top ten line items every month.
7. Now the honest comparison, which the industry avoided for a decade.
8. A single dedicated server bought outright, amortized over five years, is typically two to five times cheaper per unit of compute than the equivalent on-demand cloud instance, before staff costs.
9. The best-documented case is 37signals, the company behind Basecamp. It spent 3,201,564 US dollars on cloud in 2022, moved seven applications off AWS during 2023 onto about 700,000 US dollars of Dell hardware, and reported savings of nearly 2 million US dollars in the first full year, with total projected savings above 10 million over five years. It then moved roughly 10 petabytes off S3 as well.
10. Dropbox is the other well-known case. It moved the bulk of its storage off AWS onto its own infrastructure, a project called Magic Pocket, and its 2018 filing reported 74.6 million US dollars of infrastructure savings across 2016 and 2017.
11. Both are the same shape: large, steady, predictable workloads, with strong in-house engineering, and a bill dominated by storage and bandwidth.
12. When cloud is genuinely the better economic choice: unpredictable or seasonal load; early-stage products where the requirement is unknown; small teams with nobody to run hardware; workloads needing global reach quickly; and anything where time to market dominates unit cost.
13. When owning is better: steady load at scale; heavy egress; large storage volumes; regulatory requirements that push to dedicated hardware anyway; and organizations that already employ infrastructure staff.
14. The reasonable middle position, and the one most large companies have reached by 2026, is a split: steady baseline on owned or long-committed capacity, burst and experimentation in the cloud.

■ 43.16.6 WORDS – remember these

1. On-demand pricing — full price, no promises — per-second or per-hour billing with no commitment and no discount.
2. Reserved and savings plans — a discount for a promise — one or three year commitments giving roughly 30 to 72 per cent off.
3. Spot — very cheap, can be taken away — interruptible spare capacity at 70 to 90 per cent off with a two-minute notice.
4. Egress — the charge for data leaving — per-gigabyte data transfer out, the most common source of bill surprise.
5. Idle spend — paying for what nobody uses — unattached volumes, stopped instances still holding storage, unused addresses and forgotten environments.
6. FinOps — treating cloud spend as an engineering problem — the inform, optimize and operate practice defined by the FinOps Foundation from 2019.
7. Repatriation — moving workloads back off cloud — relocating steady, high volume workloads to owned hardware for cost reasons.

43.17 DevOps, infrastructure as code and the modern workflow

■ 43.17.1 PLAIN – in simple words

1. For decades, two groups fought. Developers were paid to ship changes. Operators were paid to keep things stable. Change is the enemy of stability, so they were structurally opposed.
2. **DevOps** is the idea of removing that opposition: one team, shared goals, shared responsibility for both shipping and running.
3. It is a way of organizing people. It is not a tool, not a job title and not a department, although the industry turned it into all three.
4. The technical half is **infrastructure as code**: instead of clicking in a web console, you write a file describing what should exist, and a tool makes reality match it.
5. That file goes into version control, gets reviewed, and can rebuild the entire environment from nothing.
6. **Immutable infrastructure** takes it further: never patch a running machine. Build a new one from a new image and throw the old one away.
7. **GitOps** takes it further still: the repository is the only source of truth, and an agent inside the cluster continuously pulls from it and corrects drift.
8. **Observability** is being able to answer questions about a running system that you did not think to ask in advance. It needs logs, metrics and traces together, because each answers a different question.
9. **Site reliability engineering** is the discipline of deciding, numerically, how reliable a service must be, and spending the remaining unreliability deliberately on shipping features.

■ 43.17.2 PLAIN – a picture in your head

1. Think of two ways to furnish a flat.
2. Way one: over three years you buy things, move them, and drill holes. It looks fine. Now furnish an identical flat next door exactly the same way. You cannot. Nobody wrote anything down.
3. Way two: you keep a plan on one sheet. Every change is drawn on the plan first, then done. Furnishing the identical flat takes an afternoon.
4. Infrastructure as code is the second way.
5. Immutable infrastructure is the rule that you never repaint a wall. You build a new wall to the new plan and remove the old one.
6. GitOps adds a caretaker who compares the flat to the plan every few minutes and undoes anything that does not match, including your own quick fix.

Where this comparison breaks: a flat has no state. A database has state, and you cannot throw it away and build a new one. The immutable rule applies cleanly to servers that hold no data, and needs careful exceptions for anything that does. That distinction, stateless versus stateful, is the whole reason people speak of cattle and pets.

■ 43.17.3 PLAIN – a worked example

1. The same load balancer and instance, written in Terraform.

```
resource "aws_security_group" "web" {
  name     = "festival-web"
  vpc_id   = aws_vpc.main.id

  ingress {
    from_port     = 8000
    to_port       = 8000
    protocol      = "tcp"
    security_groups = [aws_security_group.alb.id]
  }
  egress {
    from_port = 0
    to_port   = 0
    protocol  = "-1"
    cidr_blocks = ["0.0.0.0/0"]
  }
}

resource "aws_instance" "web" {
  count          = 2
  ami            = var.app_ami_id
  instance_type  = "t3.medium"
  subnet_id      = aws_subnet.app[count.index].id
  vpc_security_group_ids = [aws_security_group.web.id]
  iam_instance_profile = aws_iam_instance_profile.web.name

  tags = {
    Name = "festival-web-${count.index}"
    Env  = "prod"
    Cost = "festival"
  }
}
```

2. `aws_security_group.alb.id` is a reference, not a copied value. Terraform builds a dependency graph from those references and orders creation itself.

3. `count = 2` creates two instances. Changing it to four is a one-character edit and a reviewable change.
4. `var.app_ami_id` points at a machine image built in advance. Changing that variable replaces both instances, which is immutable infrastructure in practice.
5. The tags are not decoration. They are how the monthly bill gets attributed.
6. The workflow:

```
terraform init
terraform plan -out=tf.plan
terraform apply tf.plan
terraform state list
terraform destroy
```

7. `plan` is the important command. It prints exactly what will be created, changed or destroyed, before anything happens. Reviewing a plan is the equivalent of reviewing a diff.

■ 43.17.4 PLAIN – what is really happening inside

1. Terraform keeps a **state file**: a record of which real resources correspond to which blocks in your code.
2. On `plan` it does three reads: your configuration, the state file, and the actual cloud API. It then computes the difference.
3. That is why the state file matters so much. Lose it and Terraform no longer knows it owns anything, and will try to create everything again.
4. In any team the state lives remotely, in S3 or an equivalent, with locking so two engineers cannot apply at once.
5. GitOps inverts the direction of control. Instead of a pipeline pushing changes into the cluster, an agent inside the cluster pulls the repository and applies it continuously.
6. That means the cluster needs no inbound credentials from the pipeline, and any manual change made by hand is reverted within minutes.
7. Observability data flows separately. Applications emit structured logs, numeric metrics and trace spans; agents collect them; backends store and index them; dashboards and alerts read them.

■ 43.17.5 TECHNICAL – the engineer's version

1. Origins. The word DevOps comes from DevOpsDays, organized by Patrick Debois in Ghent, Belgium, in October 2009. The cultural model is often summarized as CALMS: culture, automation, lean, measurement, sharing.
2. Tooling lineage for infrastructure as code: CFEngine 1993, Puppet 2005, Chef 2009, SaltStack 2011, Ansible 2012. Those are configuration management, which converges the inside of an existing machine.
3. Provisioning tools create the machines and the surrounding cloud resources: AWS CloudFormation from February 2011, Terraform from HashiCorp in 2014, Azure Resource Manager templates and the friendlier Bicep, and Pulumi from 2018, which uses ordinary programming languages instead of a domain-specific one.
4. A licensing event worth knowing: HashiCorp changed Terraform's licence from Mozilla Public License to the Business Source License in August 2023. The community forked it as OpenTofu, adopted by the Linux Foundation in September 2023, with version 1.0 in January 2024. If you are choosing today, this is a live consideration.

Tool	Language	Scope
CloudFormation	YAML or JSON	AWS only
Terraform, OpenTofu	HCL	Multi-provider
Pulumi	Python, TS, Go	Multi-provider
Ansible	YAML	Config management

5. Immutable infrastructure practice: bake an image with Packer or an equivalent, version it, deploy by replacing instances, and forbid interactive login to production. The phrase “cattle, not pets” comes from a 2012 talk by Bill Baker of Microsoft, popularized by Randy Bias.
6. GitOps was named by Alexis Richardson of Weaveworks in 2017. The CNCF OpenGitOps project states four principles: the desired state is declarative; it is versioned and immutable; agents pull it automatically; and agents continuously reconcile actual to desired. Argo CD and Flux are the two main implementations.
7. Observability, the three signals, and why you need all three. Metrics are cheap numbers over time and tell you that something is wrong. Logs are detailed records of individual events and tell you what happened in one case. Traces follow a single request across service boundaries and tell you where the time went and which service failed.
8. Metrics alone cannot tell you which user. Logs alone cannot show a system-wide pattern or a cross-service path. Traces alone are usually sampled and cannot be the record of truth. The three are complementary, not alternatives.
9. OpenTelemetry, formed in 2019 from the merger of OpenTracing and OpenCensus under the CNCF, is now the vendor-neutral standard for emitting all three. The wire format is OTLP.
10. Site reliability engineering began at Google in 2003 under Ben Treynor Sloss and was published as the book Site Reliability Engineering in 2016. Its core vocabulary:
11. An **SLI**, service level indicator, is a measured number, such as the proportion of requests served successfully in under 300 milliseconds.
12. An **SLO**, service level objective, is your internal target for that indicator, such as 99.9 per cent over 28 days.
13. An **SLA** is the external contract, always weaker than the objective, with financial consequences.
14. An **error budget** is the allowed failure: 100 per cent minus the objective. At 99.9 per cent over 30 days it is about 43 minutes of failure.
15. The budget is the point. If it is unspent, you are being too cautious and should ship faster. If it is exhausted, feature work stops until reliability is restored. It converts an argument about risk into arithmetic.
16. Blameless postmortems, formalized at Etsy by John Allspaw and colleagues from around 2012, assume that people act reasonably given the information they had, and look for the systemic conditions that made the error possible. Naming an individual ends learning, because the next person hides the near miss.
17. On-call practice that is defensible: a rota no thinner than one week in six, documented runbooks for every alert, alerts that are actionable or deleted, compensation or time off for nights worked, and a rule that a page nobody acted on gets removed rather than ignored.

■ 43.17.6 WORDS – remember these

1. DevOps — one team owning both shipping and running — a cultural model removing the structural conflict between change and stability, from 2009.
2. Infrastructure as code — the environment written down as a file — declarative definitions applied by a tool, versioned and reviewed like source code.

3. State file — the tool's record of what it owns — Terraform's mapping between configuration blocks and real resource identifiers, stored remotely with locking.
4. Immutable infrastructure — replace, never patch — deploying new pre-built images instead of modifying running machines.
5. GitOps — the repository is the truth and an agent enforces it — declarative state pulled and continuously reconciled from version control.
6. SLI, SLO, SLA — the measurement, the internal target, the external contract — the three levels of reliability commitment in site reliability engineering.
7. Error budget — the failure you are allowed to spend — 100 per cent minus the objective, used to arbitrate between shipping and stabilizing.
8. Observability — being able to ask new questions of a live system — the combination of metrics, logs and traces, standardized by OpenTelemetry.

43.18 Microservices versus monolith, decided honestly

■ 43.18.1 PLAIN - in simple words

1. A **monolith** is one program containing all your features, built and deployed as one unit.
2. **Microservices** means splitting those features into many small programs that talk over the network and deploy independently.
3. The genuine benefit is independence. Teams ship without coordinating, and one service can be rewritten or scaled without touching the rest.
4. The genuine cost is that every internal function call you replaced with a network call can now be slow, fail, arrive twice or vanish.
5. A method call cannot half-succeed. A network call can.
6. So the question is never "which is better". It is "do I have enough teams for the independence to be worth the failure handling".
7. For a team of five, the answer is almost always no.
8. The recommendation, which is now mainstream rather than contrarian: start with a **modular monolith**. One deployable unit, with strict internal boundaries and no reaching across them.
9. Then, if a module genuinely needs to scale differently, be written in another language, or be owned by another team, extract that one module.
10. You get the mandate's discipline about boundaries without paying the network bill until you must.

■ 43.18.2 PLAIN - a picture in your head

1. Picture a restaurant kitchen with one large team in one room.
2. Anyone can shout to anyone. Coordination is instant and free. The room does not scale past a certain number of cooks.
3. Now picture five separate kitchens in five buildings, each producing one part of the meal, connected by couriers.
4. Each kitchen can be rebuilt, restaffed or expanded without closing the others.
5. But every request is now a courier trip. Couriers get stuck in traffic. Sometimes a courier arrives and the dish has already been sent again.
6. A modular monolith is one building with five clearly separated stations, fixed hatches between them, and a rule that nobody walks into another station's area.
7. If the dessert station later needs its own building, it already has a defined hatch to replace with a courier route.

Where this comparison breaks: kitchens are physically fixed, so the analogy suggests the split is

permanent and expensive. In software the split is reversible in principle, and several well-known organizations have merged services back. It also understates the failure modes. A courier who never arrives is obvious. A network call that succeeded but whose reply was lost looks exactly like one that failed, and that ambiguity is the hardest problem in the whole subject.

■ 43.18.3 PLAIN – a worked example

1. One user action, “place order”, in both designs.
2. Monolith: one process calls `reserve_stock()`, `charge_card()` and `create_shipment()` inside a single database transaction. If the card fails, the transaction rolls back and no stock was reserved. Total time about 40 milliseconds. The failure model is one exception.
3. Microservices: the order service calls the inventory service, then the payment service, then the shipping service, each over the network.
4. There is no shared transaction. If payment fails after stock was reserved, the reservation must be actively undone by a **compensating action**.
5. That pattern is called a **saga**: a sequence of local transactions where each step has a defined undo.
6. Now the hard case. The order service calls payment and the reply is lost. Was the card charged? Unknown.
7. If it retries blindly, it may charge twice. So payment must accept an **idempotency key** and treat a repeat of the same key as the same charge.
8. Timing: three network calls at roughly 2 milliseconds each, plus serialization at both ends, plus retries, gives something like 15 to 40 milliseconds instead of 40 microseconds of function calls.

Aspect	Monolith	Microservices
Call cost	Nanoseconds	Milliseconds
Failure model	Exception	Timeout, dupe, loss
Consistency	Transaction	Saga, eventual
Deploy unit	One	Many, independent

■ 43.18.4 PLAIN – what is really happening inside

1. Once a request crosses services, no single log file contains the story.
2. **Distributed tracing** fixes this. The first service creates a trace identifier and passes it to everything it calls, in an HTTP header.
3. Each service records a **span**: its own start time, duration, name, and the identifier of the span that caused it.
4. A backend collects the spans and reassembles them into one tree by trace identifier, showing exactly where the time went.
5. Without tracing, debugging a slow request across eight services means guessing and correlating timestamps by hand.
6. Eventual consistency means different services briefly hold different answers. The order exists but the shipment does not yet. Your user interface must be designed for that, not surprised by it.

■ 43.18.5 TECHNICAL – the engineer’s version

1. The **fallacies of distributed computing** are the checklist. L. Peter Deutsch wrote seven at Sun Microsystems around 1994; James Gosling added the eighth. Each is something engineers assume without noticing.
2. The network is reliable. Latency is zero. Bandwidth is infinite. The network is secure. Topology does not change. There is one administrator. Transport cost is zero. The network is homogeneous.

3. Every one is false, and every microservice architecture that ignores one will fail in exactly the way that fallacy predicts.
4. Distributed tracing derives from Google's Dapper paper, published in 2010. The modern interoperability standard is W3C Trace Context, a Recommendation since 2021, which defines the `traceparent` and `tracestate` HTTP headers.
5. Sagas come from a 1987 paper by Hector Garcia-Molina and Kenneth Salem at Princeton, originally about long-lived database transactions. Two coordination styles exist: choreography, where services react to each other's events, and orchestration, where one coordinator drives the sequence and knows the undo steps. Choreography is looser and harder to debug; orchestration is clearer and centralizes the logic.
6. The consistency background is the CAP theorem: conjectured by Eric Brewer in 2000 and proved by Seth Gilbert and Nancy Lynch in 2002. Under a network partition you must choose between consistency and availability. Most business systems choose availability and reconcile afterwards.
7. Required infrastructure before splitting, and this list is the real cost: service discovery, centralized configuration, distributed tracing, correlated structured logging, per-service alerting and ownership routing, contract testing between services, an API gateway, retries with exponential backoff and jitter, circuit breakers, idempotency keys, and a deployment pipeline per service.
8. If your organization cannot build or buy that list, splitting will make reliability worse, not better. This is the Bezos mandate lesson restated: Amazon built all of it, and that is why the structure worked.
9. Published reversals are instructive. In March 2023 an Amazon Prime Video team wrote publicly that moving their audio and video monitoring service from a distributed serverless design to a single scaled process reduced infrastructure cost by over 90 per cent. Shopify and Stack Overflow are long-standing examples of very large systems run as well-structured monoliths.
10. Martin Fowler's 2015 article *MonolithFirst* argues that almost every successful microservice system he had seen started as a monolith that was later split, and almost every system built as microservices from scratch ran into serious trouble. That remains the best short statement of the position.
11. Where experts disagree: proponents argue that organizational independence is worth the cost from a surprisingly small size, especially with many teams and high turnover. Critics argue the boundaries chosen before you understand the domain are almost always wrong, and wrong boundaries are far more expensive across a network than inside one process. The second view has gained ground since about 2022.
12. The defensible default for a small team: one deployable unit; modules with explicit interfaces; no module reading another module's tables; a single database with clear schema ownership; and extraction only when a specific, named pressure demands it.

■ 43.18.6 WORDS – remember these

1. Monolith — one program with everything in it — a single deployable unit containing all business capabilities.
2. Modular monolith — one deployable unit with strict internal walls — enforced module boundaries and no cross-module data access, without network calls.
3. Microservices — many small independently deployed programs — services owned by separate teams communicating only over the network.
4. Distributed monolith — the worst of both — services that must be deployed together, paying network costs without gaining independence.
5. Saga — a sequence of steps with defined undos — a long-running transaction composed of local transactions plus compensating actions, Garcia-Molina and Salem 1987.
6. Idempotency key — a token making a repeat safe — a client-supplied identifier letting a server recognize and collapse duplicate requests.
7. Distributed tracing — following one request across services — correlated spans under one trace identifier, propagated via W3C Trace Context headers.
8. Fallacies of distributed computing — the eight false assumptions — Deutsch's seven from about 1994 plus Gosling's eighth.

43.98 Common wrong ideas

1. Wrong: the cloud is just someone else's computer, so it is the same thing as renting a server. Right: the rented computer is the smallest part. What you are buying is self-service provisioning in seconds, elasticity, a metered bill, and roughly 200 managed services you did not have to build. A rented server with a two-week ticket queue fails the NIST definition on two of its five required characteristics.
2. Wrong: serverless means there are no servers. Right: there are many servers. You do not choose, name, patch or pay for them while idle. You still hit memory limits, execution timeouts, concurrency quotas and cold starts, all of which are properties of real machines.
3. Wrong: cloud is always cheaper. Right: cloud is cheaper for spiky, unpredictable or small workloads, and usually more expensive per unit for steady large ones. 37signals reported saving nearly 2 million US dollars a year by leaving, and Dropbox reported 74.6 million over two years. Both had large, steady, predictable workloads and their own engineers.
4. Wrong: multi-cloud avoids lock-in. Right: it usually multiplies it. You now depend on the intersection of features from two providers, need staff expert in both, pay egress between them, and lose the deep managed services that made the cloud worth using. Genuine portability comes from boundaries in your own code, not from a second account.
5. Wrong: a container is a lightweight virtual machine. Right: a container is a process on the host kernel, isolated by namespaces and limited by cgroups. There is no second operating system and no hardware boundary. That is why it starts in milliseconds and why a kernel flaw crosses it.
6. Wrong: deploying across availability zones protects me from an outage. Right: it protects you from one building. It does not protect you from a regional control plane failure, which is what actually happens most often. The AWS event of 20 October 2025 affected an entire region for more than fifteen hours while the individual zones kept their power.
7. Wrong: Kubernetes is the modern way to run applications, so we should use it. Right: Kubernetes solves problems that appear with many services, many teams and real bin-packing pressure. Below that, it is a permanent tax in upgrades, networking, certificates and new failure modes. Most teams are better served by a managed container service.

8. Wrong: the provider is responsible for security. Right: the provider secures the cloud; you secure what you put in it. Access control and data classification never transfer, in any service model. Nearly every publicized cloud breach has been a customer misconfiguration, not a provider failure.
9. Wrong: AWS was built to sell Amazon's spare Christmas capacity. Right: AWS was a deliberate new business, proposed in writing in 2003 with its own staffing plan, built on separate hardware. Amazon's Chief Technology Officer publicly denied the spare capacity story in 2011, and retail's peak coincides with customers' peak, so the arrangement could never have worked.
10. Wrong: microservices make systems more reliable. Right: they make failure partial rather than total, which is only an improvement if you have built tracing, retries, idempotency, circuit breakers and ownership routing. Split without those and you get a distributed monolith: all the network failure modes with none of the independence.

43.99 Chapter summary in 20 lines

1. The cloud is other people's computers in other people's buildings, rented by the second and reached over the internet; the mystique is marketing.
2. What genuinely changed is self-service in seconds, elasticity, metered billing and somebody else owning the hardware; what did not change is that physical machines still fail.
3. NIST SP 800-145, from September 2011, gives the five-part test: self-service, network access, pooling, elasticity and measurement.
4. A datacentre is racks measured in 44.45 millimetre units, top-of-rack switches in a spine-leaf fabric, dual power through UPS and generators, and hot and cold aisle cooling; efficiency is PUE, globally stuck near 1.54 while hyperscalers reach 1.09 to 1.15.
5. A region is a place, an availability zone is an independent failure domain inside it, and an edge location is a cache; deploy across zones always, and treat multi-region as a large project rather than a checkbox.
6. India has AWS Mumbai from 2016 and Hyderabad from 2022, Azure's three regions from 2015 plus India South Central from August 2026, and Google Mumbai from 2017 and Delhi NCR from 2021.
7. Virtualization made renting possible: a hypervisor slices one machine into many, made cheap by Intel VT-x in 2005 and AMD-V in 2006, and made nearly free by offload hardware such as AWS Nitro from 2017.
8. A container is a process with namespaces and cgroups on a shared kernel, not a small virtual machine; the idea runs back through LXC, Solaris Zones, FreeBSD jails and chroot in 1979, and Docker in 2013 supplied the packaging.
9. Kubernetes, first committed on 6 June 2014 and descended from Google's Borg, works by declarative reconciliation: state the desired end and let control loops close the gap forever.
10. Most teams do not need Kubernetes, and saying so is not contrarian; it is what the cost of upgrades, networking and new failure modes implies.
11. Around 2002 Jeff Bezos mandated that all teams expose data and functionality only through service interfaces, with no back doors, and that every interface be designed to be externalizable, on pain of dismissal.
12. That mandate forced Amazon to build service discovery, quotas and throttling, pager routing, monitoring merged with quality assurance and standard sandboxes, which is precisely the toolkit of a cloud platform.
13. It also bought latency, partial failure and operational cost; most companies copied the structure without the discipline and got a distributed monolith.

14. AWS itself came from a 2003 paper by Chris Pinkham and Benjamin Black and a parallel business proposal by Andy Jassy; SQS launched in beta in November 2004, S3 on 14 March 2006 and EC2 on 25 August 2006 at ten cents an hour.
15. It was never built from spare retail capacity, and AWS reported 128.7 billion US dollars of net sales for 2025 against Azure's 100 billion for fiscal 2026.
16. The service models differ only in where the line falls between what you manage and what the provider manages, and the security version of that line is the shared responsibility model, in which access control is always yours.
17. Serverless means per-invocation billing and no idle cost, at the price of cold starts of 200 milliseconds to two seconds, statelessness, a fifteen minute ceiling and heavy lock-in.
18. Storage splits into object, block and file; the decisive commercial fact is that storing ten terabytes costs about ten dollars a month in deep archive while reading it out once costs about nine hundred.
19. Cloud networking is a VPC of subnets and route tables, with stateful security groups on machines and stateless network ACLs on subnets, and identity is governed by policies where an explicit deny always wins.
20. Bills explode from idle resources, oversized instances, egress and cross-zone chatter rather than from compute; own the steady baseline, rent the burst, and start a small system as a modular monolith.

Security

44.0 What this chapter gives you

1. You will be able to say what security actually means, using the five properties professionals name, and build a threat model in plain words.
2. You will be able to explain what a hash is, why MD5 and SHA-1 are dead, and read real hash values computed in front of you.
3. You will be able to store passwords correctly, choose Argon2id parameters that a working engineer would accept, and explain salt versus pepper.
4. You will be able to describe symmetric and asymmetric encryption, name the modes that are safe in 2026, and say why nonce reuse destroys everything.
5. You will be able to explain post-quantum cryptography, the standards NIST approved on 13 August 2024, and why “harvest now, decrypt later” matters.
6. You will be able to describe every common web vulnerability class, the flawed pattern behind it, and the fix that removes it by construction.
7. You will be able to explain memory safety, why C allows the bugs it does, and what the 2023 to 2025 government guidance actually asks for.
8. You will be able to name the realistic ways machines get infected, recognize social engineering, and run a first hour of incident response calmly.
9. You will read this as a defender. The chapter explains how attacks work so that you can stop them, and contains no working attack code by design.
10. You will build on two earlier chapters rather than repeat them: Chapter 32 covered TLS and certificates, and Chapter 42 covered SSH keys and tokens.

44.1 What security actually means

■ 44.1.1 PLAIN – in simple words

1. Security is not one thing. It is a small set of promises about your data.
2. Promise one: only the people who should see it can see it. That is **confidentiality**.
3. Promise two: nobody can change it without you noticing. That is **integrity**.
4. Promise three: when you need it, it is there. That is **availability**.
5. Those three together have a nickname in the trade: the CIA triad. It has nothing to do with any spy agency. The letters are just the three words.
6. Two more promises matter and are often left out.
7. Promise four: the thing claiming to be Ravi really is Ravi. That is **authenticity**.
8. Promise five: once Ravi signed something, he cannot later say he did not. That is **non-repudiation**.
9. Notice that these promises can fight each other.

10. Locking a file with a key nobody has protects confidentiality perfectly and destroys availability completely.
11. So security is always a set of trade-offs, never a single maximum.
12. And this is the sentence to carry with you: security is a property of a whole system in a particular situation. It is not a product you buy.
13. A very strong lock on a door with a glass panel next to it is not security. It is a strong lock.

■ 44.1.2 PLAIN - a picture in your head

1. Think of a small jewellery shop on a busy street.
2. Confidentiality is the curtain in the back room, so passers-by cannot see the safe being opened.
3. Integrity is the sealed ledger, so nobody can quietly add a line saying they already paid.
4. Availability is the shop being open at ten in the morning, as promised.
5. Authenticity is checking the ID of the man who says he is from the insurance company.
6. Non-repudiation is the signed receipt the customer cannot later deny.
7. Now do the thing a security professional does. Ask three questions.
8. What am I protecting? The gold, the ledger, the customer list, the reputation.
9. From whom? A casual thief, a professional gang, a dishonest employee, a competitor, a government.
10. What happens if I fail? Money lost, customers gone, licence revoked, somebody physically harmed.
11. Those three questions, written down, are a **threat model**.

Where this comparison breaks: a shop thief must physically be on that street. A network attacker can be in another country, can try a million shops per hour, and can automate everything. Scale is the difference that changes everything. A lock that keeps out ninety-nine of a hundred thieves is a good lock in a street and a broken lock on the internet, because the internet will send you ten million thieves per day and only needs one to succeed.

■ 44.1.3 PLAIN - a worked example

1. Let us threat model something real: the reader's own laptop and its GitHub account, from the running example used in this book.
2. Assets, written plainly.

Asset	Why it matters	If lost
Source code	The work itself	Leak, theft
GitHub token	Can push code	Malicious commits
SSH private key	Identity to servers	Impersonation
Laptop disk	Everything at once	Total compromise

3. Adversaries, from cheapest to most expensive.
4. An automated scanner that tries known passwords on anything it finds. Cost to the attacker: near zero. Likelihood: certain, continuously.
5. A phishing email pretending to be GitHub. Cost: low. Likelihood: high.
6. A thief who steals the laptop from a cafe. Cost: moderate. Likelihood: low but real.
7. A targeted attacker who wants this specific person. Cost: high. Likelihood: low unless the person is unusually interesting.
8. Now score the risk. **Risk = likelihood x impact**. Both parts matter.

9. Stolen laptop: likelihood low, impact very high. Product: medium-high. So full disk encryption is worth it.
10. Automated password guessing: likelihood certain, impact high. Product: very high. So a hardware key or passkey on GitHub is worth it.
11. A nation-state adversary: likelihood very low for most readers. Do not spend your budget there first.
12. That last line is the whole discipline. You cannot defend everything, so you rank by likelihood times impact and start at the top.

■ 44.1.4 PLAIN – what is really happening inside

1. Every system has an **attack surface**: the complete list of places where untrusted input can reach your code.
2. Open network ports are attack surface. So are file uploads, query parameters, environment variables, image parsers and USB sockets.
3. Attackers do not “hack in” the way films show. They find one place where your assumption about input was wrong.
4. The pattern is nearly always the same. A program expected data and received instructions, or expected a small thing and received a big one.
5. There is a second, equally common pattern: the program did the right check on the wrong thing, or forgot the check on one path out of twenty.
6. Attacks chain. A low-value flaw plus another low-value flaw often equals a total compromise.
7. Example of a chain: a public page leaks internal server names, one of those servers has an old unpatched service, that service runs as administrator, and administrator can read the database credentials.
8. No single link in that chain was catastrophic. The chain was.
9. Defenders therefore think in layers, not in walls. If one control fails, the next one should still be standing. That is called **defence in depth**.
10. And defenders think about **blast radius**: when this component is fully compromised, what exactly can the attacker now reach?
11. Reducing blast radius is usually cheaper and more reliable than trying to make a component unbreakable.

The honest version: “attackers exploit vulnerabilities” is only half true. In real incident data, most intrusions begin with valid credentials or a person being tricked, not with a clever technical exploit. The technical exploit usually comes later, to move sideways once inside.

■ 44.1.5 TECHNICAL – the engineer’s version

1. The five properties are formalized in ISO/IEC 27000 and in NIST SP 800-53. Confidentiality, integrity and availability are the statutory triad in United States federal law under FISMA 2002.
2. Authenticity and non-repudiation are usually added as separate objectives; the combined five are sometimes called the Parkerian hexad when utility and possession are added as well, following Donn Parker’s 1998 formulation.
3. Threat modelling has named methodologies. STRIDE, created at Microsoft by Loren Kohnfelder and Praerit Garg in 1999, enumerates Spoofing, Tampering, Repudiation, Information disclosure, Denial of service, and Elevation of privilege.
4. PASTA (Process for Attack Simulation and Threat Analysis, 2012) and LINDDUN for privacy threats are the other two commonly taught.

5. Attacks are catalogued by MITRE ATT&CK, first published in 2013 and updated continuously. It maps real observed adversary behaviour into tactics and techniques with identifiers such as T1566 for phishing.
6. Vulnerabilities get CVE identifiers, run by MITRE since 1999. Severity is scored by CVSS, currently version 4.0, published by FIRST in November 2023.
7. Weakness classes get CWE identifiers. CWE-79 is cross-site scripting, CWE-89 is SQL injection, CWE-787 is out-of-bounds write.
8. Note the difference precisely: a CWE is a kind of mistake, a CVE is one specific instance of it in one specific product version.
9. Risk in formal work is expressed as annualized loss expectancy: $ALE = \text{single loss expectancy} \times \text{annual rate of occurrence}$. In practice the inputs are estimates, so the number is used for ranking, not for accounting.
10. FAIR (Factor Analysis of Information Risk) is the main quantitative alternative and expresses risk as probability distributions rather than single numbers.

Term	Formal meaning	Example
Threat	Actor with intent	Ransomware crew
Vulnerability	The weakness	Unpatched CVE
Exploit	Code using it	Working payload
Risk	Likelihood x impact	Ranked list

11. Tools that observe security posture on a machine you own: `nmap` for open ports, `ss -tlnp` on Linux or `lsof -i -P` on macOS for listening sockets, `osqueryd` for fleet-wide state, and `lynis` for host audit.
12. The word “secure” without a threat model attached is meaningless. Always ask: secure against whom, doing what, at what cost to them?

■ 44.1.6 WORDS - remember these

Confidentiality — only the right people can read it — protection of data from unauthorized disclosure.

Integrity — nobody changed it secretly — assurance that data has not been modified in an unauthorized or undetected way.

Availability — it works when you need it — the property of being accessible and usable on demand by an authorized entity.

Authenticity — you are who you claim — verified identity of a principal or origin of data.

Non-repudiation — you cannot deny you did it — cryptographic proof binding an action to an identity, resistant to later denial.

Threat model — who might attack and how — structured enumeration of assets, adversaries, entry points and mitigations.

Attack surface — every way in — the complete set of points where an untrusted actor can supply input or influence behaviour.

Blast radius — how far damage spreads — the set of assets reachable after a given component is fully compromised.

Risk — likelihood times impact — expected loss, used to rank work rather than to predict exact outcomes.

44.2 Hashing

■ 44.2.1 PLAIN – in simple words

1. A **hash function** takes any amount of data and produces a short, fixed-length fingerprint.
2. Feed it one letter or a two-gigabyte film. The fingerprint is the same length every time.
3. It is a one-way street. From the data you can compute the fingerprint easily. From the fingerprint you cannot get the data back.
4. Change one single bit of the input and about half the bits of the output change, in an unpredictable way.
5. That effect has a name: the **avalanche effect**.
6. The same input always gives the same output, on any machine, forever. It is not random.
7. Four properties matter, and they are worth learning in order.
8. One: it is fast to compute forwards.
9. Two: **preimage resistance**. Given a fingerprint, you cannot find any input that produces it.
10. Three: **second preimage resistance**. Given one file, you cannot find a different file with the same fingerprint.
11. Four: **collision resistance**. You cannot find any two different files with the same fingerprint, even if you get to choose both.
12. Collision resistance is the hardest of the four, and it is always the first one to fall when a hash function is broken.
13. A hash is good for checking that something did not change. A hash by itself is not a secret and not encryption. It hides nothing you can guess.

■ 44.2.2 PLAIN – a picture in your head

1. Imagine a machine that turns any book into a six-word summary.
2. The summary is always six words, whether the book is a pamphlet or a thousand pages.
3. From the six words nobody can reconstruct the book.
4. Change one comma in the book and the six words come out completely different, not slightly different.
5. So if a friend tells you the six words over the phone, you can check that the copy of the book you received is exactly the one they sent.
6. That is what people do when they publish a checksum next to a download.
7. A **collision** is two genuinely different books producing the same six words. If that ever happens, the summary can no longer prove anything.

Where this comparison breaks: a six-word summary of a book is related to the book's meaning. A cryptographic hash is deliberately not. Two files that differ by a single byte give summaries with no visible relationship at all, and that unpredictability is the entire point. Also, a real hash has a fixed tiny output while the input is unlimited, so collisions must mathematically exist. The claim is only that nobody can find one.

■ 44.2.3 PLAIN – a worked example

1. Here are real hashes, computed in the sandbox used to write this chapter, with OpenSSL 3.0.13.
2. The input is the seven characters `kedbyte`, with no newline.

```
md5      31d826fc69ac61899d792d7c21411dd5
sha1     ea431b1d4e594752169a04adea3245395d4ea7eb
sha256   7e88ddebb634ffbb28b3037dd122c08cf849ce53bd
         f3a8d0a08e13ac5b0eab3f
sha3-256 72c5e9c053ffabec027977d730987430dc98f9b553
         ac1aa248bc683385b532b1
blake2s  03b9df1f134bdfb34740d2353323dd58f48360c23c
         3af7b393fda6e52c6c14af
```

3. Note the lengths. MD5 is 32 hex characters, which is 128 bits. SHA-1 is 40 characters, 160 bits. SHA-256 is 64 characters, 256 bits.
4. Now change the last letter only, from `kedbyte` to `kedbytf`, and hash again with SHA-256.

```
kedbyte -> 7e88ddebb634ffbb28b3037dd122c08c...
kedbytf -> 718433d73cc98a937bdfce4a6c2e4d90...
```

5. Counted properly, 123 of the 256 output bits differ. The ideal is 128, which is exactly half. That is the avalanche effect measured.
6. SHA-256 of the empty input is a constant worth recognizing, because it turns up in logs and in Git internals: `e3b0c44298fc1c149afb4c8996fb92427ae41e4649b934ca495991b7852b855`.
7. On the machine used here, `openssl speed sha256` measured 400 megabytes per second on 8 kilobyte blocks, on one core.
8. That speed is wonderful for verifying downloads and terrible for storing passwords, which is the subject of the next section.

■ 44.2.4 PLAIN – what is really happening inside

1. Most classic hash functions work by chewing the input in fixed-size blocks.
2. SHA-256 uses 512-bit blocks. It keeps eight 32-bit working values, called the state, that start from fixed constants.
3. For each block it runs 64 rounds of mixing: rotations, exclusive-or, additions and a few nonlinear choices between bits.
4. After each block, the mixed values are added back into the state. That step is what makes the process irreversible.
5. At the end, the eight state values are written out as the digest.
6. The padding rule matters. The message gets a single 1 bit, then zeros, then the original length in bits. Without the length, different messages could collide trivially.
7. This design is called Merkle-Damgard, after Ralph Merkle and Ivan Damgard, both 1979 to 1989 era work.
8. It has a known quirk called **length extension**: if you know the hash of a secret message and its length, you can compute the hash of that message with extra data appended, without knowing the secret.
9. That quirk is exactly why you must never authenticate a message by hashing a secret joined to the message. You use HMAC instead, which is built to resist it.
10. SHA-3 has a completely different internal shape called a sponge. It absorbs input into a large 1600-bit state and squeezes output back out, and it is immune to length extension by design.
11. BLAKE3 goes further and splits the input into 1 kilobyte chunks arranged in a tree, so many cores can hash different chunks at the same time.

12. When a hash is “broken”, it almost never means someone can reverse it. It means someone found a shortcut to produce collisions faster than brute force. That is still fatal for signatures and certificates.

■ 44.2.5 TECHNICAL – the engineer’s version

1. MD5 was published by Ron Rivest in 1992 as RFC 1321, output 128 bits.
2. Practical MD5 collisions were announced by Wang Xiaoyun, Feng Dengguo, Lai Xuejia and Yu Hongbo at the CRYPTO 2004 rump session in August 2004.
3. By 2008 a research team used chosen-prefix MD5 collisions to forge a working certificate authority certificate. In 2012 the Flame malware used the same class of attack to forge a Microsoft code-signing certificate.
4. SHA-1 was published by NIST in 1995, output 160 bits. Theoretical attacks appeared in 2005, also from Wang’s group.
5. The first public SHA-1 collision, named SHAttered, was announced on 23 February 2017 by CWI Amsterdam and Google. It cost roughly nine quintillion SHA-1 computations, about 6,500 CPU-years and 110 GPU-years.
6. In 2020 Gaetan Leurent and Thomas Peyrin demonstrated a chosen-prefix SHA-1 collision for a rented compute cost in the tens of thousands of dollars.
7. SHA-2 is a family standardized in FIPS 180-4: SHA-224, SHA-256, SHA-384, SHA-512, and the truncated SHA-512/224 and SHA-512/256. No practical break exists as of 2026.
8. SHA-3 is Keccak, by Guido Bertoni, Joan Daemen, Michael Peeters and Gilles Van Assche. It won the NIST competition in October 2012 and was published as FIPS 202 in August 2015. It is a complement to SHA-2, not a replacement.
9. BLAKE3 was released in January 2020 by Jack O’Connor, Jean-Philippe Aumasson, Samuel Neves and Zooko Wilcox-O’Hearn. It is not a NIST standard.
10. Security levels, stated honestly. A hash with n bits of output gives about n bits against preimage attacks and only $n/2$ bits against collisions, by the birthday bound. SHA-256 therefore offers 128-bit collision resistance.

Function	Output bits	Status 2026
MD5	128	Broken 2004
SHA-1	160	Broken 2017
SHA-256	256	Recommended
SHA-3-256	256	Recommended
BLAKE3	256 default	Fast, not FIPS

11. Where each is still acceptable: MD5 and SHA-1 only for non-security uses such as cache keys and non-adversarial deduplication. Never for signatures, certificates, integrity against an attacker, or passwords.
12. Git historically used SHA-1 for object names and has a SHA-256 object format available since Git 2.29 in 2020, still not the default in 2026. Git also ships a hardened SHA-1 that detects the SHAttered attack pattern.
13. Commands to observe: `sha256sum file` and `md5sum file` on Linux, `shasum -a 256 file` on macOS, `openssl dgst -sha256 file` anywhere, `certutil -hashfile file SHA256` on Windows.
14. For message authentication use HMAC (RFC 2104, 1997), for example HMAC-SHA-256, or use a modern AEAD cipher which includes authentication.

■ 44.2.6 WORDS – remember these

Hash function — a fingerprint machine — a deterministic map from arbitrary input to fixed-length output.

Digest — the fingerprint itself — the output value of a hash function.

Collision — two inputs, one fingerprint — two distinct messages producing the same digest.

Preimage resistance — cannot work backwards — infeasibility of finding any input matching a given digest.

Avalanche effect — one bit in, half the bits out — small input change causes statistically independent output.

Length extension — appending without the secret — a Merkle-Damgard weakness allowing extension of a hashed message.

HMAC — a hash with a key done properly — keyed message authentication code defined in RFC 2104.

Checksum — a change detector — a short value used to detect accidental corruption, not necessarily cryptographic.

44.3 Password storage done properly

■ 44.3.1 PLAIN – in simple words

1. If you build a login system, you must store something that lets you check a password without storing the password.
2. Storing the password itself, readable, is the worst possible choice. One database leak and every user is exposed everywhere they reused it.
3. So we store a hash instead. The user types a password, we hash it, we compare hashes. We never need the original.
4. But a plain fast hash is almost as bad, and here is why.
5. An attacker who steals the database can guess billions of passwords per second on one graphics card and hash each guess.
6. Worse, if everyone's password is hashed the same way, the attacker can precompute a giant table once and reuse it against every stolen database.
7. Those precomputed tables are called **rainbow tables**.
8. The fix for that is a **salt**: a random value, different for every user, mixed in before hashing and stored alongside the hash.
9. Two users with the same password now get completely different stored values, so a precomputed table is useless and every user must be attacked separately.
10. A salt is not a secret. It is stored in the database in plain view. Its job is uniqueness, not secrecy.
11. Then there is a second idea: a **pepper**, a single secret value added for everyone, stored somewhere other than the database.
12. If the attacker steals only the database, the pepper is missing and the guessing cannot even start.
13. And the last idea is the important one: make the hash deliberately slow and memory-hungry.
14. If checking one password takes a quarter of a second and a lot of memory, a legitimate login is unaffected and mass guessing becomes uneconomic.

■ 44.3.2 PLAIN – a picture in your head

1. Think of a hotel that must check whether you know the door code, without keeping a list of door codes.
2. Fast hash: the clerk has a machine that instantly turns a code into a coloured token, and keeps only the tokens. A thief who steals the tokens buys the same machine and tries every code in an afternoon.
3. Salt: each guest's code is combined with a printed sticker number unique to that guest before the machine runs. The thief must now redo the whole afternoon separately for each guest.
4. Pepper: the machine also needs a small key that the manager keeps at home. Stealing the tokens gets you nowhere without visiting the manager.
5. Slow hash: the machine takes a quarter of a second per attempt and needs a whole desk covered in paper to work. One guest checking in does not care. A thief trying a billion codes now needs a warehouse and years.

Where this comparison breaks: the hotel thief cannot buy a hundred thousand machines. A password attacker can rent that many in a cloud for an hour. The slow hash is not making attack impossible; it is changing the price. Price is the real currency of security, and it is a moving target because hardware gets faster. Parameters chosen in 2015 are too weak in 2026.

■ 44.3.3 PLAIN – a worked example

1. Real timings, measured in the sandbox for this chapter, single core.

Method	Time per check	Attacker friendly?
Raw SHA-256	0.000000074 s	Extremely
PBKDF2 600k	0.42 s	No
bcrypt N=2 ¹⁷	1.08 s	No

2. Read the first row again. A raw SHA-256 took 740 nanoseconds. That is roughly 1.3 million guesses per second on one Python core.
3. On a graphics card the numbers are far worse for the defender. Published hashcat benchmarks on an NVIDIA RTX 5090 report about 220 billion MD5 hashes per second and about 28 billion SHA-256 hashes per second.
4. The same card manages only about 300,000 bcrypt hashes per second at a low work factor. That is roughly a hundred thousand times slower per guess.
5. That single ratio is the entire argument for slow password hashing.
6. Now watch the salt work. The same password, PBKDF2-HMAC-SHA256 with 600,000 iterations, with two different salts.

```

salt 00000000... -> 0460eeec7ddf8b5f91f2037b3e2ab248
salt a3f10000... -> 52e0053a9dda9d910cb58befaaf9e67

```

7. Same password, unrelated results. No shared precomputation is possible.
8. A stored record in practice looks like this. It is one string containing the algorithm, its parameters, the salt and the hash, so you can change parameters later without breaking old accounts.

```

$argon2id$v=19$m=19456,t=2,p=1$c29tZXNhbnHQ$aG...
|      |      |      |      |
algo    ver  parameters    salt    hash

```

9. The parameters live inside the record on purpose. When you raise them next year, old users still verify with the old settings, and you re-hash their password at their next successful login.

■ 44.3.4 PLAIN - what is really happening inside

1. On registration: generate a fresh random salt of at least 16 bytes from a cryptographic random source, run the slow hash, store algorithm, parameters, salt and result.
2. On login: read the stored record, take the salt and parameters out of it, hash the submitted password the same way, compare.
3. Compare in constant time. A comparison that stops at the first different byte leaks information through timing. Every good library has a constant-time compare function.
4. Never tell the user which part was wrong. "Wrong username or password" and nothing more, or you have built an account enumeration tool.
5. The slow hash resists attack in three different ways, and they are not the same thing.
6. Time hardness: many sequential iterations, so you cannot go faster than the chain allows.
7. Memory hardness: the algorithm needs a large block of memory that must stay filled during the computation. Graphics cards have thousands of small cores but limited memory per core, so memory cost hurts attackers far more than defenders.
8. Parallelism resistance: the memory accesses depend on earlier results, so the work cannot simply be split.
9. bcrypt has time hardness and a small fixed 4 kilobyte memory need. scrypt and Argon2 add real memory hardness.
10. The pepper is applied differently in good designs: not concatenated into the password, but used as an HMAC key over the password before hashing, or used to encrypt the resulting hash. Both keep it separable and rotatable.
11. Where does the pepper live? A hardware security module, a cloud key management service, or at minimum an environment variable on the application server that is not in the database backup.

The honest version: the pepper only helps in the specific case where the database leaks but the application server does not. That case is common, from SQL injection and stolen backups, so peppering is worth doing. But it is a second line, not a substitute for a proper slow hash.

■ 44.3.5 TECHNICAL - the engineer's version

1. bcrypt: Niels Provos and David Mazieres, USENIX 1999, based on the Blowfish key schedule. Cost parameter is a power of two. OWASP recommends a work factor of at least 10 as of the current Password Storage Cheat Sheet.
2. bcrypt truncates input at 72 bytes. Enforce a 72-byte maximum, or pre-hash with SHA-256 and base64 the result before feeding bcrypt, being careful about null bytes.
3. scrypt: Colin Percival, 2009, standardized as RFC 7914 in 2016. Parameters N (cost), r (block size), p (parallelism).
4. Argon2: winner of the Password Hashing Competition in July 2015, by Alex Biryukov, Daniel Dinu and Dmitry Khovratovich. Standardized as RFC 9106 in September 2021. Three variants: Argon2d, Argon2i, and Argon2id.
5. Use Argon2id. It is the hybrid: data-independent memory access in the first pass to resist side-channel attacks, data-dependent afterwards to resist time-memory trade-offs.
6. Current OWASP recommended parameters, any one of which is acceptable and equivalent in strength.

Algorithm	Parameters	Notes
Argon2id	m=47104, t=1, p=1	46 MiB memory
Argon2id	m=19456, t=2, p=1	19 MiB memory
scrypt	N=2 ¹⁷ , r=8, p=1	128 MiB memory
bcrypt	cost 10 minimum	72-byte limit

7. PBKDF2 is the fallback where FIPS validation is required. OWASP currently lists 600,000 iterations for PBKDF2-HMAC-SHA256 and 210,000 for PBKDF2-HMAC-SHA512. PBKDF2 is defined in RFC 8018.
8. Salt: 16 bytes minimum from a CSPRNG. Every modern library generates and embeds it for you. Do not hand-roll this.
9. Attack taxonomy, defensively stated. A **dictionary attack** tries a wordlist plus rules such as appending digits. A **brute force** tries all combinations, feasible only for short passwords. **Credential stuffing** replays username and password pairs stolen from another site.
10. Credential stuffing is the dominant real attack because password reuse is near universal. The attacker does not need to break your hashes at all if the user used the same password somewhere weaker.
11. That is the actual disaster of reuse: your security becomes equal to the security of the worst site the user ever signed up for.
12. Defences against stuffing: rate limiting per account and per network, device fingerprinting, checking submitted passwords against known-breached lists using a k-anonymity range API, and above all offering MFA.
13. NIST SP 800-63B revision 4, published 31 July 2025, is the current authority. Its key rules for verifiers: require at least 8 characters and encourage at least 15; allow at least 64; allow all printable characters including spaces and Unicode.
14. The same document says verifiers **shall not** impose composition rules such as requiring mixed character types, and **shall not** require periodic password rotation without evidence of compromise.
15. The reasoning is empirical, not aesthetic. Forced rotation causes predictable transformations such as incrementing a trailing digit, and composition rules push users toward the same small set of substitutions.
16. Practical advice to give a user: use a password manager, generate long random passwords per site, and use a long passphrase only for the few secrets you must type from memory, such as the manager's own master password and the disk encryption password.
17. Length beats complexity. A five-word random passphrase from a large word list carries roughly 64 bits of entropy; an eight-character password with the usual substitutions carries far less in practice.

■ 44.3.6 WORDS – remember these

Salt — a unique random extra per user — public per-record value preventing precomputation and hash reuse.

Pepper — one secret extra for everyone — site-wide secret kept outside the password database, applied via HMAC or encryption.

Rainbow table — a precomputed cracking table — time-memory trade-off structure for reversing unsalted hashes.

Work factor — the slowness dial — a tunable cost parameter of a password hashing function.

Memory hardness — needs a lot of RAM to compute — property that raises the cost of parallel hardware attacks.

Credential stuffing — reusing stolen logins elsewhere — automated replay of breached username and password pairs.

Argon2id — the current recommended choice — hybrid memory-hard password hash, RFC 9106, winner of the 2015 Password Hashing Competition.

Account enumeration — learning which users exist — information leak from differing error messages or response times.

44.4 Symmetric encryption

■ 44.4.1 PLAIN - in simple words

1. **Symmetric encryption** means both sides share one secret key. The same key locks and unlocks.
2. It is fast, which is why every real system uses it for the actual data.
3. There are two shapes of symmetric cipher.
4. A **block cipher** transforms a fixed-size chunk at a time, typically 16 bytes, and you must decide how to handle a message longer than one chunk.
5. A **stream cipher** produces an endless keystream of pseudo-random bytes which you combine with the message one byte at a time.
6. The dominant block cipher is **AES**, with key sizes of 128, 192 or 256 bits. Its block is always 128 bits regardless of key size.
7. The way you chain blocks together is called a **mode of operation**, and choosing it wrongly is the most common cryptographic mistake in the world.
8. The worst mode is ECB, which encrypts every block independently. Identical input blocks give identical output blocks, so the shape of your data leaks straight through.
9. Modern practice is not to choose a cipher and a mode separately. You choose an **authenticated encryption** scheme that also detects tampering.
10. Encryption without authentication is not enough. An attacker who cannot read your message can still flip bits in it and change what it says when decrypted.
11. Almost every cipher mode also needs a per-message unique value called an **IV** or a **nonce**. Reusing one with the same key is catastrophic.

■ 44.4.2 PLAIN - a picture in your head

1. Think of a stencil-based code where each 16-letter chunk of your message is replaced by a scrambled 16-letter chunk, using a fixed rule set by the key.
2. ECB mode is applying that stencil to each chunk independently.
3. Now imagine a photograph converted this way. Every patch of plain white sky becomes the same scrambled patch. The scrambled version still shows the outline of the picture.
4. That is why the encrypted penguin image is famous in every cryptography course. The bird is still clearly visible after ECB encryption.
5. CBC mode fixes it by mixing each chunk with the previous encrypted chunk before scrambling, so identical inputs stop looking identical.
6. CTR mode does something different: it does not encrypt your data at all. It encrypts a counter to make a keystream, then combines that with your data.
7. GCM is CTR plus a running checksum computed with the key, so any change to the ciphertext is detected on decryption.

Where this comparison breaks: real block ciphers are not letter substitution. AES mixes bits across the whole block through several layers, so one changed input bit changes the whole output block. The stencil picture also suggests the key changes the alphabet, when in reality the key changes a schedule of operations applied over many rounds.

■ 44.4.3 PLAIN – a worked example

1. Here is ECB failing, computed in the sandbox for this chapter with a real AES-128 key.
2. The plaintext is YES YES YES YES YES YES YES YES, which is exactly two identical 16-byte blocks.

```
AES-ECB block 1: 15516924691d0a3e5f81ff297ad6c86e
AES-ECB block 2: 15516924691d0a3e5f81ff297ad6c86e
identical: True
```

```
AES-CBC block 1: 15516924691d0a3e5f81ff297ad6c86e
AES-CBC block 2: 234d8347677995c4547c148bbfa58f4f
identical: False
```

3. Look at the ECB output. The repetition in the plaintext is visible in the ciphertext with no key and no effort at all.
4. CBC produced different blocks for identical input because each block was mixed with the previous ciphertext block first.
5. Now the nonce reuse problem, stated without giving an attack recipe.
6. In CTR and GCM, the ciphertext is the plaintext combined with a keystream derived from key and nonce.
7. Encrypt two different messages with the same key and the same nonce, and both use the identical keystream.
8. Combining the two ciphertexts cancels the keystream out entirely, leaving a direct relationship between the two plaintexts.
9. For GCM specifically, nonce reuse does something worse: it leaks the authentication subkey, which lets an attacker forge messages that your system will accept as genuine.
10. The rule that follows is absolute. Never reuse a nonce with the same key. Generate it randomly with enough bits, or use a strict counter you can prove never repeats.

■ 44.4.4 PLAIN – what is really happening inside

1. AES works on a 4 by 4 grid of bytes called the state.
2. Each round does four steps: substitute every byte through a fixed lookup table, shift the rows sideways by different amounts, mix each column mathematically, and add the round key with exclusive-or.
3. AES-128 does 10 rounds, AES-192 does 12, AES-256 does 14.
4. The **key schedule** expands the single key into one distinct round key per round, so no two rounds are the same.
5. The substitution table is the only nonlinear step. Without it the whole cipher would collapse into simple algebra and be trivially breakable.
6. In CBC mode, encryption is a chain: block n is combined with ciphertext n-1 before encryption, and the first block uses the IV. Chains cannot be parallelized when encrypting, though decryption can be.
7. In CTR mode, block n of the keystream is the encryption of nonce plus n. No chain, so everything parallelizes and you can decrypt from the middle.
8. GCM adds GHASH, a multiplication in a finite field over the ciphertext and any associated data, producing a 16-byte authentication tag.

9. On decryption, GCM computes the tag again and compares. If it does not match, it returns an error and no plaintext. That refusal is the whole value of authenticated encryption.
10. ChaCha20 is a different design: 20 rounds of additions, rotations and exclusive-ors on a 4 by 4 grid of 32-bit words, producing 64 bytes of keystream per invocation.
11. It uses no lookup tables, so it has no cache-timing side channel and it is fast in plain software on processors without AES hardware instructions.
12. Poly1305 is its companion authenticator, a one-time message authentication code using arithmetic modulo a large prime.

■ 44.4.5 TECHNICAL – the engineer’s version

1. AES is Rijndael, by Joan Daemen and Vincent Rijmen. It won the NIST competition in October 2000 and was published as FIPS 197 in November 2001.
2. Modern processors have hardware support: Intel AES-NI since Westmere in 2010, ARMv8 cryptographic extensions since 2011. Throughput on a single modern core is commonly several gigabytes per second.
3. Mode summary, with the practical verdict for 2026.

Mode	Authenticated?	Verdict
ECB	No	Never use
CBC	No	Legacy only
CTR	No	Only inside AEAD
GCM	Yes	Standard choice
ChaCha20-Poly1305	Yes	Standard choice

4. AES-GCM is specified in NIST SP 800-38D (2007). Its nonce is 96 bits by convention, and the standard limits a single key to about 2^{32} random nonces before collision risk becomes unacceptable.
5. AES-GCM-SIV, RFC 8452 (2019), is nonce-misuse resistant: repeating a nonce leaks only whether two plaintexts were equal, not the keystream. Use it when you cannot guarantee nonce uniqueness.
6. ChaCha20-Poly1305 is RFC 8439 (2018), by Daniel J. Bernstein. It is a TLS 1.3 mandatory-to-implement suite alongside AES-GCM and is preferred on mobile processors without AES acceleration.
7. XChaCha20-Poly1305 extends the nonce to 192 bits, making random nonce generation safe without counters.
8. CBC without authentication enabled the padding oracle class of attacks, including the 2002 Vaudenay result and the 2010 attacks on ASP.NET. That history is why encrypt-then-MAC or AEAD is mandatory now, not optional.
9. Key sizes in practice: AES-128 gives 128-bit classical security and is fine. AES-256 is chosen for long-term data and for regulatory reasons, and is the sensible default against future quantum search attacks.
10. Grover’s algorithm, published by Lov Grover in 1996, would give a quantum computer a square-root speed-up on key search, notionally halving AES-256 to 128 bits of effective strength. Doubling the key size answers it.
11. Never write your own mode, your own padding, or your own comparison of authentication tags. Use libsodium, the Go `crypto/cipher` AEAD interface, Java’s `javax.crypto` with GCM, or Python cryptography’s `AESGCM` class.

12. Commands to observe: `openssl enc -aes-256-cbc` for files, `openssl speed -evp aes-256-gcm` for throughput, `cryptsetup benchmark` on Linux for disk encryption performance including AES-XTS.
13. Disk encryption uses XTS mode rather than GCM, because a disk sector has no room to store an authentication tag. That is a real trade-off: disk encryption protects confidentiality, not integrity.

■ 44.4.6 WORDS - remember these

Symmetric encryption — one shared key both ways — encryption where the same key encrypts and decrypts.

Block cipher — scrambles fixed chunks — a keyed permutation over a fixed block size, 128 bits for AES.

Mode of operation — how chunks are chained — the construction turning a block cipher into a scheme for arbitrary-length messages.

ECB — the mode that leaks patterns — Electronic Codebook, encrypts each block independently, never acceptable.

IV / nonce — the per-message unique value — initialization vector or number used once, must never repeat under one key.

AEAD — encryption that also detects tampering — Authenticated Encryption with Associated Data, for example AES-GCM.

Authentication tag — the tamper seal — short value verified on decryption, causing refusal if the ciphertext changed.

ChaCha20-Poly1305 — the software-fast alternative — stream cipher plus one-time authenticator, RFC 8439.

44.5 Asymmetric encryption, signatures and the quantum question

■ 44.5.1 PLAIN - in simple words

1. Symmetric encryption has one hard problem: how do two strangers agree on a shared key over a network anyone can read?
2. **Asymmetric encryption** solves it with a pair of matched keys.
3. The **public key** can be published to the whole world. The **private key** never leaves its owner.
4. Anything encrypted with the public key can only be decrypted with the private key.
5. That direction gives you confidentiality: anyone can write to you, only you can read it.
6. Run it the other way and you get something different and equally useful.
7. If you transform a message with your private key, anyone with your public key can check it. That is a **digital signature**.
8. A signature proves three things at once: the message came from the holder of that private key, it has not been altered, and the signer cannot plausibly deny it later.
9. Encryption alone proves none of those. Anyone with your public key can encrypt to you, so a decrypted message tells you nothing about who sent it.
10. There is also a way to agree a shared secret without either side sending it: **Diffie-Hellman key exchange**.
11. Asymmetric operations are slow, hundreds to thousands of times slower than symmetric ones.

12. So every real system is **hybrid**: use asymmetric maths once to agree a symmetric key, then use the fast symmetric cipher for all the data.
13. That is exactly what TLS does, which Chapter 32 covered in detail.

■ 44.5.2 PLAIN – a picture in your head

1. Picture an open padlock that you hand out freely, of which you alone keep the key.
2. Anyone can put a letter in a box, snap your padlock shut, and post it. Only you can open it.
3. Signing is the mirror image: you press a seal that only your ring can make, and anyone with a picture of your seal can confirm it is genuine.
4. Diffie-Hellman is a different trick. Two people each mix a private colour into a shared public colour, swap the mixtures in the open, then each mix their own private colour into the mixture they received.
5. Both end with the same final colour. An observer saw the two mixtures but cannot unmix them to reach it.

Where this comparison breaks: paint mixing is only a metaphor for a one-way mathematical operation. Real Diffie-Hellman uses exponentiation in a group where reversing it is the discrete logarithm problem. Also, a physical padlock protects against a person with a hacksaw, while a cryptographic one protects only against computation, and computation gets cheaper every year.

■ 44.5.3 PLAIN – a worked example

1. RSA rests on multiplication being easy and factoring being hard.
2. Multiplying two 1024-bit primes takes microseconds. Recovering those primes from the 2048-bit product is beyond any known machine.
3. The largest RSA modulus ever publicly factored is RSA-250, a 829-bit number, broken in February 2020 using about 2,700 core-years.
4. That is why 2048-bit RSA keys are still standard and 1024-bit ones were deprecated by browsers around 2013 to 2014.
5. Elliptic curves get the same strength from much smaller numbers.

Security level	RSA / DH	Elliptic curve
112 bits	2048	224
128 bits	3072	256
192 bits	7680	384
256 bits	15360	512

6. Read the last row. To match a 512-bit curve you would need a 15,360-bit RSA key. That is why modern systems moved to curves.
7. Curve25519, published by Daniel J. Bernstein in 2005, gives roughly 128-bit security with 32-byte keys and is the default in SSH, Signal and TLS 1.3.
8. Its signature counterpart is Ed25519, standardized in RFC 8032 in 2017, with 64-byte signatures.
9. A sense of the speed gap: on a typical modern core, an X25519 key agreement takes tens of microseconds while an AES-GCM operation on a kilobyte takes well under one microsecond. Hence the hybrid design.

■ 44.5.4 PLAIN - what is really happening inside

1. RSA key generation: pick two large random primes p and q , multiply to get the modulus n , choose a public exponent e , usually 65537, and compute the matching private exponent d .
2. Encryption raises the message to the power e modulo n . Decryption raises the result to the power d modulo n . The maths brings you back to the start.
3. Raw RSA is unsafe. Real use requires padding: OAEP for encryption, PSS for signatures. The old PKCS#1 v1.5 padding produced the Bleichenbacher attack family from 1998 onwards and its many modern echoes.
4. Signing does not actually sign the message. It hashes the message first, then signs the hash. That is why a broken hash breaks signatures, which is what SHA-1 collisions meant for certificates.
5. Elliptic curve cryptography replaces “multiply numbers” with “add points on a curve”. The private key is a number, the public key is a point reached by adding a fixed base point to itself that many times.
6. Going forwards is fast; recovering the number from the point is the elliptic curve discrete logarithm problem, and no efficient classical method is known.
7. Diffie-Hellman in curve form is simple: each side multiplies the other’s public point by their own private number, and both land on the same point.
8. **Forward secrecy** comes from throwing the Diffie-Hellman private values away after the session. An attacker who later steals the long-term key still cannot decrypt yesterday’s recorded traffic.
9. Now the quantum part. Peter Shor published an algorithm in 1994 that, on a sufficiently large fault-tolerant quantum computer, factors integers and computes discrete logarithms in polynomial time.
10. That breaks RSA, finite-field Diffie-Hellman and every elliptic curve scheme at once. It does not break symmetric ciphers or hashes in the same way; those need only larger sizes.
11. No such machine exists in 2026. Published estimates for breaking 2048-bit RSA remain in the range of millions of physical qubits with error correction, against current devices measured in the low thousands.
12. But traffic recorded today can be stored and decrypted later. That is **harvest now, decrypt later**, and it makes migration urgent for any data that must stay secret for ten or twenty years.

■ 44.5.5 TECHNICAL - the engineer’s version

1. Diffie-Hellman was published by Whitfield Diffie and Martin Hellman in 1976 in “New Directions in Cryptography”. Ralph Merkle’s related work preceded it. RSA followed in 1977 from Ron Rivest, Adi Shamir and Leonard Adleman.
2. Elliptic curve cryptography was proposed independently by Neal Koblitz and Victor Miller in 1985.
3. British researchers at GCHQ, James Ellis, Clifford Cocks and Malcolm Williamson, developed equivalent ideas between 1969 and 1974; the work was classified until 1997.
4. NIST approved three post-quantum standards on 13 August 2024.

Standard	Name	Purpose
FIPS 203	ML-KEM	Key encapsulation
FIPS 204	ML-DSA	Digital signatures
FIPS 205	SLH-DSA	Hash-based signatures

5. ML-KEM was submitted as CRYSTALS-Kyber, ML-DSA as CRYSTALS-Dilithium, SLH-DSA as SPHINCS+. The initial announcement was 6 August 2024 and the Secretary of Commerce ap-

proved them on 13 August 2024.

6. A fourth signature scheme, FN-DSA, based on FALCON, was still in draft as FIPS 206 as of 2026. On 11 March 2025 NIST selected HQC as a fifth algorithm and a backup key encapsulation mechanism, with its own standard expected around 2027.
7. Sizes are the practical cost. ML-KEM-768 has a 1,184-byte encapsulation key and a 1,088-byte ciphertext, against 32 bytes each for X25519.
8. ML-DSA-65 signatures are about 3,309 bytes and SLH-DSA signatures range from roughly 7,856 bytes to about 49,856 bytes, against 64 bytes for Ed25519. That is why signature migration lags key exchange migration.
9. SLH-DSA exists as insurance. It relies only on hash function security, so if lattice mathematics turns out to have an unexpected weakness, hash-based signatures still stand.
10. Deployment state as of 2026, separating fact from claim. Established fact: the hybrid key agreement X25519MLKEM768 is on by default in current Chrome, Firefox and Edge. Cloudflare reported in late October 2025 that over half of human-initiated traffic to its network used post-quantum key agreement.
11. Also established: signatures and certificates have barely moved, because they need certificate authorities, root programmes and every client to change together.
12. Active research: how to shrink post-quantum certificate chains, and how to do post-quantum authentication for constrained devices.
13. Marketing claim: any product described as “quantum-proof” or “unbreakable” without naming FIPS 203, 204 or 205. Ask which standard, which parameter set, and whether it is hybridized with a classical algorithm.
14. Hybrid is the current professional consensus: run the classical and the post-quantum algorithm together, so a break in either alone is not fatal. Experts disagree on how long to keep hybrids. Some say they add complexity and should be retired soon; others argue for a decade.
15. Commands to observe: `openssl s_client -connect host:443` and read the negotiated group, `openssl list -kem-algorithms` on OpenSSL 3.5 and later, and `ssh -Q kex` to list key exchange algorithms your SSH build supports.

■ 44.5.6 WORDS – remember these

Public key — the half you publish — the shareable component of an asymmetric key pair.

Private key — the half you never share — the secret component whose exposure destroys the pair’s security.

Digital signature — proof of who and unaltered — a value verifiable with a public key, providing authenticity and non-repudiation.

Key exchange — agreeing a secret in the open — a protocol producing a shared secret without transmitting it, such as ECDH.

Forward secrecy — yesterday stays safe — property where compromise of long-term keys does not expose past sessions.

Hybrid encryption — asymmetric once, symmetric after — the standard construction combining key agreement with an AEAD cipher.

Shor’s algorithm — the quantum threat to RSA — polynomial-time quantum factoring and discrete logarithm, published 1994.

ML-KEM — the new key exchange standard — FIPS 203, lattice-based key encapsulation, approved 13 August 2024.

Harvest now, decrypt later — record today, break tomorrow — the threat model justifying migration before quantum computers exist.

44.6 Authentication and identity

■ 44.6.1 PLAIN – in simple words

1. **Authentication** answers one question: are you who you claim to be?
2. There are three classic kinds of evidence, called factors.
3. Something you **know**: a password, a PIN, an answer to a question.
4. Something you **have**: a phone, a hardware key, a smart card.
5. Something you **are**: a fingerprint, a face, a voice.
6. Multi-factor authentication means using evidence from two different kinds, not two things of the same kind.
7. A password plus a security question is not two factors. Both are things you know, and both leak in the same database breach.
8. Not all second factors are equally strong, and the gap between them is much wider than most people think.
9. A six-digit code from an app is decent. A code sent by text message is weak. A hardware key is in a different class entirely.
10. The reason hardware keys are different is that they refuse to be phished. The others can all be relayed by an attacker in real time.
11. A **passkey** is that same phishing-resistant technology, with the secret stored on your phone or laptop and unlocked by your fingerprint or face.

■ 44.6.2 PLAIN – a picture in your head

1. Think of collecting a parcel from a counter.
2. The password is knowing the reference number. Anyone who overhears it can collect your parcel.
3. The app code is a slip of paper that changes every thirty seconds. Better, but if someone phones you and talks you into reading it out within those thirty seconds, they can still collect the parcel.
4. The hardware key is different in kind. It is a stamp that only works on that one counter, in that one building.
5. Take the stamp to a fake counter in the next street and it produces nothing, because it checks the address of the counter before stamping.
6. That address check is why phishing fails against it. The user can be fully fooled and the attack still does not work.

Where this comparison breaks: a stamp can be stolen physically. A hardware key can too, which is why it usually also requires a PIN or a fingerprint. And the key does not check a street address but the exact web origin, which the browser supplies and the user cannot override by being persuaded.

■ 44.6.3 PLAIN – a worked example

1. Here is how the six-digit code in your authenticator app is actually made.
2. When you scan the QR code, the site gives your app a shared secret, usually 20 bytes, encoded in base32.
3. Both sides take the current Unix time in seconds and divide by 30, throwing away the remainder. That gives a counter that changes every 30 seconds.

4. Both compute HMAC-SHA-1 of that counter using the shared secret.
5. That produces 20 bytes. A truncation step picks 4 bytes from a position determined by the last nibble of the hash, giving a 31-bit number.
6. Take that number modulo 1,000,000 and pad to six digits. That is your code.

```
secret + floor(unixtime / 30)
-> HMAC-SHA-1
-> dynamic truncation (31 bits)
-> mod 1000000
-> "042318"
```

7. Nothing is transmitted to generate it. That is why the app works on a plane with no signal.
8. Servers usually accept the previous and next window too, to tolerate clocks being a little out.
9. Now see the weakness clearly. The code is just six digits typed by a human. A convincing fake login page collects it and replays it within 30 seconds.
10. That is not a flaw in the maths. It is a flaw in the shape of the interaction, and no amount of better hashing fixes it.

■ 44.6.4 PLAIN – what is really happening inside

1. SMS one-time codes are weaker still, for reasons outside your control.
2. **SIM swapping**: an attacker persuades a mobile operator to move your number to their SIM, using social engineering on a support agent. Your codes now arrive on their phone.
3. The mobile signalling network itself has known interception weaknesses, and messages travel through third parties in plain form.
4. Push-approval prompts fixed the typing problem but created a new one: **MFA fatigue**, where an attacker with your password sends prompt after prompt until you approve one to make it stop, often at three in the morning.
5. This is not theoretical. The September 2022 Uber breach began with a contractor's stolen password plus repeated push prompts, finished off by a message pretending to be internal IT support.
6. Number matching, where the login screen shows two digits you must type into the prompt, is the standard mitigation and is now on by default in the major identity providers.
7. Now the hardware key. Registration: the key generates a fresh key pair for that one website, keeps the private key inside the hardware, and sends the public key to the site.
8. Login: the site sends a random challenge. The browser adds the exact origin it is talking to. The key signs both together.
9. If the origin is a look-alike domain, the signature is over the wrong origin and the real site rejects it. There is no code for a human to relay.
10. The private key never leaves the device. There is no shared secret in the site's database, so a breach of the site leaks only public keys.
11. A **passkey** is the same protocol with the key material held by the operating system or password manager and typically synchronized across your devices through your platform account.
12. That synchronization is the trade-off. It makes recovery practical, at the cost of the cloud account becoming part of the security boundary.

■ 44.6.5 TECHNICAL – the engineer’s version

1. HOTP is RFC 4226 (2005), counter-based. TOTP is RFC 6238 (2011), time-based, with a default 30-second step and 6 digits. The default HMAC is SHA-1, which is acceptable here because HMAC-SHA-1 is not broken by collisions.
2. FIDO2 combines two specifications: W3C Web Authentication, WebAuthn Level 2 became a W3C Recommendation in April 2021 with Level 3 in progress, and CTAP2 from the FIDO Alliance for the link between browser and authenticator.
3. WebAuthn signs a client data structure containing the challenge, the origin and the type. Origin binding is the phishing resistance, and it is a property of the protocol, not of user training.
4. Attestation optionally proves what kind of authenticator was used. Enterprises use it to require certified hardware; consumer sites usually should not, for privacy reasons.
5. Passkeys are discoverable WebAuthn credentials. The FIDO Alliance State of Passkeys report of 7 May 2026 put around 5 billion passkeys in use, with 75 percent of surveyed consumers having enabled at least one and 68 percent of surveyed organizations deploying them.
6. Comparison of second factors, ranked honestly.

Factor	Phishing resistant	Main weakness
SMS code	No	SIM swap, relay
TOTP app	No	Real-time relay
Push approve	No	Fatigue attacks
Number match	Partly	Still relayable
FIDO2 key	Yes	Loss, recovery

7. NIST SP 800-63B revision 4, published 31 July 2025, classifies restricted authenticators and requires that risks of the public switched telephone network be assessed; SMS remains permitted but discouraged.
8. Biometrics are convenient and have real limits. They are not secrets, they cannot be revoked, and matching is probabilistic with a false accept rate and a false reject rate that trade against each other.
9. Apple published a figure of roughly 1 in 50,000 false accept for Touch ID and 1 in 1,000,000 for Face ID, per attempt, with limited retries.
10. The right mental model: on a phone, the biometric unlocks a key stored in secure hardware locally. It is a convenient local gate, not an identity sent over the network.
11. Session management matters as much as login. Rotate session identifiers on privilege change, set HttpOnly, Secure and SameSite on cookies, and give tokens the shortest lifetime the product can tolerate.
12. Account recovery is where most authentication systems actually fail. If a help desk can reset MFA after a phone call, the strength of your authenticator is irrelevant. The 2023 MGM Resorts intrusion is the textbook case.

■ 44.6.6 WORDS – remember these

Authentication — proving who you are — verification of a claimed identity against registered authenticators.

Factor — a category of evidence — knowledge, possession or inherence.

TOTP — the app’s six-digit code — time-based one-time password, RFC 6238, derived from a shared secret and the clock.

SIM swap — hijacking your phone number — social engineering a carrier into porting a number to an attacker's SIM.

MFA fatigue — approving to stop the buzzing — repeated push prompts intended to wear the user down.

WebAuthn — the browser standard for hardware login — W3C API binding a signature to a challenge and an origin.

Passkey — a synchronized hardware-grade credential — discoverable WebAuthn credential held by an OS or password manager.

Origin binding — the key checks the address — protocol-level inclusion of the verified origin in the signed data.

44.7 Authorization and access control

■ 44.7.1 PLAIN - in simple words

1. Authentication asks who you are. **Authorization** asks what you may do.
2. They are different questions, they fail differently, and mixing them up causes a large share of real breaches.
3. Being logged in is not permission. Every request must be checked, not just the first one.
4. There are four common ways to decide.
5. **Discretionary access control**: the owner of a thing decides who may use it. This is how files on your laptop work.
6. **Mandatory access control**: a central policy decides, and even the owner cannot override it. This is how classified military systems work.
7. **Role-based access control**: permissions attach to roles, and people get roles. Editor, viewer, administrator.
8. **Attribute-based access control**: a rule engine decides from facts about the user, the resource, the action and the context.
9. Two principles run through all of them.
10. **Least privilege**: every person and every program gets the minimum access needed to do its job, and no more.
11. **Separation of duties**: the person who requests a payment is not the person who approves it.
12. And one classic trap, the **confused deputy**: a program with more privilege than you does something on your behalf that you were not allowed to ask for.

■ 44.7.2 PLAIN - a picture in your head

1. A hospital. Authentication is the badge reader at the door confirming you are Dr Sharma.
2. Authorization is the separate question of which wards, which drug cabinets and which patient records Dr Sharma may open.
3. Discretionary control is a doctor lending their office key to a colleague.
4. Mandatory control is the pharmacy safe, where policy overrides everyone, including the head of the department.
5. Role-based control is the badge saying "consultant", and consultants have a fixed list of doors.
6. Attribute-based control is a rule saying: a doctor may open a record if they are the treating clinician, on shift, in this hospital, today.
7. Least privilege is not giving the night cleaner a master key to the drug store.
8. Separation of duties is two signatures for a controlled substance.

9. The confused deputy is the porter who is trusted to enter any room, being asked by a stranger to fetch a file from a locked office. The porter has the right; the stranger did not.

Where this comparison breaks: a hospital has physical friction, and a human porter might feel that a request is odd. Software has no instinct. A service with broad rights will carry out a strange request a million times a second without hesitating once.

■ 44.7.3 PLAIN – a worked example

1. Here is a real least-privilege event from the running example in this book.
2. The reader's GitHub personal access token could push code, but one push was refused because the change touched a CI workflow file and the token did not carry the workflow scope.
3. That refusal is authorization working exactly as designed.
4. The token was authenticated perfectly. GitHub knew whose token it was. It simply was not authorized for that class of change.
5. Notice the security value. If that token had leaked, an attacker could have pushed ordinary code, which review would catch, but could not have silently rewritten the pipeline that builds and deploys.
6. Now a broken example, stated as a pattern rather than a recipe. A web application shows an invoice at a path containing an invoice number, and the server checks that you are logged in but never checks the invoice belongs to you.
7. Changing the number in the address bar then shows somebody else's invoice. That is an insecure direct object reference, and it is the single most common serious web flaw found in real assessments.
8. The fix is not to hide or scramble the number. The fix is that every lookup asks the database for the invoice with that number and that owner.
9. Compare the two designs in one table.

Design	Check performed	Result
Broken	Is user logged in	Any invoice visible
Correct	Is invoice user's	Only own invoices

■ 44.7.4 PLAIN – what is really happening inside

1. Access decisions have a standard shape with two named parts.
2. The **policy decision point** works out the answer. The **policy enforcement point** actually blocks or allows the request.
3. If the enforcement point sits only in the user interface, you have no security at all. Hiding a button does not remove the endpoint behind it.
4. Enforcement belongs on the server, as close to the data as possible.
5. The strongest pattern is to make the check impossible to forget: scope every query by owner at the data layer, so an unscoped query cannot even be written.
6. Row-level security in PostgreSQL, or a mandatory tenant filter in the object-relational mapper, both achieve this.
7. Confused deputy in software, concretely. Your service holds cloud credentials that can read any file in a bucket. A user supplies a file name. Your service reads it and returns it.
8. The user has borrowed your privilege. The service was authorized; the user was not. Server-side request forgery is the same disease with network access instead of file access.

9. The cure is to never let untrusted input select the target of a privileged operation directly. Map user input through a list of allowed values that you control, and check ownership before acting.
10. Capability-based systems attack the problem from the other side. Instead of saying “who are you, and are you allowed”, you hold an unforgeable token that already names exactly what you may do.
11. A pre-signed cloud storage URL is a capability. It carries its own authority, is scoped to one object and one action, and expires.

■ 44.7.5 TECHNICAL – the engineer’s version

1. The Bell-LaPadula model, published in 1973 by David Bell and Leonard LaPadula, formalized mandatory confidentiality: no read up, no write down.
2. The Biba model, 1977, is its integrity mirror: no write up, no read down.
3. Role-based access control was formalized by David Ferraiolo and Richard Kuhn in 1992 and standardized as ANSI INCITS 359-2004.
4. Attribute-based access control is described in NIST SP 800-162 (2014). XACML is the long-standing policy language; Open Policy Agent with its Rego language is the common modern implementation.
5. The confused deputy problem was named by Norm Hardy in a 1988 paper about a compiler that could be tricked into overwriting its own billing file.
6. In cloud practice: AWS IAM policies, Azure RBAC and Google Cloud IAM are all attribute-flavoured RBAC. The recurring failure is an over-broad wildcard in the action or resource field.
7. OAuth 2.0, RFC 6749 (2012), is a delegation framework, not an authentication protocol. OpenID Connect layers authentication on top of it. Confusing the two produces real vulnerabilities.
8. Scopes in OAuth are coarse permissions granted to an application. They are not a substitute for per-object ownership checks inside your service.
9. Broken Access Control is ranked A01 in the OWASP Top 10 for both the 2021 and 2025 editions, and in the 2025 edition server-side request forgery was folded into it.
10. Practical controls to implement: deny by default, centralize the authorization function rather than scattering conditionals, log every denial, and write tests that assert a user cannot reach another user’s objects.
11. Commands and tools to observe: `aws iam simulate-principal-policy` for AWS, `kubectl auth can-i` for Kubernetes, `getfacl` and `ls -l` for POSIX file permissions, `getenforce` and `ausearch -m avc` for SELinux decisions.
12. On Linux, capabilities split the historic all-or-nothing root privilege into pieces such as `CAP_NET_BIND_SERVICE`. Granting only that is far better than running a web server as root to bind port 80.

■ 44.7.6 WORDS – remember these

Authorization — what you are allowed to do — the decision about permitted actions on resources, distinct from identity.

Least privilege — only what the job needs — granting the minimum rights required, for the minimum time.

Separation of duties — two people, two steps — splitting a sensitive operation so no single actor can complete it.

RBAC — permissions through job titles — role-based access control, ANSI INCITS 359-2004.

ABAC — permissions from rules and facts — attribute-based access control, NIST SP 800-162.

Confused deputy — borrowing someone else's power — a privileged component misused by a less privileged caller.

IDOR — changing the number in the URL — insecure direct object reference, a missing per-object ownership check.

Policy enforcement point — where the block happens — the component that actually denies or permits a request.

44.8 The web application vulnerability classes, defensively

■ 44.8.1 PLAIN - in simple words

1. Almost every web vulnerability is one of two mistakes.
2. Mistake one: data supplied by a user was treated as instructions.
3. Mistake two: a check that should have happened did not happen on this path.
4. **Injection** is mistake one against a language: SQL, shell, LDAP, XPath.
5. **Cross-site scripting** is mistake one against a browser: your page ends up carrying somebody else's script.
6. **Cross-site request forgery** is a browser being tricked into sending a request it should not, using cookies it already holds.
7. **Broken access control** is mistake two: the user is logged in but nobody checked the thing belongs to them.
8. **Server-side request forgery** is your server being used as a proxy to reach places the user cannot reach.
9. **Path traversal** is a file name from a user escaping upwards out of the directory you intended.
10. **Insecure deserialization** is rebuilding an object graph from untrusted bytes, which in many languages can run code as a side effect.
11. **XML external entities** is an XML parser being told to fetch files or URLs while parsing.
12. **Mass assignment** is a form binder copying every submitted field onto your object, including the one called `is_admin`.

■ 44.8.2 PLAIN - a picture in your head

1. Imagine a clerk who reads out a sentence you wrote on a form, into a machine that obeys sentences.
2. You write your name. The clerk reads "Ravi" and the machine files it.
3. Someone else writes a name that continues into a new sentence, and the machine obeys that too, because the clerk never knew where the name ended.
4. The bad fix is to inspect names for suspicious words. Attackers write sentences you did not think of.
5. The good fix changes the shape of the conversation. The clerk hands the machine the sentence template and the name through a separate slot.
6. The machine now knows, structurally, that the name is a name. It cannot become an instruction no matter what is written in it.
7. That is exactly the difference between building a query by gluing strings together and using a parameterized query.

Where this comparison breaks: the clerk analogy suggests the danger is only in one direction. In reality the same data may pass through several machines with different rules, a database, then a browser, then a shell, and each needs its own correct handling. Data safe for one is not automatically safe for another.

■ 44.8.3 PLAIN – a worked example

1. The flawed pattern for SQL injection, shown so you can recognize it in a code review. This is the shape to reject, not code to run.

```
# WRONG: query text is built from user input
q = "SELECT * FROM users WHERE email = '" + email + "'"
db.execute(q)
```

2. Because the value is glued into the query text, a value containing a quote character can end the string early and the rest is parsed as query structure. Nothing after that is under your control.
3. The correct version, which removes the class of bug entirely.

```
# RIGHT: structure and data travel separately
q = "SELECT * FROM users WHERE email = ?"
db.execute(q, (email,))
```

4. Why this fixes it **by construction**: the database receives the query structure first and compiles it, then receives the value as a typed parameter. The value can never be reinterpreted as syntax.
5. Escaping and filtering are weaker answers. They depend on getting every edge case right, in every encoding, forever. Parameterization does not.
6. The same principle applies to shell commands. Do not build a command string; pass an argument list to the operating system directly, so the shell never parses your data.
7. The real-world consequence of getting this wrong: the MOVEit Transfer incident of May 2023 began with a SQL injection flaw, CVE-2023-34362, which the Cl0p group used at scale. Public tracking put the total above 2,600 organizations and tens of millions of individuals.

■ 44.8.4 PLAIN – what is really happening inside

1. Cross-site scripting comes in three shapes, and the difference matters for the fix.
2. **Stored**: the attacker's text is saved in your database, and every later visitor receives it. Highest impact.
3. **Reflected**: the text comes in on the request and is echoed straight back in the response. Needs a victim to follow a crafted link.
4. **DOM-based**: the server never sees it. Client-side JavaScript reads part of the page address and writes it into the page.
5. The fix is contextual output encoding. Encode when writing out, not when reading in, because the correct encoding depends on where the value lands: HTML body, attribute, JavaScript string, URL or CSS each differ.
6. Modern frameworks encode by default. The vulnerabilities cluster around the escape hatches, the functions with names like `dangerouslySetInnerHTML` or `v-html`.
7. A **Content Security Policy** header is the second layer. It tells the browser which script sources are allowed, so injected inline script does not execute even if it reaches the page.
8. A strict policy uses per-response nonces or hashes rather than a domain allowlist, because allowlists are routinely bypassed through permissive files on the allowed domains.
9. Cross-site request forgery works because browsers attach cookies for a site automatically, whatever page triggered the request.
10. The modern structural defence is the `SameSite` cookie attribute. `Lax` is the default in current Chrome and Firefox and blocks cookies on cross-site POST requests. `Strict` is stronger and sometimes inconvenient.
11. Keep anti-CSRF tokens as well, because `SameSite` behaviour varies across browsers and versions and does not protect against same-site attackers.

■ 44.8.5 TECHNICAL – the engineer’s version

1. The current edition is the **OWASP Top 10:2025**, presented at OWASP Global AppSec on 6 November 2025, built from data across more than 2.8 million applications plus roughly 175,000 CVE-to-CWE mappings.

Rank	2025 category	Change
A01	Broken Access Control	Still first
A02	Security Misconfiguration	Up from 5
A03	Software Supply Chain	New framing
A04	Cryptographic Failures	Down from 2
A05	Injection	Down from 3

2. The remaining five in 2025 are A06 Insecure Design, A07 Authentication Failures, A08 Software or Data Integrity Failures, A09 Security Logging and Alerting Failures, and A10 Mishandling of Exceptional Conditions.
3. Two categories are new or newly framed: Software Supply Chain Failures, and Mishandling of Exceptional Conditions. Server-side request forgery, which had its own slot in 2021, was consolidated into Broken Access Control.
4. Defences by class, stated as the fix a reviewer should insist on.

Class	Fix that works by construction
SQL injection	Parameterized queries
Command injection	Argument arrays, no shell
XSS	Contextual encoding plus CSP
CSRF	SameSite plus tokens
Path traversal	Canonicalize, verify prefix
XXE	Disable DTD and entities
SSRF	Allowlist, block metadata IP

5. Path traversal, CWE-22: resolve the path to its canonical absolute form first, then confirm it starts with the intended base directory. Checking for the literal two-dot sequence before resolving fails against encodings.
6. XXE, CWE-611: disable document type definitions entirely in the parser. In Java that means setting `disallow-doctype-decl` to `true`; in Python use `defusedxml`. Many parsers changed to safe defaults after 2018, but not all.
7. Insecure deserialization, CWE-502: never deserialize untrusted data into arbitrary types. Use a data-only format such as JSON with an explicit schema. Java native serialization, Python pickle, PHP `unserialize` and .NET `BinaryFormatter` are all unsafe on untrusted input by design.
8. Mass assignment, CWE-915: bind to an explicit allowlist of fields, or use a separate data transfer object per endpoint rather than the database model.
9. SSRF, CWE-918: block link-local metadata addresses such as `169.254.169.254`, re-validate after every redirect, and resolve the hostname once and connect to that exact address to avoid time-of-check to time-of-use tricks.
10. Log4Shell, CVE-2021-44228, disclosed 9 December 2021 with a CVSS score of 10.0, was an injection flaw in a logging library: attacker-controlled text that reached a log call could trigger a remote lookup. It is the clearest reminder that logging is also an input-handling path.

11. Tools that observe: zap and Burp Suite for interactive testing, semgrep and CodeQL for static analysis, sqlmap only against systems you own or are authorized in writing to test.

■ 44.8.6 WORDS – remember these

Injection — data treated as instructions — untrusted input reaching an interpreter as part of its command structure.

Parameterized query — structure and data kept apart — precompiled statement with typed placeholders, immune to SQL injection.

XSS — someone else's script on your page — cross-site scripting, stored, reflected or DOM-based.

Content Security Policy — a browser rulebook for scripts — response header restricting which sources may execute.

CSRF — your browser sending a request it should not — forged cross-site request riding on ambient cookies.

SameSite — the cookie's travel restriction — cookie attribute limiting sending on cross-site requests, Lax by default.

SSRF — your server fetching what the user cannot — server-side request forgery against internal or metadata endpoints.

Mass assignment — the form that set `is_admin` — automatic binding of request fields to object properties without an allowlist.

44.9 Memory safety

■ 44.9.1 PLAIN – in simple words

1. Some languages let a program read and write memory outside the space it asked for. C and C++ are the important ones.
2. They do this on purpose. Bounds checking costs time, and these languages were designed when every cycle mattered.
3. A **buffer overflow** happens when a program copies more bytes into a space than that space can hold, and the extra bytes land on whatever is next.
4. What is next, on the stack, is often bookkeeping: saved registers and the address the function will return to.
5. Overwrite that return address and the processor jumps somewhere the programmer never intended when the function finishes.
6. **Use-after-free** is using a pointer to memory that was already released. The allocator may have handed that space to someone else.
7. **Double-free** is releasing the same block twice, which corrupts the allocator's own bookkeeping.
8. **Integer overflow** is a size calculation wrapping around past the largest representable value, producing a tiny allocation for a huge copy.
9. All four are the same underlying story: the program lost track of how big something is or how long it lives.

■ 44.9.2 PLAIN – a picture in your head

1. Think of a row of numbered pigeonholes on a wall, each one letter wide.
2. You are told to write an eight-letter word into a four-letter hole.

3. Nothing stops you. The last four letters spill into the next holes.
4. Now suppose the hole immediately after yours holds the room number the messenger will visit next.
5. You have just changed where the messenger goes, without touching the messenger.
6. A **stack canary** is a small agreed word placed just before that room number. Before leaving, the messenger checks the word is unchanged. If your spill overwrote it, the program stops.

Where this comparison breaks: real overflows are not always sequential and not always on the stack. Heap corruption works by damaging the allocator's own records, which is subtler and does not pass through a canary at all. And the canary only detects a contiguous overwrite, not a targeted single-word write.

■ 44.9.3 PLAIN – a worked example

1. A stack frame, drawn as it grows downwards in memory on a typical system.

2. The copy starts at the bottom of the buffer and moves up towards the canary, the frame pointer and the return address.
3. So a copy of 80 bytes into a 64-byte buffer reaches exactly the fields that control what happens when the function returns.
4. Integer overflow feeding an allocation, shown as a pattern to reject.

```
/* WRONG: count * size can wrap around */
buf = malloc(count * size);
memcpy(buf, src, count * size);
```

5. If count times size exceeds the maximum of the type, the product wraps to a small number. The allocation succeeds at that small size, and the copy then writes far past it.
6. The correct pattern checks for overflow first, or uses a checked helper such as `calloc`, or uses a language where sizes cannot silently wrap.

■ 44.9.4 PLAIN – what is really happening inside

1. Four defences are standard on modern systems, and each raises cost rather than removing the bug class.
2. **Stack canaries**, from StackGuard in 1998: a random value written before the return address and verified before returning.
3. **Non-executable memory**, called NX or DEP: pages are either writable or executable, not both, so injected data cannot be run as code.
4. Attackers answered with return-oriented programming, which chains together small fragments of code that already exist in the program. Nothing new is injected, so NX does not help.

5. **Address space layout randomization:** load the program and its libraries at unpredictable addresses so the attacker cannot know where anything is.
6. Attackers answer with information leaks that reveal one address, from which the rest follows.
7. **Control flow integrity:** check at run time that every indirect jump goes to a legitimate target. ARM Pointer Authentication and Intel CET are hardware support for this idea.
8. Honest summary: each of these turns a reliable exploit into an unreliable or expensive one. None of them makes the underlying bug disappear.
9. The real fix is a language that cannot express the bug. Rust checks lifetimes and ownership at compile time. Go, Java, C#, Python and JavaScript check bounds at run time and manage memory automatically.
10. That is not free. Garbage collection has pauses, run-time checks cost a few percent, and Rust's rules are hard to learn. But the cost is bounded and the bug class is gone.

■ 44.9.5 TECHNICAL - the engineer's version

1. Scale, from vendor data. Microsoft reported at BlueHat in 2019 that about 70 percent of the CVEs it assigned each year since 2006 were memory safety issues. Google reported a similar proportion for Chrome.
2. Google's Android security team reported that memory safety vulnerabilities fell from about 76 percent of Android vulnerabilities in 2019 to about 24 percent in 2024, as new code was written in Rust and Java rather than C++.
3. Government guidance, with dates. CISA, the NSA, the FBI and international partners published "The Case for Memory Safe Roadmaps" in December 2023.
4. The United States Office of the National Cyber Director published "Back to the Building Blocks: A Path Toward Secure and Measurable Software" in February 2024, explicitly recommending memory-safe languages.
5. The NSA and CISA published "Memory Safe Languages: Reducing Vulnerabilities in Modern Software Development" in June 2025.
6. None of these are laws. They are procurement pressure and expectation setting, and they are already changing what buyers ask for.

Weakness	CWE	Typical impact
Out-of-bounds write	CWE-787	Code execution
Out-of-bounds read	CWE-125	Memory disclosure
Use-after-free	CWE-416	Code execution
Integer overflow	CWE-190	Undersized buffer

7. Heartbleed, CVE-2014-0160, disclosed 7 April 2014, was an out-of-bounds read in OpenSSL's TLS heartbeat handling. It leaked up to 64 kilobytes of process memory per request, including private keys, and it left no trace in ordinary logs.
8. Tools that find these before shipping: AddressSanitizer and MemorySanitizer, UndefinedBehaviorSanitizer, Valgrind, the compiler flags `-fstack-protector-strong` and `-D_FORTIFY_SOURCE=3`, and fuzzing with libFuzzer, AFL++ or OSS-Fuzz.
9. Check a binary's own defences with `checksec --file=./binary` on Linux, or `otool -hv` on macOS. Confirm ASLR is enabled system-wide with `sysctl kernel.randomize_va_space`, where 2 means full randomization.

10. Where experts disagree: whether to rewrite existing C code, or only write new code in safe languages. The rewrite camp cites persistent bug rates; the incremental camp cites the risk of reintroducing logic bugs in mature, heavily tested code. Practice mostly favours the incremental route.

■ 44.9.6 WORDS – remember these

Memory safety — the program cannot stray outside its own memory — guaranteed absence of out-of-bounds and lifetime errors.

Buffer overflow — writing past the end of a space — out-of-bounds write, often CWE-787.

Use-after-free — using something already returned — dereferencing a pointer to released memory, CWE-416.

Stack canary — a tripwire before the return address — random guard value verified before function return.

ASLR — moving the furniture every boot — address space layout randomization.

NX / DEP — memory is writable or runnable, not both — hardware-enforced non-executable pages.

Control flow integrity — checking every jump is legitimate — run-time or hardware validation of indirect branch targets.

Sanitizer — a bug detector built into a test build — instrumentation such as AddressSanitizer that reports violations at run time.

44.10 Network attacks conceptually

■ 44.10.1 PLAIN – in simple words

1. Three network attacks matter for a working engineer.
2. **Man-in-the-middle**: someone sits between you and the server, reading and possibly changing what passes.
3. **Spoofing**: someone lies about an address, so your traffic goes to them instead of the real destination.
4. **Denial of service**: someone sends so much traffic or so many expensive requests that the real users cannot get through.
5. TLS answers the first one. It encrypts, so a listener sees nothing useful, and it authenticates the server by certificate, so an impostor cannot pass.
6. Chapter 32 covered how that certificate check works. The one-line version: the server proves it holds the private key for a name signed by an authority your device already trusts.
7. Spoofing works at two levels. On your local network, **ARP spoofing** lets a machine claim to be the router.
8. On the wider internet, **DNS spoofing** makes a name resolve to the wrong address.
9. Denial of service comes in three flavours: raw volume, connection exhaustion, and expensive requests that cost the server far more than the attacker.
10. **Amplification** is the nastiest volume trick: send a small question with a faked return address to a public server, and it sends a large answer to the victim.

■ 44.10.2 PLAIN – a picture in your head

1. Picture a post room in an office building.
2. ARP spoofing is somebody standing up and repeatedly announcing “I am the mail chute”, until everyone believes them and hands over their post.
3. There is no verification step in the announcement, by design. The protocol simply believes the last thing it heard.
4. DNS spoofing is somebody rewriting the internal phone directory, so calls for accounts reach a different desk.
5. Amplification is posting a one-line letter that says “send me your full catalogue”, with the victim’s return address on it, to ten thousand companies at once.
6. Each catalogue is heavy, none of them is your problem, and all of them arrive at the victim.

Where this comparison breaks: office post is slow and physical, so the flood is visible. On a network the same trick delivers terabits per second within seconds, and there is no time for a human to react. That is why the defences must be automatic.

■ 44.10.3 PLAIN – a worked example

1. Amplification factors, measured by researchers and widely published.

Service	Amplification	Notes
DNS open resolver	about 28 to 54x	Very common
NTP monlist	about 556x	Mostly patched
memcached	up to 51,000x	UDP port 11211

2. Read the last row. A single byte sent can produce tens of thousands of bytes delivered to the victim.
3. That is not theoretical. On 28 February 2018 GitHub absorbed a 1.35 terabit per second memcached amplification attack, the record at the time. It was mitigated within about ten minutes by routing traffic through a scrubbing provider.
4. Scale has moved a long way since. Cloudflare reported mitigating attacks of 22.2 terabits per second in September 2025, 29.7 in October 2025, and 31.4 during December 2025. All were attributed to the Aisuru botnet family, running largely on compromised consumer devices.
5. The December record lasted about 35 seconds. There is no human response time available in that window.
6. Attacks are not only about volume. In October 2023 the HTTP/2 Rapid Reset technique, CVE-2023-44487, produced request-rate records by opening and immediately cancelling streams, costing the server far more than the client.

■ 44.10.4 PLAIN – what is really happening inside

1. ARP has no authentication. A device asks “who has 192.168.0.1”, and any machine on that network segment can answer. Most systems accept unsolicited answers and cache them.
2. That is why untrusted local networks matter, and why a VPN or plain TLS everywhere is the practical answer for a laptop in a cafe.
3. DNS cache poisoning aims to get a false answer accepted and cached by a resolver, so every later user of that resolver is sent to the wrong place.
4. Classic DNS used a 16-bit transaction identifier and no signatures, which Dan Kaminsky showed in July 2008 was far too little entropy.

5. The immediate fix was source port randomization, which multiplied the guessing space. The structural fix is DNSSEC, which signs records.
6. The reader's own machine uses 1.1.1.1 as its resolver rather than the router. That reduces exposure to a compromised or mis-configured home router, and it moves trust to Cloudflare instead. It is a trade, not a removal of trust.
7. Encrypted DNS, DNS over HTTPS in RFC 8484 and DNS over TLS in RFC 7858, hides the query from the local network and from the internet provider. It does not prove the answer is correct; only DNSSEC does that.
8. For denial of service, the defences are layered and none works alone.
9. **Rate limiting** by address, by account and by expensive operation.
10. **Filtering** at the network edge, dropping obviously forged or malformed packets before they reach an application.
11. **Anycast**, where the same address is announced from many locations, so an attack is split across dozens of data centres instead of hitting one.
12. **Scrubbing**, where traffic is diverted through a provider that removes attack packets and forwards the rest.
13. And the structural fix nobody can do alone: source address validation at the internet provider, described in BCP 38, published as RFC 2827 in 2000. Amplification only works because forged source addresses still get forwarded.

■ 44.10.5 TECHNICAL – the engineer's version

1. What TLS does and does not do against interception. It authenticates the server's name and protects the channel. It does not protect against a client that has been made to trust an extra certificate authority, which is how corporate interception proxies work, as Chapter 32 described.
2. Certificate Transparency, RFC 6962 and its successor RFC 9162, provides public append-only logs so that mis-issued certificates for your domain can be detected after the fact. Monitoring those logs is a real control.
3. HSTS, RFC 6797, removes the plaintext first request. Preloading puts your domain in a list shipped inside browsers.
4. Layer 2 defences: dynamic ARP inspection and DHCP snooping on managed switches, and 802.1X port authentication for wired and wireless access.
5. DNS defences: DNSSEC validation on the resolver, DNS cookies in RFC 7873, and response rate limiting on authoritative servers.
6. Denial of service categories map to network layers. Volumetric floods saturate bandwidth, protocol attacks such as SYN floods exhaust connection state, and application-layer attacks exhaust processing.
7. SYN cookies, invented by Daniel J. Bernstein in 1996, remove the need to keep state for half-open connections. Enable with `sysctl net.ipv4.tcp_syncookies=1` on Linux.
8. Observation commands: `tcpdump -i any -n` and Wireshark for packet capture, `arp -a` to see the current address table, `dig +dnssec example.com` to check signature records, `mttr` for continuous path measurement, and `ss -s` for socket state counts under load.
9. Historical scale markers, for calibration.

Year	Event	Peak
2016	Mirai, Dyn and OVH	about 1.1 Tbps
2018	GitHub memcached	1.35 Tbps
2025	Aisuru, December	31.4 Tbps

10. Mirai was notable for what it infected: consumer routers and cameras with factory default passwords. Its source code was published in September 2016, which is why variants are still active a decade later.

■ 44.10.6 WORDS - remember these

Man-in-the-middle — someone sitting between you and the server — an active interception attack on a communication channel.

ARP spoofing — claiming to be the router — forged address resolution replies poisoning a local network's address cache.

DNS cache poisoning — putting a lie in the phone book — injecting a forged record that a resolver stores and reuses.

Amplification — a small question, a huge answer — reflection attack exploiting protocols with large response-to-request ratios.

Anycast — one address, many locations — routing technique spreading traffic across distributed sites.

Scrubbing — cleaning the traffic elsewhere — diverting traffic through a provider that filters attack packets.

BCP 38 — stop forged source addresses at the door — RFC 2827 ingress filtering, the structural cure for amplification.

SYN cookies — answering without remembering — stateless response encoding that defeats half-open connection floods.

44.11 Malware and how infection actually happens

■ 44.11.1 PLAIN - in simple words

1. **Malware** is any program written to work against the interests of the person whose machine it runs on.
2. A **virus** attaches itself to another file and spreads when that file is run by a person.
3. A **worm** spreads by itself across a network, needing no human at all.
4. A **trojan** pretends to be something useful so you install it willingly.
5. **Ransomware** encrypts your files and demands payment for the key.
6. **Spyware** watches you: keystrokes, screenshots, messages, location.
7. A **rootkit** hides other malware by lying to the operating system about what files and processes exist.
8. A **bootkit** goes lower still and loads before the operating system does, so the system it lies to never sees the truth.
9. A **botnet** is many infected machines taking orders from one place.
10. A **cryptominer** quietly spends your electricity and processor on mining.
11. **Fileless malware** never writes a program to disk; it lives in memory and in legitimate system tools, so file scanning finds nothing.

■ 44.11.2 PLAIN - a picture in your head

1. Think of a building and the ways an unwanted person gets in.
2. Someone posts a package that a staff member opens: that is a malicious attachment.

3. Someone phones pretending to be head office and gets a door code: phishing.
4. A supplier's cleaning contractor is bribed, and their key still works: supply chain compromise.
5. A window at the back has been unlocked for two years because nobody checked: an unpatched internet-facing service.
6. Someone leaves a labelled envelope in the car park hoping it gets carried inside: removable media.

Where this comparison breaks: a building has one entrance list. A modern company has thousands of accounts, hundreds of cloud services and dozens of suppliers, and no single person knows all of them. The unlocked window is usually one nobody remembered existed.

■ 44.11.3 PLAIN - a worked example

1. Realistic infection routes, ranked by how often they appear in incident reports, with the control that actually helps.

Route	Frequency	Control that helps
Phishing / stolen login	Very high	Phishing-resistant MFA
Unpatched public service	High	Patch within days
Malicious attachment	High	Macro blocking, sandbox
Supply chain	Growing	Pinning, provenance
Drive-by download	Medium	Browser updates
Removable media	Low	Device control policy

2. Ransomware in particular follows a pattern that has barely changed since 2019: get in, look around quietly for days or weeks, steal a copy of the data, find and destroy the backups, then encrypt everything at once.
3. Stealing the data first is deliberate. It creates a second threat, to publish, so that having good backups is no longer a complete answer.
4. Chainalysis reported that tracked ransomware payments fell about 35 percent in 2024, to roughly 813 million dollars, as more victims refused to pay.
5. The FBI Internet Crime Complaint Center reported 20.9 billion dollars in total reported losses for 2025, from more than one million complaints, in its annual report published in April 2026.

■ 44.11.4 PLAIN - what is really happening inside

1. Detection works in three different ways, and each fails differently.
2. **Signatures:** match known bad bytes or known bad file hashes. Precise, no false alarms, and useless against anything new or repacked.
3. **Heuristics:** score suspicious structure, such as packed code that unpacks itself, or a document containing a macro that reaches the network.
4. **Behaviour:** watch what the program does at run time. A process that enumerates files, opens each one, writes back encrypted content and deletes shadow copies is ransomware regardless of what its bytes look like.
5. **EDR**, endpoint detection and response, is the behavioural approach with central recording. It keeps a timeline of process launches, network connections and file changes so an analyst can reconstruct what happened.
6. That recording is often more valuable than the blocking. Without it you cannot answer the only question that matters after an incident: what did they touch?
7. Why antivirus alone is not enough: it is mostly signature and heuristic, it sees one machine, and it cannot judge whether a legitimate administrator tool is being used legitimately.

8. Attackers exploit exactly that gap with **living off the land**: using PowerShell, certutil, wmic, rundll32 and remote management tools that are already installed and already trusted.
9. For ransomware, the honest advice is unglamorous. Backups are the only reliable answer, and only if they are tested, versioned, and stored where the production credentials cannot delete them.
10. The rule of thumb is three copies, on two kinds of media, with one held offline or immutable. A backup that a compromised administrator account can erase is not a backup.

■ 44.11.5 TECHNICAL – the engineer’s version

1. History markers. The Morris worm of 2 November 1988 infected several thousand machines and led to the founding of the first CERT.
2. ILOVEYOU spread by email in May 2000. Code Red and Nimda hit in 2001. SQL Slammer in January 2003 doubled its population every 8.5 seconds.
3. Stuxnet, discovered June 2010, used four zero-day flaws and stolen code-signing certificates to damage centrifuges. WannaCry, 12 May 2017, and NotPetya, 27 June 2017, both used the Eternal-Blue SMB exploit; NotPetya caused damages widely estimated above 10 billion dollars.
4. Persistence mechanisms to look for on a compromised host: scheduled tasks, systemd units, launch agents, registry Run keys, WMI event subscriptions, browser extensions, and shell profile files.
5. Firmware and boot-level threats are real but rare. LoJax in 2018 was the first UEFI rootkit found in the wild; BlackLotus in 2023 was the first observed to bypass UEFI Secure Boot on patched systems.
6. Ransomware defensive controls that measurably work: phishing-resistant MFA on all remote access, patching internet-facing services within days, network segmentation so one workstation cannot reach every server, least-privilege service accounts, and immutable backups.
7. Tools that observe: ps, lsof, netstat, Sysinternals Process Explorer and Autoruns on Windows, osquery for fleet inspection, YARA for writing your own detection rules, and VirusTotal for reputation checks on hashes.
8. Never analyze suspicious samples on a working machine. Use an isolated virtual machine with no network path back to anything you care about.

■ 44.11.6 WORDS – remember these

Worm — spreads without a human — self-propagating malware exploiting network services directly.

Trojan — useful on the outside, hostile inside — malware disguised as legitimate software.

Ransomware — your files held hostage — encrypting malware, now usually combined with data theft and threatened publication.

Rootkit — malware that hides other malware — code that subverts the operating system’s view of files and processes.

Fileless malware — nothing on disk to scan — in-memory execution using existing signed system tools.

EDR — a flight recorder for endpoints — endpoint detection and response, behaviour-based with central telemetry.

Living off the land — using your own tools against you — abuse of legitimate administrative binaries to avoid detection.

44.12 Social engineering

■ 44.12.1 PLAIN – in simple words

1. Most breaches do not start with clever code. They start with a person being helpful.
2. **Phishing** is a message designed to make you click, log in or pay.
3. **Spear phishing** is the same, tailored to you personally, using details from your company website and social media.
4. **Pretexting** is inventing a believable story: a new supplier, an audit, a delivery problem, a colleague locked out before a big meeting.
5. **Business email compromise** is a targeted fraud in which someone with apparent authority instructs a payment or a change of bank details.
6. **Vishing** is the same by voice call. **Smishing** is the same by text message.
7. **MFA fatigue** is pushing approval prompts until someone approves one.
8. Every one of these works by putting a person under pressure and giving them a way to make the pressure stop.
9. The three levers are always the same: authority, urgency, and a plausible reason not to follow the normal process.

■ 44.12.2 PLAIN – a picture in your head

1. Imagine a new employee on their third day.
2. An email arrives from the finance director, who is travelling, about a confidential acquisition, asking for a transfer today, before close.
3. Every element is designed to disable the normal check: seniority, secrecy, time pressure, and a reason the usual approver is unreachable.
4. The employee is not stupid. They are being professional in a situation engineered so that professionalism produces the wrong action.
5. That is why blaming users is both unkind and useless. The attack was designed against the process, using the person as the tool.

Where this comparison breaks: the picture suggests one dramatic moment. Most real social engineering is patient and boring, a few emails over weeks establishing that the sender is a normal part of the working day.

■ 44.12.3 PLAIN – a worked example

1. Real costs, from published figures.
2. The FBI Internet Crime Complaint Center recorded 2.77 billion dollars in business email compromise losses in 2024 and 3.04 billion dollars in 2025.
3. Phishing remained the most-reported crime type in the 2025 report, with 191,561 complaints and 215.8 million dollars in direct losses.
4. The September 2022 Uber intrusion combined a purchased contractor password, repeated push prompts, and a message claiming to be internal IT support.
5. The September 2023 attacks on MGM Resorts and Caesars Entertainment began with phone calls to help desks, persuading staff to reset credentials and MFA for real employees. MGM disclosed an effect of roughly 100 million dollars on quarterly results.
6. Recognition signs worth teaching, in plain language.

Sign	What it looks like
Urgency	Must be done today
Authority	From a senior person
Secrecy	Do not tell the team
Process bypass	Skip the usual approval
Channel switch	Move to WhatsApp or SMS
New bank details	Same supplier, new account

■ 44.12.4 PLAIN – what is really happening inside

1. Attackers do reconnaissance first: company website, LinkedIn, job adverts, conference talks, code repositories, and out-of-office replies.
2. Job adverts leak the technology stack. Out-of-office replies leak who is away and who covers for them. Both are used directly.
3. Domain look-alikes are cheap. A domain differing by one character, or using a different top-level domain, costs a few dollars and reads correctly to a tired human.
4. Since 2023, generative AI has removed the last easy signal: bad grammar. Convincing text in any language, and cloned voices from short public audio samples, are both established capability now, not speculation.
5. So detection must move away from “does it look wrong” to “is this the normal process”.
6. The organizational answers, in order of effectiveness.
7. Phishing-resistant authentication, meaning FIDO2 or passkeys, which removes credential phishing as a category rather than reducing it.
8. Out-of-band verification for money and for access: any change of bank details or any MFA reset is confirmed by calling a number already on file, never a number in the message.
9. A named, blameless reporting route, with a target of reporting in minutes. The measure that matters is time to report, not click rate.
10. Removing single points of authority, so no one person can move money or reset an executive’s access alone.
11. Help desk identity proofing: for high-privilege accounts, require a verification step the caller cannot talk their way around, such as a manager callback or an in-person or video check against a record.

■ 44.12.5 TECHNICAL – the engineer’s version

1. Email authentication is the technical floor. SPF, RFC 7208, lists which servers may send for a domain. DKIM, RFC 6376, signs messages. DMARC, RFC 7489, ties the two to the visible From address and sets a policy.
2. Publish DMARC with `p=reject` once alignment is confirmed. A monitoring-only policy of `p=none` left in place for years is a common half-measure.
3. These stop exact-domain spoofing. They do not stop look-alike domains or compromised legitimate accounts, which is where most real fraud now lives.
4. Add external sender banners, attachment sandboxing, link rewriting with time-of-click checks, and lookalike-domain monitoring through certificate transparency logs.
5. MITRE ATT&CK identifiers to use in reporting: T1566 phishing, T1566.001 spearphishing attachment, T1598 phishing for information, T1621 multi-factor authentication request generation.
6. Training works only in a specific form: short, frequent, role-relevant, and focused on process rather than on spotting fakes. Punitive simulated phishing programmes reliably reduce reporting, which makes things worse.

7. Measure two things: median time from first delivery to first report, and the proportion of high-risk transactions confirmed out of band.

■ 44.12.6 WORDS - remember these

Phishing — a message engineered to make you act — social engineering by email or messaging, MITRE T1566.

Spear phishing — phishing written just for you — targeted variant using researched personal or organizational detail.

Pretexting — a believable cover story — fabricated scenario used to justify an unusual request.

Business email compromise — fraud by fake authority — payment or data fraud using impersonated or compromised business accounts.

Vishing and smishing — the phone and text versions — voice and SMS social engineering.

Out-of-band verification — confirm on a different channel — validating a request using contact details held independently of the request.

DMARC — the policy that ties email checks together — RFC 7489 alignment and enforcement policy over SPF and DKIM.

44.13 Supply chain security

■ 44.13.1 PLAIN - in simple words

1. Your program is mostly other people's code. A typical application pulls in hundreds of packages, and those pull in more.
2. You trust every one of them, and everyone who can publish an update to any of them.
3. **Dependency confusion**: your build tool asks for an internal package name and a public registry answers first, with a package somebody else uploaded.
4. **Typosquatting**: a package with a name one character away from the one you meant, waiting for a typing mistake.
5. **Compromised maintainer**: a real package, a real author, a stolen account.
6. **Malicious update**: version 3.4.1 is fine and 3.4.2 is not, and your build accepted it automatically because you asked for "the latest".
7. The uncomfortable part is that this attacks the trusted path. The code is signed, the download is over TLS, and the certificate is valid. Everything is correct except the contents.

■ 44.13.2 PLAIN - a picture in your head

1. Think of a kitchen buying ingredients from many suppliers.
2. Typosquatting is a sack labelled almost like your usual flour brand.
3. Dependency confusion is a stranger delivering to your door claiming to be your in-house supplier, and your staff accepting because the name matched.
4. Compromised maintainer is your genuine supplier, whose delivery van was taken over last night.
5. A lock file is writing down the exact batch number you accepted, so tomorrow's delivery must match or be questioned.
6. An SBOM is the ingredient list on the finished product, so when a contamination notice is issued you can tell in minutes whether you used it.

Where this comparison breaks: a kitchen can smell bad flour. Malicious code is designed to behave normally until a condition is met, and often only in the published archive rather than in the source repository everyone reads.

■ 44.13.3 PLAIN – a worked example

1. Four real incidents, with the mechanism and the lesson.

Incident	Year	Mechanism
event-stream	2018	Handed-over maintainership
SolarWinds	2020	Compromised build system
Codecov	2021	Altered uploader script
xz-utils	2024	Multi-year social engineering

2. event-stream, November 2018: a popular npm package's maintainer handed the project to a volunteer who then added a dependency containing code targeting a specific cryptocurrency wallet application. Downloads were in the millions per week.
3. SolarWinds, disclosed December 2020: attackers compromised the build pipeline for Orion and inserted the SUNBURST backdoor into signed releases. Roughly 18,000 customers installed it; a much smaller number were then targeted. The signature was valid because the build itself was subverted.
4. Codecov, April 2021: a flaw in a Docker image creation process leaked credentials, which were used to modify the Bash Uploader script. The change sat undetected from 31 January to 1 April 2021 and exfiltrated environment variables, meaning secrets, from users' CI runs.
5. xz-utils, March 2024: CVE-2024-3094, CVSS 10.0. An account building trust since 2021 became a co-maintainer and placed a backdoor targeting OpenSSH in release tarballs of versions 5.6.0 and 5.6.1. Andres Freund found it on 29 March 2024, from half a second of extra CPU time on SSH logins.
6. Read that last sentence again. The most sophisticated open-source supply chain attack yet found was caught by one engineer noticing a performance anomaly, not by any scanner.

■ 44.13.4 PLAIN – what is really happening inside

1. Dependency confusion, explained defensively, was published by Alex Birsan in February 2021 after he reached more than 35 companies including Apple and Microsoft, earning over 130,000 dollars in bug bounties.
2. The mechanism is resolution order. Many package managers, given a name, consult both an internal registry and the public one and prefer the highest version number. Publishing a very high version publicly wins.
3. The fixes are configuration, not vigilance: scope internal packages under a namespace you own, configure the client to use exactly one source per scope, and reserve your internal names publicly so nobody else can take them.
4. Lock files record the exact resolved version and a hash of each package's contents. `package-lock.json`, `poetry.lock`, `Cargo.lock`, `go.sum`.
5. Install in continuous integration with the command that refuses to update the lock file, such as `npm ci` rather than `npm install`.
6. Pinning to exact versions removes surprise updates but creates a second duty: something must tell you when a pinned version becomes vulnerable.

7. An **SBOM**, software bill of materials, is a machine-readable list of every component and version in a build. Its value is answering “are we affected” in minutes rather than weeks, which was the actual pain of Log4Shell.
8. Signing and provenance answer a different question: not what is inside, but who built it, from which source, on which machine.

■ 44.13.5 TECHNICAL – the engineer’s version

1. SBOM formats: SPDX, an ISO standard as ISO/IEC 5962:2021, and CycloneDX from OWASP. United States Executive Order 14028 of 12 May 2021 pushed SBOMs into federal procurement, which is why they spread.
2. Sigstore, launched in 2021 under the Open Source Security Foundation, provides keyless signing: a short-lived certificate is issued against an OpenID Connect identity, the signature is recorded in the public Rekor transparency log, and the key is discarded. cosign is the common tool.
3. SLSA, Supply-chain Levels for Software Artifacts, defines build integrity levels. Level 3 requires a hardened, non-falsifiable build service that produces signed provenance describing exactly what it built and from where.
4. npm provenance, generally available since 2023, publishes signed statements linking a published package to the exact commit and workflow that built it.
5. Reproducible builds mean identical source yields byte-identical output, so independent parties can rebuild and compare. Debian has driven this since 2013 and reports well over 90 percent reproducibility for its main archive.
6. Practical checklist for a team, in priority order: commit and honour lock files; run `npm audit`, `pip-audit`, `cargo audit` or `Dependabot` in CI; pin base container images by digest, not tag; scope internal packages; generate an SBOM per release; require signed provenance for anything you deploy.
7. Software Supply Chain Failures is A03 in the OWASP Top 10:2025, promoted and broadened from the 2021 category on vulnerable and outdated components.
8. Tools to observe: `syft` to generate an SBOM, `grype` or `trivy` to scan it, `cosign verify` to check signatures, and `osv-scanner` against the Open Source Vulnerabilities database.

■ 44.13.6 WORDS – remember these

Dependency confusion — the public registry answering an internal name — a resolution-order attack on package managers.

Typosquatting — a package named almost like yours — malicious package relying on a typing or memory error.

Lock file — the exact batch numbers you accepted — a record of resolved versions and content hashes for reproducible installs.

SBOM — the ingredient list — machine-readable inventory of components, in SPDX or CycloneDX format.

Provenance — who built it, from what — signed attestation linking an artifact to its source and build process.

Sigstore — signing without long-lived keys — keyless signing with certificate issuance and a public transparency log.

Reproducible build — same source, same bytes — property allowing independent verification that a binary matches its source.

44.14 Defence in depth for a real system

■ 44.14.1 PLAIN – in simple words

1. **Defence in depth** means assuming each control will fail and putting another one behind it.
2. **Network segmentation** divides a network into zones so a compromised laptop cannot reach the database directly.
3. A **firewall** decides which traffic may pass between zones. Default deny, with a short list of allowed paths, is the only sane setting.
4. **Zero trust** means dropping the idea that being inside the network proves anything. Every request is authenticated and authorized on its own merits.
5. **Secure boot** makes the machine refuse to load unsigned early software.
6. A **TPM** is a small chip that stores keys and measurements the main processor cannot forge.
7. **Measured boot** records a hash of each stage into the TPM, so the machine can later prove which software it actually booted.
8. **Disk encryption** protects data on a powered-off device. It does nothing at all once the machine is running and unlocked.
9. **Sandboxing** and containers limit what a compromised process can reach.
10. And the highest-value activity of all, which almost nobody does properly: **patching**, quickly and everywhere.

■ 44.14.2 PLAIN – a picture in your head

1. A castle is the traditional image, and it is the wrong one, because it suggests one wall with everything soft inside.
2. Use a ship instead. A ship has watertight compartments.
3. A hole in one compartment floods that compartment. The ship stays up.
4. Segmentation is the bulkheads. Least privilege is each compartment holding only what belongs in it.
5. Zero trust is the rule that a door between compartments needs a valid reason every single time, not just because you are already aboard.

Where this comparison breaks: bulkheads are physical and permanent. Network segments are configuration, and configuration drifts. The temporary firewall rule opened for a migration in 2022 is still open, and nobody knows why.

■ 44.14.3 PLAIN – a worked example

1. What disk encryption actually protects against, stated honestly.

Situation	Protected?
Laptop stolen, powered off	Yes
Laptop stolen, sleeping	Often not
Malware while you use it	No
Cloud provider reads disk	Yes
Someone with your password	No

2. That table is the whole point. FileVault on macOS, BitLocker on Windows and LUKS on Linux all defend the same narrow, real, valuable case: physical loss of a powered-off device.

3. The key is normally sealed to the TPM or Secure Enclave and released only if measured boot matches. That is why changing firmware settings can trigger a recovery key prompt: the measurements changed, so the seal did not open.
4. Sandboxing and containers, honestly. A container is a process with restricted namespaces and control groups, sharing one kernel.
5. That is a real boundary and a useful one. It is not the same boundary as a virtual machine, because one kernel flaw crosses it.
6. Where isolation must be strong, use virtual machines, or lightweight hypervisor-backed sandboxes such as Firecracker or gVisor.

■ 44.14.4 PLAIN – what is really happening inside

1. Zero trust in practice is three concrete changes, not a product.
2. One: identity is checked at every request, for users and for services alike.
3. Two: device health is part of the decision. Is the disk encrypted, is the operating system current, is the endpoint agent reporting?
4. Three: access is per-application rather than per-network, so being on the VPN does not grant everything on the subnet.
5. Google's BeyondCorp, published from 2014 onwards, is the reference implementation. NIST SP 800-207, published August 2020, is the reference architecture.
6. Patching is the highest-value activity because most successful intrusions use a flaw that was fixed months earlier.
7. Measure two numbers: how long from a fix being published to it being installed on internet-facing systems, and what fraction of your fleet is current. Days and percentages, not intentions.
8. CISA's Known Exploited Vulnerabilities catalogue, started November 2021, is the practical priority list. It contains only flaws with confirmed exploitation, and it is short enough to act on.
9. The reason patching does not happen is never ignorance. It is fear of breakage, and the answer is automated testing and staged rollout, which is an engineering investment, not a security one.

■ 44.14.5 TECHNICAL – the engineer's version

1. Layers, with a concrete control at each.

Layer	Control	Example
Network	Default-deny egress	Firewall, VPC rules
Host	Secure and measured boot	TPM 2.0, UEFI
Process	Mandatory access control	SELinux, AppArmor
Data	Encryption at rest	LUKS, KMS keys

2. UEFI Secure Boot verifies signatures on the bootloader and kernel. Measured boot extends PCR registers in the TPM with hashes of each stage, enabling remote attestation.
3. TPM 2.0 has been an ISO standard as ISO/IEC 11889 since 2015 and is a Windows 11 requirement. Apple's equivalent is the Secure Enclave.
4. Container hardening: run as a non-root user, drop all Linux capabilities and add back only what is needed, set a read-only root filesystem, apply a seccomp profile restricting system calls, and never mount the Docker socket into a container.
5. Kubernetes specifics: Pod Security Admission at restricted, network policies that default to deny, and short-lived projected service account tokens rather than long-lived secrets.

6. Egress filtering is underrated. Most malicious activity needs to call out. A default-deny outbound policy with a small allowlist blocks a large share of post-compromise activity and makes SSRF far less useful to an attacker.
7. Secrets belong in a manager such as HashiCorp Vault, AWS Secrets Manager or the cloud equivalent, retrieved at run time, with automatic rotation.
8. Commands to observe: `nft list ruleset` or `iptables -L -n` for firewall state, `tpm2_pcrread` for boot measurements, `cryptsetup status` for LUKS, `docker inspect` for container privileges, and `kubectrl auth can-i --list`.

■ 44.14.6 WORDS – remember these

Defence in depth — assume each layer fails — overlapping independent controls so no single failure is fatal.

Segmentation — watertight compartments — dividing networks so compromise does not spread laterally.

Zero trust — being inside proves nothing — architecture where every request is authenticated and authorized on its own merits.

TPM — the small chip that keeps secrets honestly — hardware root of trust storing keys and boot measurements, ISO/IEC 11889.

Measured boot — a signed record of what actually loaded — hashing each boot stage into TPM registers for later attestation.

Egress filtering — controlling what may call out — outbound network policy limiting destinations a host may reach.

Patch window — how long you stay exploitable — time between a fix being published and being installed.

44.15 Detection and response

■ 44.15.1 PLAIN – in simple words

1. You will not prevent everything. So you must be able to notice, and then act, without making it worse.
2. **Logging** is recording what happened. Useful logs answer who, what, when, from where, and did it succeed.
3. A **SIEM** collects logs from everywhere into one searchable place and raises alerts on patterns.
4. **Intrusion detection** watches network traffic or host behaviour for known bad patterns or unusual activity.
5. A **honeypot** is a deliberately attractive fake system. Nobody has a legitimate reason to touch it, so any interaction is a real signal.
6. The response process has six steps, and they are always taught in this order: prepare, identify, contain, eradicate, recover, learn.
7. The first hour matters most, and the most common expensive mistake is rushing to clean up before you understand what happened.

■ 44.15.2 PLAIN – a picture in your head

1. Think of a shop after a break-in.
2. The instinct is to sweep up the glass and reopen. That destroys the evidence and tells you nothing about how they got in.
3. The professional sequence is: stop the bleeding, photograph everything, then clean.
4. Containment is boarding up the broken window. Eradication is changing every lock they might have copied.
5. Recovery is reopening. Learning is the meeting where you find out the alarm had been silenced for three months.

Where this comparison breaks: a burglar leaves. An intruder in a network is often still present, watching your response, including your incident channel. That is why serious responses move to an out-of-band communication channel.

■ 44.15.3 PLAIN – a worked example

1. The first hour of a suspected breach, in order.

0-10 min	Believe it. Start a timestamped written log.
10-20 min	Assemble: security, an owner who can decide, legal.
20-30 min	Contain: isolate hosts from the network, but DO NOT power them off. Memory is evidence.
30-40 min	Preserve: snapshot disks, export logs to a separate account the attacker cannot reach.
40-50 min	Revoke: rotate credentials, tokens, sessions, starting with anything highly privileged.
50-60 min	Scope: what did that identity touch, and when? Decide on notification duties and timers.
2. Two rules inside that hour. Do not power a machine off if memory may hold evidence; isolate the network interface instead.
3. Do not discuss the incident on the systems you suspect are compromised. Move to phones or a separate messaging service.
4. What good logging looks like, as fields rather than prose.

Field	Example
Who	user or service identity
What	action and target object
When	UTC, ISO 8601, synced
From	source address, device

5. Add the outcome, success or failure, and a request identifier that follows the request across services. Without that identifier you cannot reconstruct anything in a distributed system.

■ 44.15.4 PLAIN – what is really happening inside

1. Log what matters and only what matters: authentication successes and failures, privilege changes, access to sensitive data, configuration changes, and outbound connections to new destinations.
2. Never log secrets, passwords, full card numbers, tokens or session identifiers. Logs are widely readable and widely backed up.
3. Ship logs off the machine immediately. A log stored only on the compromised host is a log the attacker can edit.

4. Retention is a real decision. Median attacker dwell time before detection has fallen over the last decade but is still measured in days to weeks, so thirty days of logs is often not enough to answer basic questions.
5. Detection tuning is the hard part. An alert that fires fifty times a day is not an alert; it is background noise that teaches people to ignore it.
6. Honeypots and honeytokens are cheap and high signal. A fake credential placed in a document that nobody should use, wired to an alert, tells you the moment someone is looking.
7. Preparation is the step that actually determines outcome: contact lists, decision authority, pre-approved isolation actions, a written plan, and one rehearsal per year.
8. Rehearse with a tabletop exercise. Read a scenario aloud and make people say what they would do. It reliably exposes the missing phone number, the unclear authority, and the backup nobody has tested restoring.

■ 44.15.5 TECHNICAL – the engineer’s version

1. The six-phase cycle is NIST SP 800-61, currently revision 3, published April 2025, which restructures incident response around the Cybersecurity Framework 2.0 functions. The older SANS six-step naming remains common.
2. Detection technologies: network intrusion detection with Suricata or Zeek, host detection with Wazuh or OSSEC, and endpoint detection and response agents for process-level telemetry.
3. Detection rules are shared as content: Sigma for log rules, YARA for file and memory patterns, and Suricata rules for network traffic.
4. Log pipelines in common use: the Elastic Stack, Splunk, Grafana Loki, or a cloud-native pairing such as CloudWatch with Athena. The important property is a separate trust boundary from the systems being logged.
5. Time synchronization is not optional. Without NTP and a single time zone, usually UTC, correlation across systems is guesswork.
6. Forensic preservation order, from most to least volatile: CPU registers and caches, memory, network state, running processes, disk, then archived logs. Capture in that order.
7. Notification timers start whether or not you are ready. GDPR Article 33 requires notifying a supervisory authority within 72 hours of becoming aware. India’s DPDP Rules 2025 require intimation without delay and a fuller report to the Data Protection Board within 72 hours.
8. Tools to observe and preserve: `journalctl`, `auditd` with `ausearch`, `dmesg`, Velociraptor for remote forensics, and `dd` or cloud snapshot APIs for disk images. Record hashes of every image you take.

■ 44.15.6 WORDS – remember these

SIEM — one searchable place for all logs — security information and event management with correlation and alerting.

IDS — a watcher for known bad patterns — intrusion detection system, network or host based.

Honeypot — bait with no legitimate use — deliberately exposed decoy whose every interaction is a signal.

Dwell time — how long they were inside unnoticed — interval between initial compromise and detection.

Containment — stopping the spread without destroying evidence — isolating affected systems while preserving volatile state.

Eradication — removing their access completely — eliminating footholds, credentials and persistence mechanisms.

Tabletop exercise — a rehearsal with no machines — discussion-based drill testing decisions and contacts.

44.16 Privacy and the law, briefly

■ 44.16.1 PLAIN – in simple words

1. Security is about stopping people who should not have access. Privacy is about limiting what you collect and what you do with it, even when you have every right to hold it.
2. You can be perfectly secure and badly privacy-invading at the same time.
3. **Personal data** is anything relating to an identified or identifiable person. That includes identifiers such as device numbers and addresses, not only names.
4. The core ideas of modern data protection law are short.
5. Have a lawful reason to process. Tell people plainly. Collect only what you need. Keep it only as long as you need it. Keep it secure. Let people see, correct and delete their data.
6. **Data minimization** is the one engineers control directly. Every field you do not collect is a field that cannot leak.
7. If a breach exposes personal data, you usually have a legal duty to tell a regulator, and often the affected people, on a clock measured in hours.

■ 44.16.2 PLAIN – a picture in your head

1. Security is the lock on the filing cabinet.
2. Privacy is the decision about which forms go into the cabinet in the first place, who may open it and why, and when the papers are shredded.
3. A shop with an excellent safe that photographs every customer and keeps the images forever is secure and privacy-invading.
4. A shop that photographs nobody has nothing to lose in a burglary.

Where this comparison breaks: paper is finite and visible. Digital data is copied silently, spreads into backups, analytics systems and third-party tools, and the copy in the log aggregator is usually the one nobody deleted.

■ 44.16.3 PLAIN – a worked example

1. Two regimes a working engineer meets most often.

Point	GDPR	India DPDP
In force	25 May 2018	Act 2023, Rules 2025
Breach to regulator	72 hours	72 hours
Top penalty	20M EUR or 4%	Rs 250 crore
Regulator	National authorities	Data Protection Board

2. GDPR fines have two tiers: up to 10 million euro or 2 percent of worldwide annual turnover for most obligations, and up to 20 million euro or 4 percent for the most serious. The higher of the fixed amount and the percentage applies.

3. India's Digital Personal Data Protection Act was passed in August 2023. The Digital Personal Data Protection Rules were notified on 14 November 2025, with the substantive obligations, including breach reporting and security safeguards, phased in over about eighteen months from that date.
4. Under the DPDP Act, failure to take reasonable security safeguards carries a penalty of up to 250 crore rupees, and failure to notify a breach up to 200 crore rupees.
5. Under the DPDP Rules, affected individuals must be informed without delay, and a fuller report reaches the Data Protection Board within 72 hours.

■ 44.16.4 PLAIN - what is really happening inside

1. The engineering consequences of these laws are concrete, not abstract.
2. You need a data inventory: what personal data exists, where it lives, who can reach it, and how long it stays. Most organizations cannot answer this.
3. You need deletion that actually works, including in backups, search indexes, analytics and every third-party processor.
4. You need to answer access requests, which means being able to find one person's data across systems.
5. You need to record consent where consent is your lawful basis, including when it was given, for what, and how it can be withdrawn.
6. Pseudonymization replaces identifiers with tokens but remains personal data, because it can be reversed with the mapping table.
7. Anonymization means the person can no longer be identified by anyone, and it is much harder than it looks. Combining a few "anonymous" fields such as postcode, birth date and sex re-identifies most individuals.
8. The cheapest compliance strategy is the same as the cheapest security strategy: do not collect it, and if you must, delete it on a schedule that runs automatically.

■ 44.16.5 TECHNICAL - the engineer's version

1. GDPR is Regulation (EU) 2016/679, applicable from 25 May 2018. Article 5 sets the principles, Article 6 lawful bases, Articles 12 to 22 data subject rights, Article 25 data protection by design and by default, Article 32 security of processing, Articles 33 and 34 breach notification.
2. Article 33 requires notification to the supervisory authority within 72 hours of becoming aware, unless the breach is unlikely to result in risk. Article 34 requires telling the individuals when the risk is high.
3. The largest single GDPR fine to date is 1.2 billion euro against Meta in May 2023, concerning transfers of European user data to the United States.
4. Other regimes worth knowing by name: the California Consumer Privacy Act as amended by CPRA, Brazil's LGPD, and sector rules such as HIPAA for United States health data and PCI DSS, currently version 4.0.1, for card data.
5. PCI DSS is a contractual standard, not a law, but it is enforced through card scheme agreements and behaves like one in practice.
6. Technical measures named in practice: encryption at rest and in transit, pseudonymization, access logging, retention policies enforced by automation, and documented data processing agreements with every processor.
7. Privacy and security overlap at Article 32 but are not the same duty. A system can satisfy every security control and still be unlawful because it collects data it has no basis to collect.

■ 44.16.6 WORDS – remember these

Personal data — anything about an identifiable person — includes indirect identifiers such as device and network addresses.

Data minimization — do not collect what you do not need — principle limiting collection to what is adequate and relevant.

Breach notification — the legal clock after an incident — duty to inform regulators and individuals, typically within 72 hours.

Pseudonymization — identifiers swapped for tokens — reversible with a separately held mapping, still personal data.

Anonymization — genuinely no longer a person — irreversible, and much harder than it looks in practice.

Lawful basis — your legal reason to process — one of the grounds required before processing personal data.

Data protection by design — build it in, not on — the requirement to embed protection into system design by default.

44.17 Security for the individual developer

■ 44.17.1 PLAIN – in simple words

1. Most of what protects you is a short list of habits, not expensive tools.
2. Keep your machine current. Turn on automatic updates for the operating system and the browser.
3. Encrypt the disk. FileVault, BitLocker or LUKS, with a real passphrase.
4. Use a password manager, and put a hardware key or passkey on the accounts that matter most: email first, then code hosting, then cloud.
5. Email first, because email resets everything else.
6. Never commit a secret. Not a token, not a password, not a private key, not a connection string.
7. Assume that anything committed once is compromised forever, even after you delete it, because history is public and cloned within minutes.
8. Keep your dependencies current and know what they are.
9. Read code with security in mind, which is a specific skill, not general attentiveness.
10. And if you find a flaw in somebody else's software, report it responsibly rather than publishing it or exploiting it.

■ 44.17.2 PLAIN – a picture in your head

1. Think of a workshop. Locked door, tools accounted for, dangerous materials in a cabinet rather than on the bench.
2. Committing a secret is leaving the spare key taped to the outside of the door, then painting over it and believing it is gone.
3. Automated scanners crawl public repositories continuously. Published measurements repeatedly show credentials being found and used within minutes of being pushed.
4. So the moment of exposure is not when someone reads your code. It is when the commit lands.

Where this comparison breaks: a taped key can be removed. A committed secret is in every clone, every fork, every cache, and every scraper's archive. The only real remedy is revocation and rotation, not deletion.

■ 44.17.3 PLAIN – a worked example

1. Practical checklist, grouped, in the order worth doing it.

Area	Action
Machine	Auto-update, disk encryption
Accounts	Manager, passkey on email
Secrets	Manager, never in git
Dependencies	Lock files, audit in CI
Code	Review checklist, static scan

2. Secrets handling in practice. Keep values in environment variables loaded from a file that is listed in `.gitignore`, or in a real secret manager.
3. Commit a `.env.example` with the names and no values, so the next person knows what is needed.
4. Install a pre-commit hook that blocks obvious secret patterns, and enable push protection on the hosting side as a second net.
5. If a secret is exposed, the order is fixed and not negotiable.
 1. Revoke the credential immediately.
 2. Issue a replacement and deploy it.
 3. Check logs for use of the old one.
 4. Only then clean the history, if worth it.
6. Rewriting history is the last step and the least important. The credential is already public; rotating it is what actually ends the exposure.

■ 44.17.4 PLAIN – what is really happening inside

1. Reading code for security means asking a different set of questions from normal review.
2. Where does untrusted input enter, and where does it end up? Trace it from the boundary to every interpreter it touches.
3. Is authorization checked on every path to this object, including the new endpoint added last week?
4. Are errors handled on every branch, and does the failure path fail closed rather than open?
5. Is anything constructed by string concatenation that should be parameterized: SQL, shell commands, HTML, file paths, URLs?
6. Is any cryptography home-made, and is any random value coming from a non-cryptographic generator?
7. Do log statements or error messages contain secrets or personal data?
8. Two kinds of tool help, and they see different things.
9. **Static analysis** reads code without running it. It finds patterns and scales to every file, at the cost of false positives.
10. **Dynamic analysis** runs the system and observes it. It finds real behaviour including configuration problems, but only on the paths it exercises.
11. **Fuzzing** is dynamic analysis with automatically generated inputs, and it is the most effective way to find memory safety and parsing bugs.
12. None of these replaces a person who understands what the application is supposed to protect.

■ 44.17.5 TECHNICAL – the engineer's version

1. Secret scanning: `gitleaks`, `trufflehog`, GitHub secret scanning with push protection, and `detect-secrets` as a pre-commit hook.

2. Static analysis: `semgrep` with community rule packs, `CodeQL`, `bandit` for Python, `gosec` for Go, `cargo clippy` for Rust lints, `brakeman` for Rails.
3. Dependency scanning: `npm audit`, `pip-audit`, `cargo audit`, `osv-scanner`, `Dependabot` or `Renovate` for automated update pull requests.
4. Dynamic analysis: `OWASP ZAP` for web scanning, `nuclei` for templated checks, `trivy` for container and infrastructure-as-code scanning.
5. Fuzzing: `libFuzzer` and `AFL++` for native code, `go-fuzz` and Go's built-in fuzzing since Go 1.18, `Atheris` for Python, and `OSS-Fuzz` for open-source projects that qualify.
6. Coordinated disclosure, the correct process when you find a flaw in software you do not own.
7. Look for a `security.txt` file at `/.well-known/security.txt`, standardized as RFC 9116 in April 2022, or a `SECURITY.md` in the repository, or a bug bounty programme.
8. Report privately with enough detail to reproduce. Propose a disclosure timeline. Ninety days is the widely used norm, following Google Project Zero's policy since 2014, with a shorter clock if active exploitation is observed.
9. Do not test against systems you do not own or have written authorization for. In many jurisdictions, including under India's Information Technology Act 2000 and the United States Computer Fraud and Abuse Act, unauthorized access is a criminal offence regardless of intent.
10. Request a CVE identifier through the vendor if they are a CVE Numbering Authority, or through MITRE otherwise. Coordinate publication with the fix.
11. If the vendor does not respond, escalate to a national CERT, such as CERT-In in India or CISA in the United States, rather than publishing.
12. Keep a written record of every contact attempt with dates. If disclosure ever becomes contested, that record is what protects you.

■ 44.17.6 WORDS - remember these

Secret scanning — automated hunting for committed credentials — pre-commit and server-side detection of key patterns.

Rotation — replacing a credential — issuing a new secret and invalidating the old one, the only real remedy for exposure.

Static analysis — reading code without running it — pattern and dataflow analysis over source, SAST.

Dynamic analysis — testing the running system — behavioural testing against a deployed instance, DAST.

Fuzzing — throwing generated inputs at it — automated input generation to find crashes and parsing flaws.

Coordinated disclosure — report privately, publish together — agreed process between finder and vendor with a timeline.

`security.txt` — where to send a vulnerability report — RFC 9116 file at a well-known path listing security contacts.

44.18 Famous breaches and what each teaches

■ 44.18.1 PLAIN - in simple words

1. Six incidents, chosen because they are well documented and because each fails in a different way.
2. Read them as a list of things that were possible, not as a list of villains.
3. In every one of them, the technical flaw was known and fixable beforehand.

■ 44.18.2 PLAIN – a picture in your head

1. Think of aviation accident reports. Nobody reads them for blame.
2. They are read because one crew's bad day becomes every other crew's checklist item.
3. Security has the same discipline available and uses it far less often.

Where this comparison breaks: aviation has a legal duty to publish investigations. Most breach reports are written by lawyers, and the technically interesting details are usually the ones removed.

■ 44.18.3 PLAIN – a worked example

1. The six, with root cause and lesson.

Incident	Year	Root cause
Target	2013	Supplier access, flat network
Equifax	2017	Unpatched Apache Struts
WannaCry	2017	Unpatched SMB, no segmentation
SolarWinds	2020	Compromised build pipeline
Colonial Pipeline	2021	VPN password, no MFA
Change Healthcare	2024	Citrix portal without MFA

2. Target, December 2013: credentials belonging to a refrigeration contractor reached the payment network because the network was flat. About 40 million card records and 70 million customer records were exposed.
3. Equifax, 2017: a fix for Apache Struts flaw CVE-2017-5638 was available on 7 March 2017. Intrusion began around 13 May and was discovered on 29 July. About 147 million people were affected; the settlement was up to 700 million dollars.
4. WannaCry, 12 May 2017: ransomware using the EternalBlue SMB exploit, for which Microsoft had shipped a patch on 14 March 2017. It reached about 200,000 machines in 150 countries and disrupted parts of the NHS.
5. SolarWinds, disclosed December 2020: the build system was subverted, so the malicious code carried a valid vendor signature. Roughly 18,000 customers installed the trojanized update.
6. Colonial Pipeline, 7 May 2021: a legacy VPN account with a leaked password and no multi-factor authentication. Fuel supply to the United States east coast was disrupted and a 4.4 million dollar ransom was paid.
7. Change Healthcare, February 2024: a Citrix remote access portal without multi-factor authentication. It became the largest health data breach ever reported in the United States, at 192.7 million individuals, with a reported 22 million dollar ransom payment.

■ 44.18.4 PLAIN – what is really happening inside

1. The lessons, one line each, in the same order.
2. Target: a supplier's access is your access. Segment the network so a contractor's account cannot see a payment terminal.
3. Equifax: the gap between a patch existing and a patch being installed is the whole vulnerability. Measure that gap in days.
4. WannaCry: a patch you did not deploy is a patch you did not have. And a flat internal network turns one infection into all of them.
5. SolarWinds: a valid signature proves who built it, not that the build was honest. Protect the build system as tightly as production.

6. Colonial Pipeline: every remote access path needs multi-factor authentication, including the old one nobody uses.
7. Change Healthcare: the same lesson again, three years later, at a much larger scale. This is the single most repeated root cause in the record.
8. The pattern across all six is dull and consistent. Known flaw, known fix, missing basic control, insufficient segmentation.
9. Not one of them required a novel attack technique.

■ 44.18.5 TECHNICAL – the engineer’s version

1. Detection times are the other lesson. Equifax ran for roughly 76 days before discovery. The Codecov modification ran for 60 days. The SolarWinds implant ran for months before Mandiant identified it in December 2020.
2. Notable data-handling failures worth naming separately, because they are about storage rather than intrusion.
3. RockYou, December 2009: 32 million passwords stored in plain text. The resulting list is still the standard wordlist in password auditing tools.
4. LinkedIn, June 2012: 6.5 million password hashes leaked, SHA-1 with no salt. The full set later proved to be about 117 million accounts.
5. Adobe, October 2013: about 153 million records, passwords encrypted with 3DES in ECB mode rather than hashed, with plaintext password hints alongside. Identical passwords produced identical ciphertext.
6. Yahoo, breaches in 2013 and 2014 disclosed in 2016 and 2017: 3 billion accounts, with MD5 hashing on a portion of them.
7. Each of those is a direct illustration of section 44.3. Plain text, fast unsalted hashes, and encryption used where hashing was required.
8. For breach data, the checkable public sources are the Have I Been Pwned service, the annual Verizon Data Breach Investigations Report published each spring since 2008, and the United States Department of Health and Human Services breach portal for health-sector figures.

■ 44.18.6 WORDS – remember these

Root cause — the thing that actually let it happen — the earliest correctable failure, not the final symptom.

Dwell time — how long they stayed unnoticed — interval from compromise to detection, often weeks.

Lateral movement — spreading sideways once inside — using one foothold to reach further systems.

Flat network — everything can reach everything — an unsegmented network where one compromise exposes all.

Patch gap — the window between fix and install — the period during which a known, fixed flaw remains exploitable.

Third-party risk — their weakness becomes yours — exposure arising from suppliers, contractors and integrations.

44.98 Common wrong ideas

1. Wrong: we are too small to be a target. Right: most attacks are automated and indiscriminate. Scanners find every internet-facing service within hours, and ransomware crews prefer small organizations because they pay faster and have weaker controls.

2. Wrong: the padlock in the browser means the site is safe. Right: it means the connection is encrypted to whoever holds a valid certificate for that name. A phishing site can obtain one for free in minutes. It says nothing about who runs the site or what they do with your data.
3. Wrong: antivirus protects me. Right: signature-based scanning misses new, repacked and fileless malware, and cannot judge whether a legitimate administrative tool is being misused. It is one useful layer among several, not a boundary.
4. Wrong: open source is less secure because anyone can read the code. Right: visibility helps defenders more than attackers, since attackers can analyze closed binaries too. The real open-source risk is different: unpaid, unsupported maintainers of critical components, which is exactly what the xz-utils backdoor exploited in 2024.
5. Wrong: a strong password is enough. Right: length and randomness do not help if the password is phished, reused on a breached site, or stolen by malware. Phishing-resistant multi-factor authentication is the control that changes the outcome.
6. Wrong: encryption solves security. Right: encryption protects confidentiality in transit and at rest. It does nothing about broken access control, injection, social engineering, or an attacker using your own application while it is unlocked and running.
7. Wrong: we passed a penetration test, so we are secure. Right: a test is a sample of one moment by one team within a fixed scope. It shows what was found, not what exists.
8. Wrong: internal systems do not need the same protection. Right: that assumption is exactly what turned the Target and WannaCry incidents into catastrophes. Assume the attacker is already inside and design accordingly.
9. Wrong: hashing a password with SHA-256 is fine because SHA-256 is secure. Right: SHA-256 is secure as a hash and terrible as a password function precisely because it is fast. Use Argon2id, scrypt or bcrypt.
10. Wrong: we have backups, so ransomware cannot hurt us. Right: modern ransomware finds and deletes backups first and steals the data before encrypting, so publication remains a threat. Backups must be tested, versioned and beyond the reach of production credentials.

44.99 Chapter summary in 20 lines

1. Security is five promises about data: confidentiality, integrity, availability, authenticity and non-repudiation, always in trade-off.
2. It is a property of a whole system in a context, never a product you buy.
3. Threat modelling is three questions: what am I protecting, from whom, and what happens if I fail. Rank the answers by likelihood times impact.
4. A hash is a one-way fingerprint. MD5 fell to collisions in August 2004 and SHA-1 to the SHattered attack on 23 February 2017. Use SHA-2, SHA-3 or BLAKE3, and never a bare hash for passwords.
5. Store passwords with a deliberately slow, memory-hard function: Argon2id at 19 MiB with two passes, scrypt, or bcrypt at cost 10 or above, always with a unique per-user salt and ideally a separately stored pepper.
6. NIST SP 800-63B revision 4, published 31 July 2025, forbids composition rules and routine expiry. Length beats complexity, and a manager beats both.
7. Symmetric encryption must be authenticated. Use AES-GCM or ChaCha20-Poly1305, never ECB, and never reuse a nonce with the same key.
8. Asymmetric cryptography solves key agreement and gives signatures, which prove origin and integrity in a way encryption alone never does. Every real system is hybrid: asymmetric once, symmetric thereafter.
9. NIST approved ML-KEM, ML-DSA and SLH-DSA as FIPS 203, 204 and 205 on 13 August 2024,

and selected HQC as a fifth algorithm on 11 March 2025. Harvest-now-decrypt-later makes key exchange migration urgent today.

10. Authentication factors are not equal. SMS is weak, app codes are relayable, and only FIDO2 and passkeys resist phishing by binding to the origin.
11. Authorization is a separate question from authentication, checked on every request, at the data layer, with least privilege and deny by default.
12. Broken Access Control has been number one in the OWASP Top 10 in both the 2021 and the current 2025 edition, which was presented on 6 November 2025.
13. Injection is fixed by construction with parameterized queries and argument arrays, never by filtering. Cross-site scripting is fixed by contextual output encoding plus a strict Content Security Policy.
14. Memory safety bugs have been roughly seventy percent of the vulnerabilities at major vendors. Canaries, non-executable memory, ASLR and control flow integrity raise cost; memory-safe languages remove the class.
15. Network defence rests on TLS against interception, DNSSEC and encrypted DNS for name lookups, and rate limiting, filtering, anycast and scrubbing against floods that now exceed 30 terabits per second.
16. Most intrusions begin with a person or a stolen credential, not an exploit. Business email compromise alone cost 3.04 billion dollars in 2025.
17. Your dependencies are your attack surface. Use lock files, pin by digest, generate SBOMs, and require signed provenance. Remember that xz-utils in March 2024 was caught by one engineer noticing half a second of CPU time.
18. Defend in depth: segment, patch fast, encrypt disks, sandbox, and give everything the least privilege it can function with.
19. Prepare for the incident you will have. Log the right fields off-host, rehearse once a year, and in the first hour contain without destroying evidence, preserve, revoke and scope before you clean.
20. Every famous breach in section 44.18 had a known flaw and an available fix. The advantage is almost never in exotic defence; it is in doing the dull things quickly and everywhere.

PART H

Games and Machine Intelligence

How a game runs sixty times a second, and how a language model is built, judged and used.

Games — How They Are Made and How They Run

45.0 What this chapter gives you

1. You will be able to say exactly what makes a game different from every other program on your machine, in one sentence, and defend it.
2. You will be able to write a correct game loop with a fixed physics step, an accumulator and interpolation, and explain every line of it.
3. You will be able to do frame budget arithmetic in your head, and explain why “average frames per second” hides the thing that actually annoys you.
4. You will be able to describe how a real game project is staffed and funded, from a one-person hobby project to a three-hundred-person AAA title, with real money figures.
5. You will be able to compare Unity, Unreal Engine and Godot honestly on cost, language and licence, including the 2023 Unity fee episode.
6. You will be able to explain what an asset pipeline does, why a build takes hours, and what “cooking” content means.
7. You will be able to work through a collision resolution by hand and check that momentum is conserved.
8. You will be able to run the A-star pathfinding algorithm on a grid by hand, and explain why game AI is designed to be beaten.
9. You will be able to explain client-side prediction, server reconciliation, entity interpolation and lag compensation, and say precisely why you get shot after you reached cover.
10. You will be able to trace what happens between the double-click and the first frame of gameplay, in twenty-five steps with real timings.

45.1 What a game actually is as a program

■ 45.1.1 PLAIN – in simple words

1. Most programs are lazy. They sit still and wait for you to do something.
2. A text editor draws your document once, then does nothing until you press a key. If you walk away for an hour, it does nothing for an hour.
3. A game is the opposite. A game never sits still.
4. A game runs the same short list of jobs over and over, very fast, forever, whether or not you touched anything.
5. That list is: read the controls, work out what the world looks like now, draw it, show it. Then do it again.

6. One trip round that list is called a **frame**.
7. At 60 frames a second, the game does this 60 times every second. That is once every 16.67 thousandths of a second.
8. It keeps doing it even when you stand perfectly still in an empty room.
9. Why? Because the world keeps moving. Water flows, clouds drift, an enemy walks somewhere far away, a timer counts down.
10. The game cannot know in advance whether anything changed. Working that out would cost more than just redoing the work.
11. So it redoes all of it, every single time, on a strict clock.
12. That one decision, “redo everything on a clock”, explains almost every other odd thing about how games are built.

■ 45.1.2 PLAIN – a picture in your head

1. Think of two people who work in the same building.
2. The first is a receptionist. She sits at a desk and does nothing until someone walks in. Then she deals with them and goes back to waiting.
3. Her day is quiet. Her energy use is low. Nothing happens between visitors.
4. The second is a film projectionist in an old cinema.
5. He cannot wait for anything. Twenty-four times a second a new picture must be in front of the lamp, whether the film is exciting or boring.
6. If he is late by even a fraction of a second, the audience sees a flicker and the illusion of motion breaks.
7. The receptionist is an ordinary application. The projectionist is a game.
8. Now notice what this does to the projectionist’s job. He cannot go and make tea. He cannot take a long phone call. He has a deadline every 41 thousandths of a second, all day.
9. Everything about how he arranges his booth is decided by that deadline.

Where this comparison breaks: the projectionist is only showing pictures that already exist on the film. A game invents each picture from scratch, having first worked out what the world looks like at that instant. It is closer to a projectionist who must also draw each frame in the time between showing them. Also, real film runs at a fixed 24 frames per second and cannot be late. A game can be late, and when it is, you see it as a stutter rather than a flicker.

■ 45.1.3 PLAIN – a worked example

1. Take one hour of a person using a word processor, and one hour of the same person playing a game.
2. In the word processor, the screen is redrawn when something changes: a letter typed, a scroll, a menu opened.
3. A fast typist hits about 400 keys a minute, so about 24,000 keys an hour.
4. Even if each key caused one redraw, that is 24,000 redraws in an hour.
5. In the game at 60 frames a second: $60 \times 60 \times 60 = 216,000$ frames an hour.
6. That is nine times more drawing, and the drawing itself is far heavier: millions of triangles instead of a page of text.
7. Now watch what the machine does.

Program state	Word processor	Game at 60 fps
Screen updates per hour	~24,000	216,000

Program state	Word processor	Game at 60 fps
CPU while idle	near 0 percent	one core busy
GPU while idle	near 0 watts	150 to 450 watts
Deadline per update	none	16.67 ms

8. The word processor has no deadline at all. If a redraw takes 200 milliseconds, nobody dies.
9. The game has a hard deadline, 60 times a second, and missing it is visible.
10. This is why your laptop fans spin up for a game and stay silent for a document, even though both are “just a program”.

■ 45.1.4 PLAIN – what is really happening inside

1. Both kinds of program start the same way. The operating system loads them and calls a starting function.
2. The lazy program then enters a **message loop**. It asks the operating system: “is there anything for me?” and, if not, it goes to sleep.
3. Going to sleep is the key. The program is removed from the list of things that need the processor. It uses no time at all.
4. The operating system wakes it only when a real event arrives: a key, a mouse click, a window resize, a timer.
5. When it wakes, it handles the one event, redraws only the part of the window that changed, and goes back to sleep.
6. A game also has a message loop, because the operating system still sends it events. But it never sleeps in it.
7. Instead it asks “is there anything for me?”, takes whatever is there without waiting, and immediately moves on to its own work.
8. Its own work is: read the current state of every input device, advance the simulated world by a small slice of time, and build a new picture.
9. Then it asks the graphics system to show that picture, and starts again.
10. The only place it ever waits is at the very end, when it hands the finished picture to the display and waits for the screen’s next refresh.
11. That single wait is what keeps a game at exactly 60 or 120 frames a second instead of running as fast as the hardware allows.

■ 45.1.5 TECHNICAL – the engineer’s version

1. An event-driven application on Windows blocks in GetMessage, which does not return until a message is in the thread’s queue. The thread is in a wait state and consumes no scheduler quantum.
2. It redraws in response to WM_PAINT, and the system tracks an **update region** so only invalidated rectangles are repainted. On macOS the equivalent is setNeedsDisplay and drawRect; on X11 it is Expose.
3. A real-time application instead uses PeekMessage with PM_REMOVE, which returns immediately whether or not a message is waiting, then falls through to its own frame code. This is the standard game shape and has been since the Win32 era.
4. The frame ends with a present: IDXGISwapChain::Present in Direct3D, vkQueuePresentKHR in Vulkan, [CAMetalDrawable present] in Metal, SDL_GL_SwapWindow or eglSwapBuffers in the portable stacks.

5. The swap chain holds two or three back buffers. With a sync interval of 1, Present blocks until the display's vertical blanking interval, which is what pins the frame rate to the refresh rate.
6. With variable refresh rate displays (VESA Adaptive-Sync, marketed as AMD FreeSync from 2015 and NVIDIA G-Sync from 2013) the panel waits for the game rather than the other way round, within a supported range, typically 48 to 144 Hz or wider.
7. The consequences of the loop shape are measurable. A game pins at least one CPU core near 100 percent and keeps the GPU in its highest power state. A discrete GPU that idles at 10 to 25 W will draw 150 to 450 W under load.
8. The other big consequence is memory behaviour. An event-driven application can allocate freely, because a 5 ms garbage collection pause is invisible. A game cannot: a 5 ms pause inside a 16.67 ms budget is 30 percent of the frame, and a 30 ms pause is a visible hitch.
9. This is why game code pre-allocates pools, avoids per-frame heap allocation, and why C# game code is written to keep the generation 0 heap quiet rather than in idiomatic allocating style.

Property	Event-driven app	Real-time game
Blocking call	GetMessage	none, PeekMessage
Redraw trigger	invalidated region	every frame
Frame deadline	none	16.67 ms at 60 Hz
Allocation policy	free	pooled, per-frame zero

10. Tools that show the difference: Windows Task Manager and powermetrics on macOS for power draw, perf top on Linux for the busy loop, PresentMon on Windows for per-frame present timings, and RenderDoc for a captured frame.

■ 45.1.6 WORDS – remember these

1. Frame — one complete picture — one iteration of the game loop producing one presented back buffer.
2. Game loop — the list of jobs done over and over — the input, update, render, present cycle running at the target frame rate.
3. Event-driven — waits until poked — blocks on a message queue and repaints only invalidated regions.
4. Present — showing the finished picture — handing a back buffer to the display engine, optionally synchronized to vertical blank.
5. Swap chain — the queue of pictures waiting to be shown — a set of back buffers rotated between the renderer and the display controller.
6. Vertical blank — the pause between screen refreshes — the interval in which a buffer swap can occur without tearing.

45.2 A history of video games as technology

■ 45.2.1 PLAIN – in simple words

1. Video games did not start as a business. They started as people playing with expensive laboratory equipment.
2. In 1958 a physicist wired an analogue computer to a small round screen so that visitors to his laboratory's open day would have something to do.
3. In 1962 students at a university did something similar on a room-sized computer, and the program spread to every machine of that type.

4. The first machines you could buy for a home, in 1972, had no computer inside at all. They were built from simple switching parts wired together.
5. Then chips got cheap. Arcade cabinets became small computers with one game burned into them.
6. Then home consoles became small computers with a slot for a cartridge.
7. Then home computers became fast enough to draw a three-dimensional world, and then extra chips were added just for drawing.
8. Then the internet arrived, and games stopped being finished things and started being services that keep changing.
9. Then phones arrived, and more people played games than ever before, mostly for free, paying in small amounts inside the game.
10. Every one of those steps was a technical step first, and a business step second.

■ 45.2.2 PLAIN – a picture in your head

1. Think about how photography grew up.
2. First there were one-off chemical experiments by scientists, making a single image with enormous effort.
3. Then there were heavy plate cameras owned by professionals with studios.
4. Then a company put film in a small box and said “you press the button, we do the rest”, and ordinary people took pictures.
5. Then colour arrived, then instant prints, then video, then digital, then a camera in every pocket connected to the whole world.
6. Games followed the same shape, about eighty years later and much faster.
7. The laboratory oscilloscope is the chemical experiment. The arcade cabinet is the professional studio. The home console is the box with film in it. The phone is the camera in every pocket.

Where this comparison breaks: photography captures something that already exists. A game must create everything, so each step forward needed not just better hardware but also new mathematics and new ways of organizing a team. And unlike photography, games have kept the old forms alive: people still make and play games that would run on 1985 hardware.

■ 45.2.3 PLAIN – a worked example

1. Compare one specific thing across the decades: how many moving pictures per second the machine had to produce, and what it had to remember.

Machine and year	Working memory	Screen
Odyssey, 1972	none	3 white dots
Atari 2600, 1977	128 bytes	160x192, 4 colours
NES, 1983	2 KB	256x240, 25 colours
PlayStation, 1994	2 MB + 1 MB video	320x240 to 640x480
PlayStation 5, 2020	16 GB shared	3840x2160

2. Read the memory column again. 128 bytes on the Atari 2600 is not a typing error. That is 128 individual bytes for all game state.
3. The whole screen would not fit in that memory, so the machine did not have a screen buffer at all.
4. Instead the processor had to change the graphics chip’s registers while the television’s electron beam was sweeping across the screen, line by line.
5. Programmers called this **racing the beam**. You had about 76 processor cycles per scan line to set up the next line.

6. From 128 bytes to 16 gigabytes is a factor of 134 million in about 43 years.

■ 45.2.4 PLAIN – what is really happening inside

1. Each era solved one specific bottleneck, and the games of that era look the way they do because of that one bottleneck.
2. The 1972 machines had no processor, so the game was fixed in wiring. You could not have a game with rules that changed.
3. The 1977 to 1983 machines had a processor but almost no memory, so the world had to be tiny and mostly regenerated each frame.
4. The 1983 to 1990 machines added dedicated graphics hardware that could move small pictures around cheaply, so games became about sprites and scrolling.
5. The early 1990s machines were fast enough to compute perspective in software, so first-person games appeared, with clever mathematics used to avoid work rather than to do it.
6. From 1996 a separate chip did the triangle filling, so the limit moved from “how many pixels can we fill” to “how many triangles can we send”.
7. From about 2001 those chips became programmable, so the limit moved again to “what can we compute per pixel”.
8. From about 2013 the limit for many games became not the hardware but the cost of making enough content to fill it.
9. That last shift is the reason a modern game costs two hundred million dollars and a 1985 game cost a few hundred thousand.

■ 45.2.5 TECHNICAL – the engineer’s version

Year	Milestone	Technical advance
1958	Tennis for Two	Real-time analogue graphics
1962	Spacewar, PDP-1	Stored-program interactive
1971	Computer Space	First coin-operated cabinet
1972	Magnavox Odyssey	Home console, discrete logic
1972	Pong arcade	TTL logic, no CPU, no code
1977	Atari VCS / 2600	Cartridge ROM, 6507 CPU
1978	Space Invaders	Microprocessor arcade game
1983	Market crash	Quality control matters
1983	Famicom in Japan	Sprite and scroll hardware
1985	NES in North America	Lockout chip, licensing model
1988	Mega Drive	16-bit 68000, bigger sprites
1990	Super Famicom	Mode 7 affine transforms
1992	Wolfenstein 3D	Ray-cast pseudo-3D at speed
1993	Doom	BSP trees, modding, LAN play
1994	PlayStation	Hardware triangle rasterizer
1996	3dfx Voodoo Graphics	Consumer 3D acceleration
1999	Dreamcast online	Built-in modem, online play
2002	Xbox Live	Unified console online service
2003	Steam	Digital distribution, patching
2008	Apple App Store	Mobile mass market
2017	Fortnite Battle Royale	Live service at scale
2020	PS5 and Xbox Series X	NVMe streaming, RT hardware
2024	PS5 Pro	Machine-learning upscaling
2025	Nintendo Switch 2	DLSS on a handheld

1. Tennis for Two was shown on 18 October 1958 at Brookhaven National Laboratory in Upton, New York, built by William Higinbotham with technician Robert V. Dvorak. It ran on a Donner Model 30 analogue computer with a five-inch oscilloscope as the display. Each player had an aluminium box with a knob to set the angle and a button to hit the ball.
2. Spacewar was written in 1962 by Steve Russell and others at MIT on a DEC PDP-1 with 9 kilowords of core memory and a Type 30 point-plotting display. It was copied to essentially every PDP-1 installation, which makes it the first game with a distribution story.
3. The Magnavox Odyssey, designed by Ralph Baer at Sanders Associates from the 1967 “Brown Box” prototype, shipped in September 1972. It had no processor, no memory and no software: transistor and diode logic produced three white spots, and coloured plastic overlays taped to the television supplied the backgrounds.
4. Pong, designed by Allan Alcorn at Atari and installed in November 1972, was also built from discrete transistor-transistor logic. There is no program to disassemble because there is no program.
5. The Atari Video Computer System, later the 2600, launched 11 September 1977 with a MOS 6507 at about 1.19 MHz, 128 bytes of RAM, and the Television Interface Adaptor. It had no frame buffer, so the CPU had to modify the TIA registers within each of the 262 scan lines of an NTSC field.
6. The 1983 crash is well documented in numbers: United States home video game revenue fell from roughly 3.2 billion dollars in 1983 to roughly 100 million dollars in 1985, a drop of about 97 percent. Contributing factors were oversupply, poor quality third-party titles, and cheap home computers. Atari buried roughly 728,000 cartridges in a New Mexico landfill in September 1983, confirmed by an excavation in 2014.
7. Nintendo’s answer was a hardware lock. The Famicom launched 15 July 1983 in Japan; the re-designed Nintendo Entertainment System launched in New York on 18 October 1985. Its 10NES system used a Checking Integrated Circuit in the console and an identical one in the cartridge, sharing a 4 MHz clock. The console’s chip sends a challenge and the cartridge’s chip must return a matching pseudo-random stream. On mismatch the console pulls the CPU and picture processing unit reset lines low with a 1 Hz square wave, producing the flashing screen. Different part numbers enforced regions: 3193 and 6113 for NTSC, 3197 for PAL-A, 3195 for PAL-B, 3196 for Asia.
8. The honest version: the lockout chip was not security in the modern sense. It was a business control. It let Nintendo decide who published on its platform, cap the number of titles per publisher, and manufacture all cartridges itself. Every console since has had some version of that control, and it is the reason the certification process in section 45.14 exists.
9. Doom shipped on 10 December 1993. Its renderer precomputed a binary space partitioning tree at level build time so that walls could be drawn in correct depth order without a depth buffer. Walls were drawn as vertical texture columns; floors and ceilings as horizontal spans called visplanes, with a hard limit of 128 of them. All arithmetic was 16.16 fixed point. It could not do rooms above rooms, sloped floors, or a proper look up and down. It also shipped as shareware, kept its data in an editable WAD file, and supported four-player networked deathmatch over IPX, which created the modding and competitive scenes at the same time.
10. 3dfx Voodoo Graphics arrived in late 1996 as an add-in card that did only 3D and passed 2D through from the existing card. GLQuake in January 1997 was the demonstration that made the category mainstream.
11. The PlayStation launched 3 December 1994 in Japan and 9 September 1995 in North America. Its geometry engine had no floating-point unit and its rasterizer had no depth buffer, so it used fixed-point maths and sorted polygons into ordering tables, which is why its textures wobble and polygons sometimes pop through each other.

12. Console online gaming became normal in stages: the Dreamcast shipped with a 56k modem in 1998 in Japan and 1999 elsewhere, and Xbox Live launched on 15 November 2002 with a broadband-only, subscription, unified-identity model that everyone else eventually copied.
13. As of August 2026 the current landscape is: PlayStation 5 and PlayStation 5 Pro, Xbox Series X and Series S, Nintendo Switch 2 released 5 June 2025, a PC market dominated by Steam, a handheld PC category led by the Steam Deck, and a mobile market larger by player count than all of them together.

■ 45.2.6 WORDS - remember these

1. Racing the beam — changing the picture while the screen draws it — writing video registers in sync with horizontal scan timing on a frame-buffer-less system.
2. Sprite — a small movable picture — a hardware-composited image layer with its own position registers, independent of the background.
3. Lockout chip — the part that says which cartridges are allowed — a challenge-response micro-controller pair gating the console reset line.
4. BSP tree — a way of pre-sorting a level — a binary space partitioning structure allowing back-to-front or front-to-back traversal from any point.
5. Shareware — try the first part free — a distribution model splitting a game into a freely copyable episode and paid episodes.
6. Fixed point — fractions stored as whole numbers — a numeric format such as 16.16 with an implicit binary scaling factor, used where no FPU exists.

45.3 The game loop in detail

■ 45.3.1 PLAIN - in simple words

1. The loop has four jobs, always in this order.
2. **Input:** find out what the player is doing right now. Which keys are down, where the mouse moved, how far the trigger is pulled.
3. **Update:** move the world forward by a small slice of time. Apply gravity, move characters, run the enemy brains, check what hit what.
4. **Render:** build the picture that shows the world in its new state.
5. **Present:** hand that picture to the screen.
6. Then start again from input.
7. There is one hard question in the middle of this: how big is that “small slice of time”?
8. The obvious answer is “however long the last frame took”. That is called a **variable timestep**, and it is wrong for physics.
9. The reason is that physics maths gives different answers for different slice sizes. Big slices lose detail and small slices keep it.
10. So if your machine is fast and mine is slow, a jump that clears a gap on your machine can fail on mine. That is not acceptable.
11. The fix is to always advance physics by exactly the same slice, for example one sixtieth of a second, no matter how long the frame took.
12. If the frame took longer, you run the physics slice more than once. If it took less, sometimes you do not run it at all.
13. That is called a **fixed timestep**, and it is what almost every serious game does.

■ 45.3.2 PLAIN – a picture in your head

1. Imagine filling a bucket from a tap, and every time the bucket is full you must pour it into a barrel.
2. The tap is real time flowing past. The bucket is a store of time you have not simulated yet. The bucket's size is your fixed step, say 16.67 thousandths of a second.
3. Each time round the loop, you measure how much water came out of the tap since last time and add it to the bucket.
4. Then, while the bucket has at least one bucketful in it, you empty one bucketful into the barrel. That emptying is one physics step.
5. Sometimes you empty it twice, because the frame was slow and two bucketfuls collected. Sometimes you empty it zero times, because the frame was fast.
6. The leftover water in the bucket is real time that has passed but has not been simulated. It is always less than one full bucket.
7. That leftover is not wasted. You use it to decide how far between the last two physics positions to draw the picture. Half a bucket left means draw halfway between.
8. That last trick is called **interpolation**, and it is why a game with a 60-step physics simulation can look perfectly smooth at 144 frames per second.

Where this comparison breaks: water is continuous and time in a computer is not. Real clocks are read as whole counts of a hardware timer. Also, a real bucket cannot overflow into an infinite queue; a game must put a limit on how much time it will try to catch up, or a slow frame causes a longer frame, which causes a longer one, and the game locks up. That failure is called the **spiral of death** and the fix is to clamp the measured frame time.

■ 45.3.3 PLAIN – a worked example

1. Fixed step is 16.67 ms, which is 1/60 of a second. The screen refreshes at 144 Hz, so a frame arrives every 6.94 ms.
2. Start with the bucket empty. Follow ten frames.

Frame	Real time added	Bucket after	Steps run
1	6.94 ms	6.94 ms	0
2	6.94 ms	13.88 ms	0
3	6.94 ms	4.15 ms	1
4	6.94 ms	11.09 ms	0
5	6.94 ms	1.36 ms	1
6	6.94 ms	8.30 ms	0
7	6.94 ms	15.24 ms	0
8	6.94 ms	5.51 ms	1

3. Over eight frames, three physics steps ran. That is $3 \times 16.67 = 50$ ms of simulated time for $8 \times 6.94 = 55.5$ ms of real time, with 5.5 ms still in the bucket. The books balance.
4. Notice that the picture changed on all eight frames, even the five where no physics ran. Those five frames were drawn by interpolating.
5. On frame 4 the bucket held 11.09 ms out of a 16.67 ms step, so the interpolation factor was $11.09 / 16.67 = 0.665$. Draw the world 66.5 percent of the way from the previous physics position to the current one.
6. Now the frame budget arithmetic, which you should know by heart.

Target rate	Budget per frame	Ticks per second
30 fps	33.33 ms	30
60 fps	16.67 ms	60
90 fps	11.11 ms	90
120 fps	8.33 ms	120
144 fps	6.94 ms	144
240 fps	4.17 ms	240

- The budget is 1000 divided by the target rate. That budget covers everything: input, physics, AI, animation, audio submission, all the render commands, and the driver's own work.
- At 144 fps you have 6.94 ms total. If your shadow pass alone takes 3 ms you have already spent 43 percent of the frame on shadows.

■ 45.3.4 PLAIN – what is really happening inside

- Here is the real loop, with the fixed step, the accumulator and the interpolation. Every line is explained underneath.

```
const double dt = 1.0 / 60.0;    /* fixed step: 16.667 ms */
double accumulator = 0.0;        /* unsimulated time store */
double t = 0.0;                  /* total simulated time */
double currentTime = now();       /* clock at loop start */

while (running) {
    double newTime = now();
    double frameTime = newTime - currentTime;
    if (frameTime > 0.25) frameTime = 0.25; /* clamp */
    currentTime = newTime;

    accumulator += frameTime;

    poll_input();

    while (accumulator >= dt) {
        previous_state = current_state;
        simulate(&current_state, t, dt);
        t += dt;
        accumulator -= dt;
    }

    double alpha = accumulator / dt;
    State view = lerp(previous_state, current_state, alpha);

    render(view);
    present();
}
```

- dt is the fixed simulation step. It never changes at run time. Every physics calculation in the game is written knowing this exact number.
- accumulator holds real time that has passed but has not yet been fed to the simulation. It is always between 0 and dt at the bottom of the loop.
- t is total simulated time. Effects, animations and networked timestamps are keyed off this, not off the wall clock.
- currentTime remembers when the previous loop iteration started, so we can subtract and get the elapsed time.

6. `now()` must be a monotonic high-resolution clock. On Windows that is `QueryPerformanceCounter`; on Linux `clock_gettime(CLOCK_MONOTONIC)`; on macOS `mach_absolute_time`. Never use wall-clock time, because it can jump backwards when the machine syncs with a time server.
7. `frameTime` is how long the previous whole frame took, in seconds.
8. The clamp to 0.25 seconds is the spiral-of-death guard. If the process was suspended, or a big file loaded, or you dragged the window, `frameTime` might be 8 seconds. Without the clamp the loop would try to run 480 physics steps in one frame, take even longer, and never recover. With the clamp the game simply loses that time. Slow motion is better than a freeze.
9. `poll_input` reads the devices once per frame, before any simulation, so that every physics step inside this frame sees the same input.
10. The inner while is the fixed-step loop. It runs zero, one or more times, consuming one `dt` of accumulator each time.
11. `previous_state = current_state` saves the state before stepping, so we have two snapshots to interpolate between.
12. `simulate` advances the world by exactly `dt`. It never sees the real frame time and never needs to.
13. `alpha` is the leftover fraction, between 0 and 1. It says how far past the last physics step the display moment is.
14. `lerp` is linear interpolation: $a + (b - a) * \alpha$. Applied to positions it is straightforward; applied to rotations you use spherical interpolation of quaternions instead.
15. `render` draws the interpolated view, not the simulation state. This is the line most beginners get wrong, and getting it wrong causes visible judder when the frame rate is not an exact multiple of the tick rate.
16. `present` hands the buffer to the display and, with vertical sync on, blocks until the next refresh.

■ 45.3.5 TECHNICAL - the engineer's version

1. The accumulator pattern above is the one popularized by Glenn Fiedler's article "Fix Your Timestep", first published in 2004 and widely revised since. It is a convention, not a standard, but it is close to universal.
2. Fixed step is required whenever the integration scheme is not step-size-invariant, which is every scheme used in games. Semi-implicit Euler with a 33 ms step and with a 4 ms step give different trajectories, and constraint solvers converge differently at different step sizes.
3. Typical simulation rates: 60 Hz is the default for most engines; 30 Hz for large-world console titles that trade physics fidelity for CPU; 120 Hz or 240 Hz for racing, fighting and VR titles; 128 Hz for competitive shooters on the server.
4. Substepping is separate: a solver may internally split one 16.67 ms step into 4 substeps of 4.17 ms to improve stability for fast objects, while the game still ticks at 60 Hz.
5. **Frame time** is the wall-clock duration of one frame in milliseconds. **Frames per second** is 1000 divided by the mean frame time. Frame time is the primary measurement; frames per second is a derived, compressed and lossy summary of it.
6. Why the average lies. Take 100 frames: 99 of them at 8.00 ms and one at 100 ms. Total elapsed is $99 \times 8 + 100 = 892$ ms. Mean frame time is 8.92 ms, so the reported average is 112.1 fps. But the player saw one frame held on screen for a tenth of a second, which reads as a clear hitch.
7. This is why reviewers and profilers report percentiles. The **1 percent low** is, by the most common convention, the average frame rate of the slowest 1 percent of frames; some tools instead report the frame time at the 99th percentile. The two definitions give different numbers and the industry has not settled on one. When comparing figures, check which was used.
8. In the example above, the 1 percent low is 10 fps by either definition, against a 112 fps average.

That gap is exactly the complaint people describe as “the frame rate is fine but it feels bad”.

9. **Frame pacing** is a separate problem from frame rate. A sequence of frame times of 8, 8, 8, 8 ms feels smoother than 4, 12, 4, 12 ms even though both average 8 ms, because the second sequence presents images at uneven intervals against an even display refresh.
10. The full click-to-photon latency chain, with realistic numbers for a PC at 60 Hz with vertical sync and a 2-frame render queue:

Stage	Typical latency
Mouse sample and USB	1 to 8 ms
Input poll to sim	0 to 16.7 ms
Simulate and render	16.7 ms
Render queue depth	16.7 to 33.4 ms
Display scanout and panel	5 to 20 ms

11. That totals roughly 40 to 95 ms, which is why competitive players disable vertical sync, cap frames just below the refresh rate, use variable refresh, and enable low-latency modes such as NVIDIA Reflex (2020) or AMD Anti-Lag, all of which mainly work by shortening the render queue.
12. Measuring tools: PresentMon and its front ends on Windows give per-frame present timings and a latency estimate; stat unit and Unreal Insights in Unreal Engine; the Unity Profiler; RenderDoc and PIX for GPU timings; perf and Tracy for CPU timeline capture.
13. The distinction between CPU frame time and GPU frame time matters. If the GPU is the bottleneck the CPU finishes early and waits; if the CPU is the bottleneck the GPU starves. Profilers report both, and the larger one is your frame time.

```

frame N          frame N+1          frame N+2
CPU [sim|render cmds] [sim|render cmds] [sim|...
GPU      [ draw N ]      [ draw N+1 ]      [ ...
DISP                [show N ]      [show N+1]

CPU builds frame N while GPU draws N-1: this is pipelining.
It raises throughput and adds one frame of latency.
```

■ 45.3.6 WORDS – remember these

1. Timestep — the slice of time simulated at once — the Δt passed to the integrator each simulation tick.
2. Fixed timestep — always the same slice — a constant Δt decoupled from frame duration, required for reproducible integration.
3. Accumulator — the store of unsimulated time — a scalar holding elapsed real time not yet consumed by fixed steps.
4. Interpolation — drawing between two known positions — blending previous and current simulation states by the leftover accumulator fraction.
5. Spiral of death — the game falls further and further behind — unbounded catch-up stepping where step cost exceeds real time elapsed.
6. Frame time — how long one frame took — wall-clock duration in milliseconds, the primary performance measurement.
7. 1 percent low — how bad the worst frames are — the mean frame rate of the slowest one percent of frames, or the 99th-percentile frame time.
8. Frame pacing — whether frames arrive evenly — the variance of frame intervals relative to the display refresh period.

45.4 How a game is built, as a project

■ 45.4.1 PLAIN – in simple words

1. A game is not written. It is built, the way a film is shot or a building is put up, by people with very different skills.
2. The **designer** decides what the player does and why it is fun. Levels, rules, numbers, pacing.
3. The **programmer** makes the machine do it. Gameplay code, engine code, graphics code, tools for everyone else, network code.
4. The **artist** makes what you see. Concept art first, then the actual models, textures, environments and characters.
5. The **animator** makes things move: walking, reloading, dying, a door opening, a face speaking.
6. The **audio** people make what you hear: footsteps, gunfire, wind, music, voices.
7. **Quality assurance**, usually called QA, plays the game deliberately and methodically to find what is broken, and writes it down precisely.
8. The **producer** keeps the whole thing on a schedule and decides what gets cut when there is not enough time. There is never enough time.
9. On a big game there are more roles: technical artist, user interface designer, writer, localization, build engineer, live operations, community.
10. The single most important fact about this list is that programmers are a minority. On a large modern game, roughly one person in five writes code.

■ 45.4.2 PLAIN – a picture in your head

1. Think of a restaurant opening.
2. Somebody decides what kind of restaurant it is and writes the menu. That is the designer.
3. Somebody builds the kitchen and makes the equipment work. That is the programmer.
4. Chefs cook. Decorators decorate. Someone chooses the music. Those are the artists, animators and audio people.
5. Before opening, friends come in and eat for free and say what was wrong. That is QA and playtesting.
6. Someone watches the money and the calendar and says “the dessert menu is cut, we open in three weeks”. That is the producer.
7. And a restaurant is never finished on opening night. The first month is fixing what real customers break. That is the launch patch and live operations.

Where this comparison breaks: a restaurant can open with a small menu and add dishes. A game usually has to ship one enormous simultaneous thing, and a missing piece in the middle stops everything. Also, a bad dish affects one diner; a bad save-file bug affects everyone at once, everywhere, at 3 a.m.

■ 45.4.3 PLAIN – a worked example

1. The phases, in order, with what each one actually means.
2. **Concept**: a few people, a few weeks to a few months. A document, some sketches, maybe a rough playable thing. Most concepts die here, and that is the cheapest place to die.
3. **Pre-production**: build the risky bits. Answer “can we even do this”. Small team, six months to two years on a big project.
4. **Vertical slice**: one small part of the game at full final quality. Ten minutes that look and feel exactly like the finished game. It exists to prove the vision and to unlock funding.
5. **Production**: the big, expensive middle. Make all the content. The team is at its largest here.

6. **Alpha:** feature complete. Every system exists, even if content is missing and it is full of bugs.
7. **Beta:** content complete. Everything is in. From here you only fix.
8. **Certification:** for consoles, the platform holder tests the build against a long checklist. See section 45.14.
9. **Gold and launch:** the build is locked and manufactured or uploaded.
10. **Live operations:** patches, seasons, events, balance changes, and sometimes years of new content.

Scale	Team size	Time	Budget range
Solo hobby	1	6 to 24 months	0 to 20k
Small indie	2 to 8	1 to 3 years	50k to 1M
Mid-size (AA)	30 to 80	2 to 3 years	5M to 30M
AAA	200 to 600	4 to 6 years	80M to 300M

11. Those budget figures are in United States dollars and exclude marketing, which on a AAA title is often as much again as development.

■ 45.4.4 PLAIN - what is really happening inside

1. The reason production is expensive is content, not code.
2. A gun in a modern shooter is not one job. It is a concept sketch, a high-detail model, a low-detail game model, several texture maps, a rig, reload and inspect and fire animations, muzzle flash effects, four or five layered sounds, a tuning pass on damage and recoil, a first-person and a third-person version, and an entry in the user interface.
3. That is roughly two to six person-weeks for one weapon, and a game may have forty.
4. Multiply that pattern across characters, environments, vehicles and cutscenes and you get the two hundred million dollars.
5. Code is a smaller share, but it gates everything: nobody can build a level until the level tools work.
6. This is why the tools programmers are quietly the most valuable people on a big team. A one-second improvement in the editor's save time, times 200 people, times 50 saves a day, is 2.8 hours of team time per day.
7. And this is why the schedule always slips at the end. Content work is parallel and estimable. Integration, bug fixing and certification are serial and are not.

■ 45.4.5 TECHNICAL - the engineer's version

1. Real documented budgets, from court filings and leaks rather than press releases, which is why they are trustworthy.

Game	Reported cost	Source and year
The Last of Us Part II	~220M, ~200 devs	Court exhibit, 2023
Horizon Forbidden West	~212M, ~300 devs	Court exhibit, 2023
Grand Theft Auto V	~265M with marketing	Reported, 2013
Cyberpunk 2077	~316M with marketing	CD Projekt, 2021
Stardew Valley	one person, 4.5 years	Developer, 2016

2. The Sony figures became public in June 2023 through poorly redacted documents filed in the United States Federal Trade Commission case about the Microsoft acquisition of Activision Blizzard. The Cyberpunk 2077 number is roughly 1.2 billion Polish zloty of combined development and marketing spend, converted at the rates of the time, and should be treated as approximate.

3. Team composition on a typical 250-person AAA project is roughly: 45 to 60 artists, 30 to 45 engineers, 20 to 30 designers, 20 to 30 animators, 10 to 15 audio, 30 to 60 QA, plus production, writing, user interface and localization. External outsourcing studios may add another 200 people who never appear on the internal headcount.
4. Costs per head, fully loaded with salary, benefits, hardware, software and office, run roughly 120,000 to 250,000 US dollars per person-year in North America and Western Europe, less elsewhere. A 250-person team for four years at 160,000 is 160 million dollars, which is where these budgets come from.
5. Now the honest part, because the reader asked for honesty.
6. **Crunch** means long mandatory overtime near milestones. Sixty to eighty hour weeks for months are documented at many studios. It is often unpaid for salaried staff. It correlates with burnout, health damage and people leaving the industry in their thirties.
7. The industry has argued about it publicly since the 2004 “EA Spouse” open letter, which led to overtime lawsuits and settlements at Electronic Arts. It recurred publicly around Rockstar Games in 2018 and CD Projekt Red in 2020.
8. The structural cause is not villainy. It is that games are fixed-date, fixed-scope products with an unpredictable final integration phase, sold in a market with a hit-driven revenue distribution. Cutting scope is the only real fix and it is the hardest decision to make.
9. **Layoffs** became the defining industry story of the 2020s. Trackers recorded roughly 10,500 games industry job losses in 2023 and roughly 14,600 in 2024, with further large numbers through 2025 and 2026. Studios have been closed within months of shipping well-reviewed games.
10. **Unionization** started to take hold in the same period, with organized bargaining units at several large studios from 2023 onward. Whether this changes crunch materially is still open.
11. Where experts disagree: some argue budgets are unsustainable and the AAA model must shrink; others argue the top few titles will keep growing and the middle will disappear. The evidence in 2026 supports both, because the middle has in fact been shrinking while the top has grown.

■ 45.4.6 WORDS – remember these

1. Vertical slice — a small piece at final quality — a fully polished representative segment used to validate the design and secure funding.
2. Alpha — every feature exists — feature complete, content incomplete.
3. Beta — everything is in — content complete, bug fixing only.
4. Gold master — the locked build — the final candidate submitted for manufacture or platform release.
5. Crunch — mandatory long hours — sustained overtime at milestone boundaries, often uncompensated for salaried staff.
6. Live operations — running the game after launch — the ongoing content, balance, event and monetization pipeline for a service game.

45.5 Game engines

■ 45.5.1 PLAIN – in simple words

1. An **engine** is the pile of reusable machinery that every game needs and that is not about your particular game.
2. It draws things. It plays sounds. It reads controllers. It works out what hit what. It loads files. It runs on Windows and consoles and phones.
3. It also gives you an **editor**: a program where you place objects, light a scene and press play, without writing code for any of it.
4. What it does not give you is a game. It gives you the ability to make one.
5. Studios use one instead of writing their own for a plain reason: writing your own costs several engineer-years before you can show anything.
6. Worse, you must then keep it working on five platforms as those platforms change, forever, with a team of maybe three people.
7. Big studios that do write their own do it because they need something the commercial engines do not do well: enormous open worlds, very specific physics, or an existing pile of tools twenty years deep.

■ 45.5.2 PLAIN – a picture in your head

1. Think about building a house.
2. You could make your own bricks, mill your own timber and wind your own wire. People did, once.
3. Today you buy standard bricks, standard wire in standard colours, standard window units and standard plumbing fittings.
4. The standard parts are not what makes your house yours. The plan is.
5. But the standard parts decide a lot: what shapes are cheap, what is awkward, and what will simply not fit.
6. An engine is the standard parts. It makes some games cheap to build and others painful, and you feel that pressure the whole way through.

Where this comparison breaks: bricks do not change their price after you have built half the house. Engine licences can, and in 2023 one of them tried to. Section 45.5.5 tells that story exactly.

■ 45.5.3 PLAIN – a worked example

1. What is actually inside an engine, listed as the parts you would otherwise have to write.

Part	What it does
Renderer	Turns a scene into pixels
Physics	Moves bodies, finds collisions
Audio	Mixes and positions sound
Input	Reads keyboard, mouse, pads
Scene system	Holds and finds objects
Asset pipeline	Imports and converts content
Scripting	Runs gameplay code safely
Editor	Lets non-programmers build
Build system	Packages for each platform
Networking	Replicates state to clients

2. A bare version of the first four is roughly 50,000 to 150,000 lines of code and two to four engineer-years for a competent small team.
3. A version with an editor, a working asset pipeline and console support is a decade of work by a real team. That is the honest scale.
4. Which is why a two-person studio using Godot ships in eighteen months, and a two-person studio writing an engine ships never.

■ 45.5.4 PLAIN – what is really happening inside

1. Two ways of organizing the objects in a game world dominate, and the difference is about how the computer's memory works.
2. A **scene graph** is a tree. A car is a node; its wheels are children of the car; a mirror is a child of a door which is a child of the car.
3. Moving the car moves everything under it automatically, because each child position is stored relative to its parent.
4. This is natural for humans and it matches how artists think. It is what Unity's GameObject hierarchy and Godot's node tree give you.
5. Its weakness is speed. Each object is a separate lump of memory with pointers to its children, scattered across the heap.
6. When the game walks 10,000 objects to move them, it jumps all over memory, and the processor spends most of its time waiting for memory rather than computing.
7. An **entity-component-system**, always abbreviated ECS, is the answer.
8. An **entity** is just a number, an identity with no data of its own.
9. A **component** is a small plain lump of data, such as a position or a health value, stored in one big array with all the other positions.
10. A **system** is a function that runs over every entity that has a particular set of components, walking those arrays straight through.
11. Because all the positions sit next to each other in memory, the processor can fetch them in order and predict what comes next. That is the whole trick, and it can be several times faster.

■ 45.5.5 TECHNICAL – the engineer's version

1. The cache arithmetic that makes ECS worth the awkwardness. A cache line on every current x86-64 and ARM64 processor is 64 bytes.
2. Suppose 10,000 objects, each a 256-byte object, and you want to add velocity to position: 12 bytes read, 12 bytes written per object.
3. In the object-oriented layout, each object touches at least one 64-byte line, usually two because the fields straddle. Memory traffic is at least $10,000 \times 64 = 640$ KB, in an access pattern the hardware prefetcher cannot predict.
4. In the component layout, positions are one contiguous 120 KB array and velocities another. Total traffic is 240 KB, perfectly sequential, fully prefetched. That is under half the traffic and far better latency hiding.
5. Blizzard's Overwatch is the best-documented shipped example. In Timothy Ford's GDC 2017 talk "Overwatch Gameplay Architecture and Netcode" the client is described as having about 46 systems and about 103 component types, with only three systems involved in gameplay networking.
6. Now the engines themselves, as of August 2026.

Engine	Language	Cost model
Unity 6	C#	Free under 200k revenue

Engine	Language	Cost model
Unreal Engine 5	C++ and Blueprints	Free under 1M lifetime
Godot 4	GDScript, C#, C++	MIT licence, free
In-house	usually C++	Salaries and years

7. **Unity** was announced at Apple’s Worldwide Developers Conference in June 2005 as a Mac-only engine. It now targets more than nineteen platforms. It scripts in C#; the old UnityScript was deprecated in August 2017. Unity Personal is free below 200,000 US dollars of annual revenue and funding. Unity Pro is required above that; its list price was 2,200 dollars per seat per year from 1 January 2025 and 2,310 dollars per seat per year from 12 January 2026. Unity Enterprise is required above 25 million dollars.
8. The 2023 episode, stated precisely. On 12 September 2023 Unity announced a **Runtime Fee**: a per-install charge on games above revenue and install thresholds, to begin 1 January 2024. The reaction was severe, because the fee applied retroactively to already-shipped games built under different terms, was based on installs rather than sales, and had no clear way to count them.
9. Unity revised the terms on 22 September 2023. Chief executive John Riccitiello retired on 9 October 2023. Matthew Bromberg became chief executive in May 2024. On 12 September 2024, exactly one year after the announcement, Unity cancelled the Runtime Fee outright and returned to seat-based subscriptions, doubling the Personal threshold from 100,000 to 200,000 dollars and raising Pro by 8 percent and Enterprise by 25 percent instead.
10. The lesson is not “Unity is bad”. It is that a licence is part of your technology stack, it is a contract with a company that has shareholders, and it can change under a project that is already three years in. Read the terms, keep an exit plan, and prefer terms fixed at the version you ship.
11. **Unreal Engine** licensing has moved the other way over time. In March 2014 Unreal Engine 4 was 19 dollars per month plus a 5 percent royalty. In March 2015 it became free with a 5 percent royalty above 3,000 dollars per calendar quarter. In May 2020, retroactive to 1 January 2020, the exemption became 1,000,000 dollars of lifetime gross revenue per title. Revenue from the Epic Games Store is royalty-free. Since 2024 there is also a seat licence, 1,850 dollars per seat per year, for companies over 1 million dollars doing non-game work such as film and architecture. Unreal Engine 5.7 shipped in November 2025.
12. **Godot** is MIT licensed and has been open source since February 2014. There is no fee, no royalty and no threshold, and the licence cannot be revoked for a version you already have. The latest stable release at the time of writing is 4.7.1 from 13 July 2026. It is developed by the Godot Foundation on donations, which is its own risk: a much smaller budget than either commercial competitor.
13. **In-house engines** still dominate the top end: RE Engine at Capcom, Decima at Guerrilla, Frostbite at Electronic Arts, Anvil at Ubisoft, id Tech at id Software, Creation at Bethesda, Source 2 at Valve, and Rockstar’s RAGE. The reason is usually a genre the commercial engines handle badly, plus twenty years of tooling that a team already knows.
14. Where experts disagree: some argue in-house engines are a strategic asset; others argue they are a tax that diverts engineers from the game. Several large publishers have moved to Unreal Engine 5 since 2022, which is evidence for the second view but not proof.

■ 45.5.6 WORDS – remember these

1. Engine — the reusable machinery — the platform layer, renderer, physics, audio, tools and pipeline shared across titles.
2. Scene graph — a tree of objects — a hierarchy of transforms where child transforms are expressed relative to their parent.

3. ECS — data in flat arrays with functions over them — entity-component-system architecture separating identity, plain data and behaviour for cache locality.
4. Cache line — the smallest chunk memory moves in — 64 bytes on current x86-64 and ARM64 processors.
5. Royalty — a share of revenue paid to the engine maker — a percentage of gross above a stated threshold, as in Unreal's 5 percent above 1 million.
6. Runtime fee — a charge per install — the per-installation model Unity announced in September 2023 and cancelled in September 2024.

45.6 Assets and the content pipeline

■ 45.6.1 PLAIN – in simple words

1. Everything in a game that is not code is an **asset**: models, pictures, sounds, animations, fonts, levels, text.
2. Assets are made in other programs. A model is made in a modelling tool, a texture in a painting tool, a sound in an audio tool.
3. Those programs save in formats designed for editing, not for playing. They are big, flexible and slow to read.
4. So there is a step in the middle that converts everything into the exact form the target machine wants. That step is the **asset pipeline**.
5. It compresses textures into a format the graphics chip can read directly. It simplifies models into several versions for different distances. It packs thousands of small files into a few big ones.
6. It also computes things in advance that would be too slow to compute while playing: how light falls on a static wall, where characters can walk, how sound travels in a room.
7. Doing all that for an entire game is why a full build takes hours.
8. In Unreal Engine this conversion step is called **cooking**, and the phrase “cook the content for PlayStation” means “convert every asset into the exact form that machine wants”.

■ 45.6.2 PLAIN – a picture in your head

1. Think of a professional kitchen before service.
2. The raw ingredients arrive as whole vegetables, whole fish, sacks of flour. Flexible, but useless during a busy service.
3. So in the morning the kitchen does **prep**: chopping, portioning, making stocks, part-cooking things that take an hour.
4. During service nothing takes an hour, because the hour already happened.
5. Prep is the asset pipeline. Raw ingredients are the source files. The prepped trays are the cooked assets.
6. And if the chef changes the menu at 5 p.m., all the prep for that dish is wasted and must be redone. That is why artists hate late changes.

Where this comparison breaks: a kitchen preps for one evening. A game preps for every machine it will ever run on, and each target wants different prep, so the same source is prepped four or five times in parallel.

■ 45.6.3 PLAIN – a worked example

1. Follow one texture from painting to screen.
2. An artist paints a 4096 by 4096 colour map in a painting program and saves a 32-bit-per-pixel file.
3. Raw size: $4096 \times 4096 \times 4$ bytes = 67,108,864 bytes, which is 64 mebibytes for one texture.

4. The pipeline generates **mipmaps**, smaller copies at half size, quarter size and so on down to one pixel. That adds about 33 percent, so about 85 mebibytes.
5. Then it compresses to a format the graphics chip can sample directly. On PC and console that is usually BC7, which is one byte per pixel.
6. BC7 size: $4096 \times 4096 \times 1 = 16$ mebibytes, plus mipmaps, about 21.3 mebibytes. That is a quarter of the raw size and it stays compressed in video memory, which is the point.
7. On a phone the same texture is compressed to ASTC instead, because mobile graphics chips do not read BC7.

Format	Target	Bits per pixel
RGBA8 uncompressed	none	32
BC1 (DXT1)	PC, console	4
BC7	PC, console	8
ETC2 RGBA	Android, GLES 3	8
ASTC 4x4	mobile, Apple	8
ASTC 6x6	mobile, Apple	3.56

8. Now do that for 4,000 textures. At 64 mebibytes raw each, the source is 256 gibibytes; cooked to BC7 with mipmaps it is about 85 gibibytes; after packaging and further lossless compression, perhaps 45 gibibytes on disk.
9. And the compression itself is not free. High-quality BC7 encoding is roughly 0.5 to 5 seconds per 4K texture on one core. Four thousand of them is 30 minutes to 5 hours of single-core work, which is why studios run distributed build farms and shared caches.

■ 45.6.4 PLAIN - what is really happening inside

1. The full pipeline, in order, for a 3D character.
2. **Model:** the artist builds a mesh, a set of points joined into triangles. A hero character might be 60,000 to 150,000 triangles.
3. **UV unwrap:** the artist flattens the surface onto a square so a two-dimensional picture can be painted onto it.
4. **Texture:** several pictures are painted, not one. Base colour, roughness, metalness, a normal map that fakes small bumps, sometimes ambient occlusion and emissive.
5. **Rig:** a skeleton of bones is built inside the mesh, and each vertex is assigned weights saying which bones move it and how much.
6. **Animate:** the animator poses the skeleton over time, or motion capture data is cleaned up and retargeted onto it. Each clip is a list of bone rotations at keyframes.
7. **Export:** everything is written to an interchange format, usually FBX, or increasingly glTF 2.0 or USD.
8. **Import:** the engine reads that file and converts it. Triangles are reordered for the graphics chip's vertex cache. Normals and tangents are computed. Animation curves are compressed, often to about a tenth of their size, by dropping keys within an error tolerance.
9. **Level of detail:** simplified copies are generated. A common ladder is 100 percent, 50 percent, 25 percent and 12 percent of the triangles, swapped by screen size.
10. **Bake:** things that never change are computed once. Light maps for static geometry, a navigation mesh for where characters can walk, occlusion data for what can see what.
11. **Package:** everything is written into a few large archive files, sorted so that things loaded together sit next to each other on disk, and compressed with a fast codec.
12. **Ship:** the archive plus the executable is what the player downloads.

■ 45.6.5 TECHNICAL – the engineer’s version

1. Tools in common use: Blender (free, GPL) and Autodesk Maya for modelling and animation; ZBrush for sculpting; Adobe Substance 3D Painter and Designer for textures; Houdini for procedural content and effects; Photoshop or Krita for two-dimensional art; Reaper, Pro Tools and iZotope RX for audio.
2. Interchange formats: FBX (Autodesk, proprietary but ubiquitous), glTF 2.0 (Khronos, 2017, open and runtime-friendly), USD (Pixar, open-sourced 2016, now standard for large scene assembly), Alembic for baked geometry caches, OBJ for simple static meshes.
3. Cooking, precisely, means: convert every source asset into a platform-specific, engine-specific binary that can be memory-mapped or streamed with minimal parsing, and drop all editor-only data.
4. Why full builds take hours, itemized for a large project:

Stage	Typical duration
Code compile and link	20 to 90 minutes
Shader compilation	1 to 6 hours
Texture compression	30 to 180 minutes
Lightmap baking	1 to 12 hours
Packaging and compress	20 to 90 minutes

5. Shader compilation is usually the worst offender because of **permutations**. One material shader with 12 independent boolean features is 2 to the power 12, which is 4,096 variants, and a real project has hundreds of such shaders. Large titles ship tens of thousands to hundreds of thousands of compiled pipeline states.
6. The countermeasures are a **derived data cache** (a shared server storing the result of every conversion keyed by a hash of the input plus the settings, so nobody converts the same asset twice), distributed compilation systems such as Incredibuild or FASTBuild, and incremental cooking that touches only changed assets. With a warm cache, an incremental cook is minutes rather than hours.
7. Runtime compression codecs matter as much as the format. Oodle Kraken, Zstandard and LZ4 are the common choices; consoles decompress in hardware, with the PlayStation 5 Kraken decompressor rated at roughly 5.5 gigabytes per second of compressed input and the Xbox Series X BCPack path similar in spirit.
8. Virtualized geometry changes the level-of-detail story. Unreal Engine 5’s Nanite, introduced in 2021, stores meshes as a hierarchy of triangle clusters and selects detail per cluster per pixel at run time, removing hand-authored LODs for static opaque geometry. It does not remove the need for LODs on skinned characters, foliage or translucent materials, which is a caveat often skipped in marketing material.
9. Virtual texturing solves the matching problem for textures: only the pages of a texture actually visible at the current screen resolution are resident in video memory, so a scene can reference far more texture data than fits.
10. Observation tools: Unreal’s `-run=DerivedDataCache` and cook logs, Unity’s Build Report and Addressables analysis, `ls -la` on the packaged archives, RenderDoc to see which textures a frame actually sampled, and the platform’s own memory profiler to see what is resident.

■ 45.6.6 WORDS – remember these

1. Asset — anything that is not code — content data authored in an external tool and consumed by the engine.
2. Cooking — converting content for one machine — transforming source assets into a platform-specific runtime binary form.
3. Mipmap — smaller copies of a texture — a precomputed pyramid of half-resolution levels used to avoid aliasing at distance.
4. Level of detail — simpler versions for far away — a set of decimated meshes selected by projected screen size.
5. Baking — computing it in advance — precomputing lighting, navigation or occlusion data at build time rather than at run time.
6. Derived data cache — a shared store of conversion results — a server keyed by input hash so that each conversion is performed once for the whole team.
7. Shader permutation — one variant of a shader — a compiled pipeline state for one specific combination of features and platform.

45.7 Physics and collision

■ 45.7.1 PLAIN – in simple words

1. A physics system answers two questions, sixty times a second: where is everything now, and did anything touch anything.
2. Each movable object is a **rigid body**: a shape that does not bend, with a mass, a position, a speed and a spin.
3. Forces such as gravity change its speed. Its speed changes its position. Doing that arithmetic step by step is called **integration**.
4. Finding touches is done in two passes, because checking every pair is far too slow.
5. The first pass, the **broad phase**, cheaply throws away pairs that are obviously nowhere near each other, using a grid or a tree of boxes.
6. The second pass, the **narrow phase**, does the real shape test on the few pairs that survived.
7. When two things do touch, the system pushes them apart and changes their speeds. How bouncy that is depends on a number between 0 and 1 called **restitution**.
8. Ropes, hinges, doors and ragdolls are the same machinery plus rules that say “these two bodies must stay joined here”. Those rules are constraints.

■ 45.7.2 PLAIN – a picture in your head

1. Imagine a large hall with 1,000 people walking around, and you must report every collision.
2. Checking every pair means $1,000 \times 999 / 2 = 499,500$ checks. At sixty times a second that is 30 million checks a second, for nothing.
3. So you chalk the floor into a grid of squares. Each person reports which square they are in.
4. Now you only compare people in the same square or in touching squares. Almost every pair is eliminated without looking at them.
5. That is the broad phase. The remaining few hundred pairs get the careful look, which is the narrow phase.

Where this comparison breaks: people are all about the same size, so one grid square size works. Game objects range from a bullet to a cathedral, and one grid size cannot serve both. Real engines therefore use trees of boxes that adapt, not a flat grid.

■ 45.7.3 PLAIN – a worked example

- Two balls hit head-on. Ball A weighs 2 kg and moves at +5 metres per second along x. Ball B weighs 1 kg and is still. Restitution is 0.5.
- The collision normal n points from A to B, so it is (1, 0, 0).
- Relative velocity along the normal: $v_{rel} = (v_B - v_A) \cdot n = 0 - 5 = -5$. Negative means they are approaching, so we must respond.
- Impulse magnitude uses this formula:

$$j = \frac{-(1 + e) \cdot v_{rel}}{1/m_A + 1/m_B}$$

- Put the numbers in: $j = -(1 + 0.5)(-5) / (1/2 + 1/1) = 7.5 / 1.5 = 5$. The unit is kilogram metres per second.
- Apply it: $v_A' = 5 - j/m_A = 5 - 5/2 = 2.5$ m/s, and $v_B' = 0 + j/m_B = 0 + 5/1 = 5.0$ m/s.
- Check momentum. Before: $2 \times 5 + 1 \times 0 = 10$. After: $2 \times 2.5 + 1 \times 5 = 10$. Conserved, as it must be.
- Check restitution. Separation speed after is $5 - 2.5 = 2.5$, and the approach speed was 5. The ratio is 0.5, which is exactly e .
- Check energy. Before: $0.5 \times 2 \times 25 = 25$ joules. After: $0.5 \times 2 \times 6.25$ plus $0.5 \times 1 \times 25 = 6.25 + 12.5 = 18.75$ joules. 6.25 joules were lost as heat and sound, which is what a restitution below 1 means.

■ 45.7.4 PLAIN – what is really happening inside

- The integration step. The naive version, called explicit Euler, is $x = x + v \cdot dt$ then $v = v + a \cdot dt$. It quietly adds energy on every step and a spring simulated this way will slowly explode.
- Games use **semi-implicit Euler** instead: update velocity first, then use the new velocity to update position. One line swapped, and the system is stable enough for gameplay.
- Verlet integration** stores the previous position instead of velocity: $x_{new} = 2 \cdot x - x_{prev} + a \cdot dt^2$. It handles distance constraints very well, which makes it the standard choice for cloth, rope and hair.
- The broad phase in a real engine is usually a bounding volume hierarchy: a tree where each node is a box containing its children's boxes. Testing a ray or a box against it costs about log of the object count.
- The narrow phase uses exact tests for simple pairs, such as sphere against sphere, and a general algorithm for convex shapes.
- Contacts are not resolved one at a time in isolation, because a box resting on the floor has four contacts that must agree. The solver runs over all contacts several times per step, nudging each towards consistency.
- That is why a tall stack of boxes in a game jitters. The solver has a fixed number of iterations and simply runs out of time before the stack agrees.

■ 45.7.5 TECHNICAL – the engineer's version

- Broad-phase structures in use: uniform grids and spatial hashes for same-size objects; sweep and prune, which keeps objects sorted along an axis and exploits frame-to-frame coherence; quadtrees and octrees; and dynamic AABB trees, which is what Box2D, Bullet, PhysX and Jolt all use.
- Narrow phase: analytic tests for sphere, capsule and axis-aligned box pairs; the separating axis theorem for oriented boxes and convex polygons; and GJK, published by Gilbert, Johnson and Keerthi in 1988, plus the expanding polytope algorithm to recover penetration depth, for general

convex shapes. Concave meshes are decomposed into convex pieces or treated as static triangle soups.

3. Constraint solving is almost always **sequential impulses**, also called projected Gauss-Seidel, popularized by Erin Catto in Box2D and his GDC presentations from 2005 onward. Typical settings are 4 to 10 velocity iterations and 1 to 4 position iterations per step. Baumgarte stabilization or a split-impulse pass removes penetration without injecting energy.
4. Joint types: hinge (revolute), ball and socket (spherical), slider (prismatic), fixed, distance, and six-degree-of-freedom with per-axis limits and motors. A **ragdoll** is a set of rigid bodies matched to the skeleton's bones with joints whose limits mimic human range of motion, plus a blend that hands control from animation to physics on death or impact.
5. Continuous collision detection exists because a bullet moving 600 metres per second travels 10 metres in a 16.67 ms step and will tunnel straight through a wall. Solutions are conservative advancement, swept shape tests, or simply raycasting bullets instead of simulating them, which is what most shooters do.
6. Common engines and their defaults:

Engine	Physics	Default rate
Unity 6	PhysX 4 or Unity Physics	50 Hz
Unreal Engine 5	Chaos	30 or 60 Hz
Godot 4	Godot Physics or Jolt	60 Hz
Custom	Bullet, Jolt, Box2D	60 Hz

7. Determinism, stated precisely. IEEE 754-2019 fully specifies addition, subtraction, multiplication, division and square root: given the same inputs, rounding mode and precision, every conforming machine returns the same bits.
8. It does not specify $\sin$, $\cos$, $\exp$, $\log$ or pow , so two maths libraries can legally differ in the last bit. That is the first source of divergence.
9. The others are: compilers reordering floating-point expressions or contracting $a*b+c$ into a fused multiply-add with different rounding; fast-math flags; historic x87 80-bit intermediates versus SSE 64-bit; different SIMD widths taking different code paths; and multi-threaded solvers where the order contacts are summed changes between runs.
10. The consequence for multiplayer: you cannot assume two machines simulating the same inputs reach the same state. A one-bit difference in one frame becomes a visibly different world within seconds, because contact resolution amplifies small differences.
11. If you need determinism, you must either use fixed-point arithmetic, or lock down compiler flags, library versions, thread counts and instruction sets across every platform you ship on. This is why deterministic lockstep networking, described in section 45.11, is hard.

■ 45.7.6 WORDS - remember these

1. Rigid body — a solid that does not bend — a body with mass, inertia tensor, linear and angular velocity, and no internal deformation.
2. Integration — stepping the maths forward — advancing state by dt using a scheme such as semi-implicit Euler or Verlet.
3. Broad phase — the cheap first filter — spatial culling that produces a candidate pair list, typically via a dynamic AABB tree.
4. Narrow phase — the careful shape test — exact intersection tests producing contact points, normals and penetration depths.

5. Restitution — how bouncy it is — the coefficient e relating separation speed to approach speed along the contact normal.
6. Impulse — an instant change of momentum — the quantity j applied along the contact normal to resolve a collision.
7. Tunnelling — moving straight through a wall — a fast body crossing thin geometry within one timestep, fixed by continuous collision detection.

45.8 Game AI

■ 45.8.1 PLAIN – in simple words

1. Game AI is the code that decides what a character that is not you does next.
2. It has two halves: **decide what to do**, and **work out how to get there**.
3. The simplest way to decide is a **state machine**. The guard is in one state at a time: idle, patrol, investigate, chase, attack, flee. Events move it between states.
4. When there are twenty states, the arrows between them become unmanageable, so bigger games use a **behaviour tree**: a tree of small tasks read from the top, left to right, until one succeeds.
5. Another way is a **utility system**: score every possible action with a number and do the highest-scoring one.
6. The most elaborate is a **planner**: describe the goal, describe what each action requires and produces, and let the machine search for a sequence.
7. The second half, getting there, is **pathfinding**, and the standard algorithm has been the same since 1968.

■ 45.8.2 PLAIN – a picture in your head

1. Think about how you decide what to do at work.
2. Some of it is a state machine: you are in a meeting, or at your desk, or at lunch, and only certain moves make sense from each.
3. Some of it is a checklist read top down: is anything on fire, no; is anyone waiting for me, no; then do the next task on the list. That is a behaviour tree, and the order encodes priority.
4. Some of it is scoring: three things could be done, and you weigh urgency against effort and pick one. That is a utility system.
5. And occasionally you plan: to get the report signed you need the data, which needs the export, which needs access. Working backwards from the goal is what a planner does.
6. All four are used in games, often in the same game, for different characters.

Where this comparison breaks: you have a goal of your own. A game character does not. Its goal is that you enjoy fighting it, which is not the same thing as winning, and that changes every design decision underneath.

■ 45.8.3 PLAIN – a worked example

1. A-star pathfinding, by hand, on a five by five grid. S is the start, G is the goal, # is a wall. Moves are up, down, left and right, each costing 1.

y=4	.	.	.	.	.
y=3	.	.	#	.	.
y=2	S	.	#	.	G
y=1	.	.	#	.	.
y=0	.	.	.	.	.
	x0	x1	x2	x3	x4

2. A-star keeps a score for each square: $f = g + h$.
3. g is the real cost from the start to that square, counted so far.
4. h is a guess of the cost from that square to the goal. Here it is the Manhattan distance, $|4 - x| + |2 - y|$, which never overestimates because you cannot reach the goal in fewer steps than that.
5. Always expand the open square with the lowest f .
6. Start: S at (0,2) has $g=0$, $h=4$, $f=4$.
7. Expand S. Neighbours (0,1) and (0,3) get $g=1$, $h=5$, $f=6$. Neighbour (1,2) gets $g=1$, $h=3$, $f=4$.
8. Lowest f is (1,2) at 4, so expand it. (2,2) is a wall. (1,1) and (1,3) get $g=2$, $h=4$, $f=6$.
9. Now four squares are tied at $f=6$. Ties are broken towards higher g , which pushes the search forwards rather than sideways.
10. Expanding those gives (1,0) and (1,4) at $f=8$, and later (0,0) and (0,4) at $f=8$.
11. From (1,4) the search runs along the top: (2,4) $g=4$ $h=4$ $f=8$, (3,4) $g=5$ $h=3$ $f=8$, (3,3) $g=6$ $h=2$ $f=8$, (3,2) $g=7$ $h=1$ $f=8$, and finally the goal at $g=8$, $h=0$, $f=8$.
12. The answer is an eight-step path around the top of the wall. Note the heuristic said 4 at the start and the truth was 8. That is allowed, and that gap is exactly why the search had to look around.

Algorithm	Squares expanded	Path length
Breadth-first / Dijkstra	~22 of 22	8
A-star, Manhattan h	~13 of 22	8
Greedy best-first	~9 of 22	may exceed 8

13. A-star found the same shortest path as Dijkstra while looking at about forty percent fewer squares. Greedy search looks at fewer still but can return a worse path, because it ignores the cost already paid.

■ 45.8.4 PLAIN - what is really happening inside

1. A-star holds two collections: an **open set** of squares discovered but not yet expanded, and a **closed set** of squares already expanded.
2. The open set is a priority queue ordered by f , so taking the best square is fast.
3. Each square records which square it came from. When the goal is reached, you follow those links backwards to build the path.
4. Grids are convenient for teaching and terrible for large 3D worlds, because the number of squares grows with area and the paths look like staircases.
5. Real 3D games use a **navigation mesh**: the walkable floor is covered with a few thousand convex polygons instead of a million squares.
6. A-star then runs over polygons, and a second step called the funnel algorithm pulls the resulting corridor tight into a straight-line path.
7. Finally, **steering** turns that path into motion: the character seeks the next corner, slows as it arrives, avoids other characters, and blends with its animation so the feet do not slide.

■ 45.8.5 TECHNICAL – the engineer’s version

1. A-star was published in 1968 by Peter Hart, Nils Nilsson and Bertram Raphael as “A Formal Basis for the Heuristic Determination of Minimum Cost Paths” in IEEE Transactions on Systems Science and Cybernetics. It is optimal if the heuristic is **admissible**, meaning it never overestimates, and needs no node reopening if the heuristic is also **consistent**.
2. Heuristics by grid type: Manhattan for four-way movement; octile, $dx + dy + (\sqrt{2} - 2) * \min(dx, dy)$, for eight-way; Euclidean for navigation meshes. Using Euclidean on a four-way grid is admissible but weaker, so the search expands more nodes.
3. Variants shipped in real games: hierarchical A-star over a coarse graph then a fine one; jump point search for uniform grids; theta-star for any-angle paths; D-star Lite for replanning in changing worlds; and flow fields, where one Dijkstra pass from the goal produces a direction for every cell, which is how real-time strategy games move 500 units at once without 500 searches.
4. The standard open-source navigation toolkit is Recast and Detour by Mikko Mononen: Recast voxelizes the level and extracts walkable convex polygons; Detour does the queries, path corridors and local avoidance. Unity and Unreal both ship navigation mesh baking built on the same ideas.
5. Decision architectures with their shipped examples: hierarchical finite state machines everywhere; behaviour trees popularized by Damian Isla’s GDC 2005 talk on the Halo 2 AI; utility scoring used in The Sims from 2000; and goal-oriented action planning described in Jeff Orkin’s GDC 2006 paper “Three States and a Plan: The A.I. of F.E.A.R.”, where the state machine has only three states and a planner sequences them at run time.
6. Steering behaviours come from Craig Reynolds. His 1987 SIGGRAPH paper “Flocks, Herds, and Schools: A Distributed Behavioral Model” introduced boids with three rules: separation, alignment and cohesion. His 1999 GDC paper added seek, flee, arrive, pursue, evade, wander, obstacle avoidance and path following. Flocking that looks alive is those three rules and nothing else.
7. Now the honest part. Game AI is not optimizing for winning. It is optimizing for the player’s experience, and the two are usually opposed. A perfect aimbot enemy is trivial to write and miserable to play against.
8. Deliberate handicaps that ship in real games: enemies miss the first one or two shots on purpose; only one or two enemies attack at a time while the rest circle, a pattern used widely in third-person action games; attacks have long telegraph animations so you can react; enemies announce their intentions out loud, which is a user interface disguised as dialogue; vision cones and hearing radii are far worse than a human’s; racing games rubber-band opponents to keep the pack close.
9. The Pac-Man ghosts from 1980 remain the best teaching example. Four ghosts with four short, deterministic targeting rules read as four personalities, and none of them contains anything a modern programmer would call intelligence.
10. Separating fact from marketing: established fact is that shipped game AI is overwhelmingly hand-authored logic. Active research is reinforcement learning agents such as OpenAI Five for Dota 2 in 2018 and DeepMind’s AlphaStar for StarCraft II in 2019, which beat strong humans but are expensive to train, hard to tune and generally not fun opponents. Marketing claim is “AI-powered characters” in trailers, which in 2026 almost always means a language model generating dialogue lines, not the combat behaviour.

■ 45.8.6 WORDS – remember these

1. Finite state machine — one mode at a time — a set of states with guarded transitions, the simplest decision architecture.
2. Behaviour tree — a prioritized checklist as a tree — composites, decorators and leaf tasks ticked from the root each evaluation.
3. Utility AI — score everything and pick the best — action selection by evaluating scoring curves over world variables.
4. GOAP — describe the goal, let it plan — goal-oriented action planning, an A-star search over world states using action preconditions and effects.
5. Heuristic — an educated guess of remaining cost — the h term in A-star, admissible if it never overestimates.
6. Navigation mesh — the walkable floor as polygons — a convex polygon decomposition of traversable surfaces used as the pathfinding graph.
7. Steering — turning a path into movement — force-based local motion such as seek, arrive, separation and obstacle avoidance.

45.9 Rendering a game frame, specifically

■ 45.9.1 PLAIN – in simple words

1. In one line, the drawing pipeline is: points in space, moved into camera view, turned into triangles, filled in as pixels, shaded, depth-tested and written to a picture.
2. A game adds a lot of decisions around that, because it must do all of it in under 16.67 milliseconds.
3. First it works out what it does not need to draw at all. That is **culling**. Anything behind you or outside the camera's cone is thrown away immediately, and anything fully hidden behind a wall as well.
4. Second it groups what is left so the processor talks to the graphics chip as few times as possible. Each of those conversations is a **draw call** and they are expensive on the processor side.
5. Third it sorts. Solid things are drawn nearest first, so far-away pixels are rejected cheaply. See-through things must be drawn furthest first, so the blending is right.
6. Then it draws shadows, then the world, then the see-through things, then a stack of full-screen effects, and finally the user interface on top.

■ 45.9.2 PLAIN – a picture in your head

1. Think of a stage crew setting up a theatre scene in one minute.
2. First they check the script: what is actually visible from where the audience sits. Everything else stays in the wings. That is culling.
3. Then they carry things on in loads rather than one item at a time, because every trip costs time regardless of what is on it. That is batching.
4. They set the lights before the actors walk on, because moving lights during the scene is expensive. That is the shadow pass.
5. Glass and gauze go on last and in the right order, because you can see through them and the order changes what you see.
6. And the surtitles are projected on top of everything at the end, in their own crisp resolution. That is the user interface.

Where this comparison breaks: the stage crew works once and the scene runs. The renderer redoes the entire setup from nothing, sixty times a second, with the camera in a new place each time.

■ 45.9.3 PLAIN – a worked example

1. A real frame breakdown, taken from a profiler on a mid-range PC at 2560 by 1440 with a 60 frames per second target. The numbers are typical rather than from one specific game.

Stage	Time (ms)	Share
Shadow map passes	2.4	14 percent
Depth prepass and G-buffer	3.1	19 percent
Lighting and reflections	3.8	23 percent
Transparency and effects	1.6	10 percent
Post-processing stack	2.7	16 percent
Upscale and interface	1.1	7 percent
Present and slack	1.9	11 percent

2. Total is 16.6 ms, just inside the 16.67 ms budget.
3. Read the first row again. Shadows cost 2.4 ms, which is more than the entire user interface and post-processing of many older games, and they are just one lighting feature.
4. This is why the graphics settings menu exists. Dropping shadow resolution from 2048 to 1024 per cascade typically saves 30 to 50 percent of that row.

■ 45.9.4 PLAIN – what is really happening inside

1. **Frustum culling** tests each object's bounding sphere or box against the six planes of the camera's viewing pyramid. A sphere fully outside any one plane is rejected. This is a handful of arithmetic operations per object.
2. **Occlusion culling** removes what is hidden behind other things. It is harder, because you must know what is in front before you know what is hidden. Common approaches are precomputed visibility per region, a low-resolution software depth buffer rendered on the processor, and graphics-chip queries whose answers arrive a frame or two late.
3. **Batching** merges objects that share a material into one draw call. **Instancing** goes further: send one mesh and a list of 5,000 positions, and the chip draws all 5,000 in one call.
4. **Sorting** solid objects front to back lets the depth test discard hidden pixels before shading them. On modern hardware a depth prepass, which draws depth only and then shades with the depth test set to equal, guarantees every pixel is shaded exactly once.
5. **Forward rendering** shades each object against every light that touches it. Cost grows as objects times lights. It handles transparency and hardware anti-aliasing naturally.
6. **Deferred rendering** first writes surface properties into several full-screen buffers, together called the **G-buffer**, then computes lighting once per screen pixel. Cost is decoupled from scene complexity, which is why it won for scenes with many lights.
7. Deferred rendering's costs are memory bandwidth and transparency. See-through surfaces cannot be written into a single G-buffer pixel, so they are drawn afterwards in a separate forward pass.

■ 45.9.5 TECHNICAL – the engineer's version

1. G-buffer bandwidth arithmetic. At 1920 by 1080 with four 32-bit render targets plus a 32-bit depth buffer, that is $5 \times 4 \text{ bytes} \times 2,073,600 \text{ pixels}$, about 41.5 megabytes written per frame, or 2.5 gigabytes per second at 60 frames per second, before the lighting pass reads it all back.
2. At 3840 by 2160 the same layout is about 166 megabytes per frame and about 10 gigabytes per second of writes. This is why 4K deferred rendering is a bandwidth problem before it is a compute problem.

3. Modern engines mostly use clustered or tiled deferred and forward variants, which bin lights into screen tiles or view-space clusters so each pixel only evaluates the lights that reach it. Unreal Engine 5 and Unity's High Definition Render Pipeline both do this.
4. Draw call budgets. Under Direct3D 11 the per-call driver cost made 1,000 to 3,000 calls per frame a common ceiling. Direct3D 12, Vulkan and Metal cut that cost sharply, and with instancing, bindless resources and GPU-driven indirect draws, 10,000 to 30,000 batched calls per frame is normal in 2026.
5. Transparency ordering has no cheap correct answer. Per-object sorting fails for intersecting or concave transparent geometry. The options are alpha testing, which is opaque and sortable; per-triangle sorting, which is expensive; depth peeling, which costs one pass per layer; or weighted blended order-independent transparency, published by McGuire and Bavoil in 2013, which is approximate but cheap and widely shipped.
6. Shadows in practice are cascaded shadow maps for the sun: the view frustum is split into 3 or 4 depth ranges, each rendered from the light into a 1024 to 2048 square depth texture. Each cascade is another full scene traversal of shadow casters. Point lights need six faces. Filtering ranges from simple percentage-closer filtering to variance and moment methods.
7. A typical post-processing stack, in execution order: depth of field, motion blur, bloom, auto-exposure, tone mapping (commonly an ACES curve), colour grading through a 3D lookup texture, temporal anti-aliasing, upscaling, sharpening, then film grain and vignette.
8. Upscalers such as DLSS, FSR and XeSS are inserted after the main scene and before the user interface, so the interface renders at native output resolution and stays sharp. Getting that order wrong makes text blurry, and it is a common bug in early builds.
9. The interface is drawn last, usually as batched textured quads from a texture atlas with a signed distance field font, in a separate orthographic pass, sometimes at a different resolution from the scene.
10. Capture and profiling tools: RenderDoc for a full frame capture on almost any API; PIX on Windows for Direct3D 12 timing; NVIDIA Nsight Graphics and Radeon GPU Profiler for hardware counters; Xcode's Metal debugger on Apple platforms; Unity's Frame Debugger; Unreal's stat gpu, stat unit and ProfileGPU console commands.

■ 45.9.6 WORDS - remember these

1. Frustum culling — skip what is off-screen — rejecting bounding volumes against the six camera planes.
2. Occlusion culling — skip what is hidden — rejecting objects proven to be behind other opaque geometry.
3. Draw call — one instruction to draw something — a submitted command with a bound pipeline state, costing processor time regardless of triangle count.
4. Instancing — one command, many copies — drawing N copies of a mesh from one call with per-instance data.
5. G-buffer — the sheet of surface facts — the set of render targets holding albedo, normal, roughness, metalness and depth in deferred rendering.
6. Deferred rendering — light once per pixel, not per object — decoupling shading from geometry by writing surface data first.
7. Post-processing — the full-screen effects at the end — the ordered chain from depth of field through tone mapping to anti-aliasing and upscaling.

45.10 Audio in games

■ 45.10.1 PLAIN – in simple words

1. Sound is a pressure wave in air, and a computer stores it as a long list of numbers, typically 48,000 numbers per second per channel.
2. A game does not play files. It plays **events**: “footstep on gravel”, “pistol fire”, “door creak”. One event may pick one of eight recordings at random and change its pitch slightly so it does not sound repetitive.
3. Those recordings are packed into **sound banks**, loaded and unloaded in groups, usually one bank per level or per character.
4. A sound in the world has a position. The mixer works out how loud it should be from the distance, and how much goes to each speaker from the angle.
5. If a wall is in the way, the game fires a ray from the source to your ears, and if it is blocked, it turns the volume down and removes the high frequencies, because that is what walls do to sound.
6. All the sounds are grouped into **buses**: music, effects, dialogue, interface. Each bus has its own volume, and rules such as “duck the music by 6 decibels while anyone is speaking”.
7. Music in a modern game is not one track. It is layers that fade in as danger rises, and blocks that swap at musical boundaries.

■ 45.10.2 PLAIN – a picture in your head

1. Imagine a live sound engineer at a theatre with a mixing desk.
2. Every microphone and every playback source is a channel on the desk. Channels are grouped into buses: cast, orchestra, effects.
3. She rides the faders as the scene changes, pulls the music down when somebody speaks, and adds reverb when the scene moves to a cathedral.
4. She also has a limit: the desk has 64 channels. If a 65th sound is needed, something quiet must be dropped.
5. A game audio engine is that desk, run by rules instead of a person, updated sixty times a second.

Where this comparison breaks: the theatre engineer knows the script. The game engine does not know what will happen next, so every rule must be written to handle any order of events, including 200 sounds at once.

■ 45.10.3 PLAIN – a worked example

1. Audio memory arithmetic, which is what decides whether a sound is kept decompressed in memory or streamed from disk.
2. Uncompressed 48 kHz, 16-bit stereo is $48,000 \times 2 \times 2 = 192,000$ bytes per second. One minute is 11.5 megabytes. One hour is 691 megabytes.
3. The same audio in Vorbis at 128 kilobits per second is 16,000 bytes per second: 0.96 megabytes per minute, 57.6 megabytes per hour, a saving of about 12 to 1.
4. So the rule of thumb is: short and frequent sounds are decompressed into memory once and played from there; long music and dialogue are streamed from storage and decoded on the fly.

Content	Typical handling	Cost
Footsteps, gunfire	Decompressed in RAM	~50 KB each
Ambience loops	Compressed in RAM	~1 MB each
Music tracks	Streamed from disk	2 buffers

Content	Typical handling	Cost
Voice lines	Streamed, bank per scene	2 buffers

5. A console game commonly budgets 100 to 500 megabytes of memory for audio, which is a real constraint against a script with 40,000 recorded lines.

■ 45.10.4 PLAIN – what is really happening inside

1. The audio system does not run on the frame clock. It runs on its own high-priority thread with its own deadline.
2. That deadline is the buffer size. A 512-sample buffer at 48 kHz must be filled every $512 / 48,000$ seconds, which is 10.67 milliseconds. A 256-sample buffer is 5.33 milliseconds.
3. If the audio thread misses that deadline, the hardware plays whatever was in the buffer, and you hear a click or a stutter. There is no equivalent of a dropped frame that merely looks bad.
4. This is why audio must never wait for the game. The game posts events into a queue, and the audio thread reads them when it wakes.
5. Each buffer fill is: gather the active voices, decode any compressed ones, apply per-voice volume, pitch and filters, sum them into buses, apply bus effects such as reverb and compression, and write the result out.
6. Voice limits exist because that work is per voice. A budget of 32 to 128 simultaneous voices is normal, and beyond it the quietest and most distant sounds are stolen.

■ 45.10.5 TECHNICAL – the engineer’s version

1. Distance attenuation. The physical law is inverse square, which is minus 6 decibels per doubling of distance. Games rarely use it directly; they use authored curves with a minimum distance, inside which volume is constant, and a maximum distance, beyond which the sound is culled entirely.
2. Occlusion versus obstruction: **occlusion** is a full barrier between source and listener and attenuates both the direct and reverberant paths; **obstruction** blocks the direct path only while sound still arrives via reflections. Both are usually implemented as raycasts driving a low-pass filter cutoff and a gain.
3. Spatialization ranges from cheap stereo panning, through vector-based amplitude panning for surround layouts, to head-related transfer function convolution for binaural headphone output. Shipping implementations include Sony’s Tempest 3D AudioTech on PlayStation 5, Dolby Atmos, Windows Sonic and Valve’s Steam Audio.
4. Adaptive music has two standard techniques. **Vertical layering** plays several stems at once and cross-fades them with game intensity. **Horizontal re-sequencing** switches between composed blocks at musical boundaries, using short transition segments so the change lands on a beat.
5. Middleware exists because building all of this well takes years. The two dominant products are FMOD Studio from Firelight Technologies and Wwise from Audiokinetic, which Sony acquired in 2019. Both give composers and sound designers an editor that produces data the game loads, so audio changes do not require a programmer or a rebuild.
6. Wwise pricing per title, from the published rate card, as an example of how middleware is sold:

Tier	Budget cap	First platform
Indie	250k USD	Free
Pro	2M USD	7,000 USD
Premium	none	22,000 USD

Tier	Budget cap	First platform
Platinum	none	40,000 USD

- Additional platforms cost extra on the paid tiers, which is why a small team shipping on five platforms must budget for audio middleware as a real line item rather than an afterthought.
- Streaming considerations: each streamed voice needs at least two buffers so one can be filled while the other plays, plus a seek-and-decode budget. On consoles with a hardware decompressor, audio streaming competes with texture streaming for the same input-output bandwidth, and audio must win, because a late texture is a blurry wall and a late sound is a click.
- Diagnostic tools: the FMOD Studio and Wwise live profilers connect to a running game and show every active voice, bus level and memory pool; Unreal's `stat audio` and `au.Debug` commands; Unity's Audio Profiler module; and `pw-top` or `pactl` on Linux for the system side.

■ 45.10.6 WORDS – remember these

- Sound bank — a group of sounds loaded together — a packaged set of audio assets and event metadata with a shared lifetime.
- Voice — one sound currently playing — an active mixer channel consuming decode and processing budget.
- Attenuation — getting quieter with distance — a gain curve over distance, physically minus 6 dB per doubling.
- Occlusion — a wall in the way — attenuation and low-pass filtering applied when the direct path to the listener is blocked.
- Bus — a group fader — a mix group through which many voices are summed before further processing.
- Middleware — audio tools bought in — FMOD or Wwise, giving designers an authoring environment decoupled from engine code.

45.11 Multiplayer and netcode

■ 45.11.1 PLAIN – in simple words

- Here is the problem, and it cannot be solved, only hidden.
- Information takes time to travel. Light in a glass fibre goes about 200,000 kilometres a second, which is fast but not instant.
- Mumbai to Singapore and back is roughly 60 milliseconds of round trip in practice. Mumbai to Frankfurt is roughly 120. Mumbai to the United States east coast is roughly 240.
- So when you press fire, the server learns about it at best 30 milliseconds later, and you learn its answer 30 milliseconds after that.
- Meanwhile your screen must keep drawing at 60 frames a second. It cannot wait for the answer.
- So the game lies to you, carefully. It shows you what it believes will happen, and corrects itself later when the truth arrives.
- Everything in netcode is a variation on that one trick, plus the question of who is allowed to decide the truth.
- The answer to that question is: a server that nobody plays on, owned by the game company. That is an **authoritative server**, and it won because any other arrangement lets a player's own machine cheat.

■ 45.11.2 PLAIN – a picture in your head

1. Imagine two people playing chess by post, with letters taking three days.
2. If each waits for the other's letter before thinking, a game takes a year.
3. So each of them keeps a board at home and moves their own piece immediately, guessing what the opponent will do.
4. When the letter arrives, they compare. If the guess was right, nothing changes. If it was wrong, they must undo their guessed moves and redo them from the true position.
5. That undo-and-redo is exactly what your game does, sixty times a second, with the postal delay measured in milliseconds instead of days.
6. And there is a referee whose board is the only one that counts. If your board disagrees with the referee's, yours is wrong by definition.

Where this comparison breaks: chess players can wait, and a game cannot. Also, in chess both boards are complete. In a game the referee deliberately does not tell you about pieces you cannot see, because if it did, you could cheat.

■ 45.11.3 PLAIN – a worked example

1. The full sequence for one shot, with real numbers. Round trip time is 80 milliseconds, so one-way delay is 40 milliseconds. The server runs at 64 ticks per second, so a tick is 15.6 milliseconds. Your interpolation delay is 100 milliseconds.

```
t=0    you press fire; client predicts the shot at once
t=0    input #4471 stamped and sent over UDP
t=40   server receives input #4471
t=40   server rewinds all hitboxes by 40 + 100 = 140 ms
t=40   server tests the ray against the rewind world
t=47   next server tick packages the result
t=87   you receive "hit confirmed, input #4471 processed"
t=87   client reconciles: state matches, nothing visible
```

2. Now the same event from the victim's point of view. On their screen they ran behind a wall at their local time $t=-20$ milliseconds, that is, 20 milliseconds before you pressed fire.
3. The server still counted the hit, because it rewound the world to where you saw them, and there they were in the open.
4. How far can that be? At a running speed of 6 metres per second, 140 milliseconds is 0.84 metres. That is most of a body width, which is exactly why it feels like being shot through a wall.
5. The 140 milliseconds is not padding. It is 40 milliseconds of network delay plus the 100 milliseconds of deliberate interpolation delay your client uses to smooth other players' movement.

■ 45.11.4 PLAIN – what is really happening inside

1. **Client-side prediction.** Your client never sends "I am at position X". It sends "I held forward and pressed fire, and this is input number 4471". Then it immediately applies that input locally so the screen responds now.
2. It keeps every unacknowledged input in a list.
3. **Server reconciliation.** The server replies with "here is your true state after I processed input 4471". Your client snaps to that state and then replays inputs 4472 onwards on top of it.
4. If the prediction was correct, the replay lands exactly where you already were and you see nothing. If it was wrong, you see a small correction.

5. **Entity interpolation.** Other players are not predicted. Instead your client deliberately renders them slightly in the past, between the last two snapshots it received, so their movement is smooth even though the snapshots arrive unevenly.
6. **Lag compensation.** The server records where every hitbox was for the last half second or so. When your shot arrives, it rewinds to what you were actually looking at, tests the hit there, then restores the present.
7. That is the entire architecture. Prediction hides your own latency. Interpolation hides everyone else's jitter. Lag compensation makes aiming fair. The cost is paid by the person being shot.

■ 45.11.5 TECHNICAL – the engineer's version

1. The techniques above were set out publicly in Yahn Bernier's 2001 paper for Valve, "Latency Compensating Methods in Client/Server In-game Protocol Design and Optimization", building on the prediction work in QuakeWorld from 1996. Almost every shooter since uses this model.
2. Blizzard's Overwatch, described in Timothy Ford's GDC 2017 talk, runs 16 millisecond command frames, about 62.5 per second, tightened to about 7 milliseconds in tournament configuration. The client clock runs ahead of the server by roughly half the round trip plus one buffered command frame, so at 160 milliseconds of latency it predicts about 96 milliseconds ahead. Above about 220 milliseconds round trip it stops predicting hits.
3. **Tick rate** is how often the server simulates. 64 ticks is one every 15.625 milliseconds; 128 ticks is one every 7.8125 milliseconds. Halving the tick interval halves the average quantization error on event timing, from about 7.8 to about 3.9 milliseconds, and doubles both server processor cost and downstream bandwidth. That is a money decision, not a technical one, which is why third-party services ran 128-tick Counter-Strike servers while official matchmaking ran 64.
4. Counter-Strike 2, released in September 2023, introduced **sub-tick** input: the client timestamps each input with its exact moment inside the tick, and the server uses that timestamp rather than snapping to the tick boundary. Valorant instead runs 128-tick servers. Whether sub-tick fully matches a true 128-tick server is genuinely disputed by players and analysts, and there is no neutral published measurement that settles it.
5. **Deterministic lockstep** is the other architecture. Only player commands are transmitted; every machine runs an identical simulation. Bandwidth is independent of the number of units, which is why real-time strategy games use it. The canonical write-up is Mark Terrano and Paul Bettner's GDC 2001 paper "1500 Archers on a 28.8", about Age of Empires.
6. Lockstep requires bit-identical simulation across every machine, for the reasons given in section 45.7: unspecified transcendental functions, compiler reordering, fused multiply-add, and non-deterministic thread ordering will all desynchronize it. It also needs a command delay of two to five turns, typically 100 to 250 milliseconds, so that all commands arrive before the turn executes. That delay is why strategy games feel slightly sluggish by design.
7. Rollback netcode for fighting games, popularized by Tony Cannon's GGPO from 2006, is lockstep plus speculation: assume the opponent pressed nothing, and when the real input arrives, restore the saved state and re-simulate the intervening frames. It needs a fast full state save and restore every frame, which constrains how the game is written.
8. **Bandwidth.** A worked example: 64 players, 20 snapshots per second, 200 bytes per snapshot after delta compression and relevancy culling, gives $64 \times 20 \times 200 = 256,000$ bytes per second, about 2.05 megabits per second outbound per server, before packet headers.

Genre	Snapshot rate	Down per client
Competitive shooter	60 to 128 Hz	200 to 800 kbps
Battle royale, 100 players	20 to 30 Hz	150 to 500 kbps
MMO	5 to 20 Hz	30 to 150 kbps
Strategy, lockstep	5 to 10 Hz	5 to 30 kbps

9. **Delta compression** sends only what changed since the last snapshot the client acknowledged, a model established by Quake 3 in 1999. Combined with quantization it is dramatic: a position stored as three 32-bit floats is 12 bytes; quantized to 16-bit fixed point over a bounded world it is 6 bytes; as a delta from the previous value with variable-length bit packing it is often 1 to 3 bytes.
10. **Relevancy culling**, sending a client only what it could plausibly perceive, saves bandwidth and is also the single most effective anti-cheat measure that exists, because a wallhack cannot draw data it never received. Riot's Fog of War in Valorant, shipped in 2020, is the best-known example.
11. **Why UDP**. TCP, standardized in RFC 793 in 1981 and now RFC 9293 from 2022, guarantees an ordered reliable byte stream. If packet 5 is lost, packets 6, 7 and 8 sit in the kernel buffer until 5 is retransmitted. That is head-of-line blocking, and it costs at least one round trip. For position updates it is exactly wrong: by the time packet 5 arrives it is stale and you already hold newer truth.
12. UDP, RFC 768 from 1980, has no ordering, no retransmission and no congestion control. Games build their own reliability layer and choose per message: unreliable for positions, since the next update supersedes this one; reliable and ordered for chat and inventory; reliable but unordered for one-off events. QUIC, RFC 9000 from 2021, offers independent streams over UDP and is used for some game backend traffic, but action games generally still roll their own.
13. Practical UDP detail: since there is no connection, NAT devices time out idle mappings, commonly after 30 to 120 seconds, so games send small keep-alive packets.
14. **Matchmaking** is a multi-objective search over skill, latency, party size, role and queue time, widening its tolerances as the wait grows. Skill systems descend from Arpad Elo's chess rating from the 1960s, through Glicko, to Microsoft's TrueSkill from 2007, which models skill as a distribution with an uncertainty that shrinks as it observes you.
15. **NAT traversal** matters because most home connections, and every carrier-grade NAT connection, have no reachable public address. STUN, currently RFC 8489 from February 2020, which obsoletes RFC 5389 of 2008 and RFC 3489 of 2003, lets a host discover the public address and port its NAT assigned. TURN, currently RFC 8656 from February 2020, relays traffic when a direct path cannot be established. ICE, RFC 8445 from 2018, gathers all candidate addresses and systematically tests pairs.
16. Hole punching works when both sides send outbound packets simultaneously so each NAT creates a mapping the other can use. It fails when both ends use symmetric NAT, which allocates a different external port per destination. A relay is then the only option, and a single-digit to low-double-digit percentage of connection attempts need one in practice.
17. **Relays** such as Steam Datagram Relay carry game traffic over a provider's private backbone. The benefits are that the server's real address is never exposed, which prevents denial-of-service attacks on individual players; routing is often better than the public internet; and NAT problems disappear.
18. The unfixable part: a player far from any datacentre cannot be given a competitive experience. No amount of netcode removes 240 milliseconds. This is a real and often-ignored fairness issue for players in regions without local server presence.

■ 45.11.6 WORDS – remember these

1. Authoritative server — the referee whose word counts — a server that simulates canonically and treats client messages as inputs, never as state.
2. Client-side prediction — acting before permission — applying local input immediately and retaining it for later replay.
3. Reconciliation — correcting the guess — snapping to the server state and replaying unacknowledged inputs on top of it.
4. Entity interpolation — drawing others slightly in the past — rendering remote entities between two received snapshots with a fixed delay buffer.
5. Lag compensation — rewinding to what the shooter saw — server-side historical hitbox rewind by the shooter's latency plus interpolation delay.
6. Tick rate — how often the server thinks — simulation steps per second, 64 ticks being 15.625 ms and 128 ticks 7.8125 ms.
7. Delta compression — send only what changed — encoding a snapshot as a difference from the last one the client acknowledged.
8. Deterministic lockstep — send commands, not state — identical simulation on every machine, requiring bit-exact reproducibility.

45.12 Cheating and anti-cheat

■ 45.12.1 PLAIN – in simple words

1. Cheating in an online game means making your copy of the program do something the designers did not intend, to gain an advantage.
2. An **aimbot** reads the game's memory to find where other players are, then points your weapon at them for you.
3. A **wallhack** draws other players through walls. It works only because your machine was told where they are.
4. A **speed hack** changes the clock the game reads, so your character moves faster than everyone else's.
5. **Packet manipulation** means interfering with the messages themselves: a lag switch drops your outgoing packets so others cannot hit you.
6. Some cheating is not technical at all: paying someone to play your account, deliberately losing to face weaker opponents, or trading wins.
7. The one rule that explains all defences is this: your machine belongs to the attacker. Anything the game checks on your machine, the attacker can remove.
8. So the only real defence is to check on the server, and to never send your machine information it is not entitled to.

■ 45.12.2 PLAIN – a picture in your head

1. Think of an examination hall.
2. Asking candidates to mark their own papers is the client trusting itself. Some will cheat, and you will never know.
3. Collecting the papers and marking them centrally is server-side validation. Now the cheating must happen in the room, not in the marking.
4. Not printing the answers on the back of the paper is relevancy culling. You cannot copy what you were never given.
5. Invigilators watching for suspicious behaviour are statistical detection.

6. And searching candidates at the door, going through their pockets, is kernel-level anti-cheat. It works, and people reasonably object to it.

Where this comparison breaks: an exam lasts three hours. Anti-cheat software that runs at boot is searching your pockets every day whether or not there is an exam, which is precisely the objection people raise.

■ 45.12.3 PLAIN – a worked example

1. How server-side validation actually looks, for movement.
2. The client sends: “input 4471, held forward, delta time 15.6 milliseconds”.
3. The server does not read a position. It runs the same movement code the client ran, from the state it already holds.
4. Maximum run speed is 5.2 metres per second. In 15.6 milliseconds the maximum possible movement is $5.2 \times 0.0156 = 0.081$ metres.
5. If the client claims a delta time of 100 milliseconds while only 15.6 have passed on the server’s clock, that is a speed hack, and it is rejected by comparing the client’s claimed time budget against elapsed server time.
6. The same pattern applies everywhere: fire rate against the weapon’s cooldown, damage against the weapon’s table, line of sight against the server’s own geometry, and inventory against the server’s own database.

Cheat	Defence that works
Aimbot	Statistical aim analysis
Wallhack	Do not send hidden positions
Speed hack	Server-side time budget
Damage edit	Server owns the damage table
Item duplication	Atomic server transactions

■ 45.12.4 PLAIN – what is really happening inside

1. Statistical detection looks at how you aim rather than at your files.
2. Human aim has tremor, overshoot, correction and a reaction time that never drops below about 150 milliseconds for a genuinely unexpected event.
3. A machine has none of those. Its angular snap to a target is too fast, too precise, and too consistent across distances.
4. Detectors measure the distribution of flick times, the time between a target becoming visible and the first shot, the hit rate as a function of range, and the smoothness of the mouse path.
5. The output is a probability, not a verdict, which is why bans are issued in waves rather than instantly: batching hides which specific detection fired, so cheat authors cannot binary-search their way around it.
6. False positives are the hard part. At a 0.1 percent false positive rate across 10 million players, 10,000 innocent people are banned. This is why detections are usually required to be independently corroborated.

■ 45.12.5 TECHNICAL – the engineer’s version

1. Categories in more detail: memory-reading external cheats; injected internal cheats hooking the rendering or input path; triggerbots; radar overlays; automated recoil control macros in hardware mice; lag switches and packet delay; and account services such as boosting and win trading.

2. Two categories defeat all software-only defences. **DMA cheats** use a second computer with a PCIe direct memory access card reading the gaming machine's memory over the bus, so nothing runs on the machine being watched. **Screen-reading cheats** capture the video output with a capture card, run object detection on a second machine, and drive a hardware device that emulates a mouse. Both are a live problem in 2026 and neither is detectable by inspecting the game machine's software.
3. Kernel-level anti-cheat runs a driver at ring 0 so it can see and block things user-mode code cannot: other drivers loading, handles opened to the game process, hooked system calls, and tampered kernel structures. Shipped examples include Riot Vanguard, introduced with Valorant in 2020 and extended to League of Legends in 2024; Easy Anti-Cheat, now owned by Epic Games; BattlEye; and Activision's Ricochet, introduced in 2021.
4. The honest debate, both sides in full. For: cheats themselves run in the kernel, and a user-mode watcher simply cannot see a kernel-mode cheat, so without a kernel presence the defender has already lost the privilege race. Games with kernel anti-cheat measurably have fewer visible cheaters.
5. Against: it is a signed driver with total access to your machine, shipped by a game company, usually loading at boot whether or not you play. A bug in it is a system-wide vulnerability. This is not hypothetical: the mhyprot2.sys driver shipped with Genshin Impact was abused by ransomware operators to disable antivirus software, and the July 2024 CrowdStrike incident showed what a single faulty kernel-mode update does at scale.
6. It also excludes people. Kernel anti-cheat generally does not work under Proton on Linux or the Steam Deck unless the developer explicitly enables the vendor's Linux support, which many competitive titles decline to do.
7. The platform direction is changing. Microsoft announced the Windows Resiliency Initiative in November 2024 and from 2025 began moving endpoint security products out of kernel mode into a supported user-mode platform, with security vendors involved in the design. As of August 2026 this is a live transition rather than a completed one, and how anti-cheat fits into it is not yet settled.
8. Hardware-backed identity raises the cost of ban evasion. Valorant requires TPM 2.0 and Secure Boot on Windows 11, which lets bans attach to something harder to change than an account or a network address.
9. Machine learning detection is real and shipped: Valve described VACnet, a classifier trained on human-reviewed cases, at GDC in 2018, and comparable systems exist at other publishers. It is a filter that raises human review efficiency, not an oracle.
10. The arms race is structural and permanent. Cheat development is a paid industry with subscription pricing, private builds to avoid signature detection, and customer support. Anti-cheat cannot win; it can only make cheating expensive, unreliable and short-lived enough that most people do not bother.

■ 45.12.6 WORDS – remember these

1. Aimbot — the machine aims for you — automated target acquisition driven by memory-read entity positions or screen-space detection.
2. Wallhack — seeing through walls — rendering entity positions the client received but should not have been told about.
3. Server-side validation — the server checks everything — simulating client inputs authoritatively and rejecting physically impossible claims.
4. Relevancy culling — do not send what cannot be seen — filtering network state by visibility, which prevents wallhacks at the source.
5. Kernel-level anti-cheat — a watcher with full system access — a ring 0 driver monitoring for tampering, with the privilege and stability trade-off that implies.
6. Ban wave — punishing in batches — delayed enforcement that obscures which detection triggered, slowing the cheat authors' feedback loop.

45.13 What actually happens when you double-click a game

■ 45.13.1 PLAIN – in simple words

1. The short version of the ordinary part: the operating system reads the file's header, works out how much memory the program needs, copies the code and data into that memory, fills in the addresses of the system libraries the program uses, and jumps to its first instruction.
2. That is true for every program. A game then does a great deal more before you see anything.
3. It usually starts a **launcher** first, which checks for updates, verifies that your files have not been altered, and logs you in.
4. It starts the anti-cheat service, if there is one.
5. Then it starts the real game program, which must find a graphics card, ask the driver for a device, and set up the chain of pictures it will draw into.
6. Then it must turn its shader source into machine code for your specific graphics chip. On the first run this can take minutes, and if it is done lazily while you play, you get the famous first-run stutter.
7. Then it loads a small amount of content for the menu, and only then does the loop from section 45.3 start running.
8. Choosing a level starts a second, much bigger load, and finally you play.

■ 45.13.2 PLAIN – a picture in your head

1. Think of an aircraft before a flight.
2. Opening the door is the double-click. Nothing is running yet.
3. Ground power, then auxiliary power, then engines: that is the loader, the launcher and the engine start.
4. The pre-flight checklist is the device and swap chain creation. Every item must be confirmed before the next.
5. Loading passengers and fuel is asset loading. It is the slowest part and it scales with how far you are going.
6. Taxiing is the main menu: you are moving, everything is running, but the real work has not started.
7. Take-off is entering the level.

Where this comparison breaks: an aircraft does the same checklist every time. A game's first run is dramatically different from its second, because the shader cache, the file system cache and the driver cache are all empty the first time.

■ 45.13.3 PLAIN – a worked example

1. The twenty-five step trace, with realistic timings for a Windows PC with an NVMe solid-state drive, a mid-range graphics card and a broadband connection. Cold means first ever run; warm means a later run.

Step	What happens	Warm time
1	Shell creates the process	20 ms
2	Loader maps the launcher	30 ms
3	Launcher checks for updates	200 to 2000 ms
4	File integrity spot check	500 ms to 30 s
5	Anti-cheat service starts	50 to 500 ms
6	Launcher spawns the game	50 ms
7	Loader maps the game image	100 to 400 ms
8	Runtime and static init	20 to 100 ms
9	Read config and command line	5 to 20 ms
10	Memory pools reserved	10 to 50 ms
11	Job system threads start	5 to 20 ms
12	Archives mounted, index read	50 to 300 ms
13	Enumerate adapters, device	100 to 500 ms
14	Create swap chain buffers	50 to 200 ms
15	Allocate render targets	50 to 200 ms
16	Load or compile shader states	2 s warm, minutes cold
17	Audio device and mixer graph	50 to 200 ms
18	Enumerate input devices	10 to 100 ms
19	Sockets, DNS, account login	200 to 1500 ms
20	Load front-end bundle	500 to 3000 ms
21	Main menu, loop now running	first frame
22	You pick a level, load list	10 ms
23	Stream, decompress, upload	3 to 30 s
24	Warm-up frames force work	1 to 5 s
25	Gameplay loop settles	steady state

2. Warm total to the main menu is roughly 4 to 8 seconds. Cold total can be several minutes, almost all of it in step 16.
3. Step 16 is the one worth understanding. Shader source is compiled at build time into an intermediate form, but the final translation into your exact graphics chip's instructions can only happen on your machine, because the developer does not know which chip you have.
4. A game may have 20,000 to 200,000 pipeline states. If each takes 20 milliseconds to build, 50,000 of them is about 17 minutes of one core, or roughly one minute spread across sixteen cores.
5. If the game builds them lazily instead, the first time a new effect appears the frame stops for 20 to 200 milliseconds. That is the stutter. Consoles never have it, because the chip is known and the compilation happened at build time.

■ 45.13.4 PLAIN – what is really happening inside

1. A **save file** is a written-down copy of the parts of the world the designer decided matter.
2. It is never the whole world. Nobody stores every leaf position. It stores your position, your inventory, quest flags, which doors are open, which enemies are dead, and a version number.
3. Turning live objects into a flat sequence of bytes is called **serialization**, and reading it back is **deserialization**.

4. The formats used, in rough order of how common they are:

Format	Example use	Trade-off
Chunked binary	Most console games	Fast, opaque
Tagged binary	Minecraft NBT	Flexible, compact
JSON, often gzipped	Many indie games	Readable, large
SQLite database	Mobile, big worlds	Robust, heavier
Engine key-value	Unity PlayerPrefs	Settings only

5. Minecraft's NBT, standing for Named Binary Tag, is a tagged tree of typed values, gzip-compressed, with world data grouped into region files that each hold a 32 by 32 block of chunk columns.
6. The correct way to write a save is: write to a temporary file, flush it to the storage device, then rename it over the old one. Rename is atomic on every mainstream file system, so a power cut leaves either the old save or the new one, never half of each. Games that write in place corrupt saves.
7. Saves must carry a version number, because patch 1.20 must still load a save written by 1.00, which means keeping an upgrade path for every old version. This is why some games break saves at a major update and why players are right to be annoyed about it.
8. Online games sign or checksum saves and usually store them server-side, so that editing them is pointless. Single-player games often do not, which is why save editors exist and are harmless.

■ 45.13.5 TECHNICAL - the engineer's version

1. On Windows the image is a PE file: the loader maps sections according to the section table, applies base relocations if the preferred base is taken, resolves the import address table, runs TLS callbacks, then calls the entry point. On Linux it is an ELF file handled by `ld.so`. Section 45.13 does not repeat that machinery; it only notes where it sits in the sequence.
2. Graphics initialization in Direct3D 12 is: create a DXGI factory, enumerate adapters, `D3D12CreateDevice`, create command queues, then `CreateSwapChainForHwnd` with 2 or 3 buffers and a chosen swap effect, usually flip-model. In Vulkan it is `vkCreateInstance`, physical device selection, `vkCreateDevice`, then a surface and a `VkSwapchainKHR`.
3. Pipeline state objects bundle shaders, blend, depth, rasterizer and vertex layout into one immutable object, which is why they are compiled up front rather than assembled per draw. Both APIs support a pipeline cache blob that can be saved to disk and reloaded, which is what makes the warm run fast. Steam additionally distributes precompiled Vulkan pipeline caches for Proton titles so a Steam Deck rarely compiles at play time.
4. Asset streaming on modern consoles uses hardware decompression and a direct storage path: the PlayStation 5 Kraken decompressor is rated at about 5.5 gigabytes per second of compressed input, and Microsoft's DirectStorage on Windows, with GPU decompression from version 1.1 in 2022, brings a similar path to PC.
5. Useful observation commands: Process Monitor to watch every file the game opens in order; `strace -f` or `ltrace` on Linux; Windows Performance Recorder or `xperf` for a boot-to-first-frame trace; `nvidia-smi` or GPU-Z to watch video memory fill during load; and the engine's own load-time trace, such as Unreal Insights with the LoadTime channel.

■ 45.13.6 WORDS – remember these

1. Launcher — the small program that runs first — an updater, integrity checker and authentication front end that spawns the real executable.
2. Swap chain — the queue of pictures — the set of back buffers created at startup and rotated between renderer and display.
3. Pipeline state object — a frozen graphics configuration — an immutable bundle of shaders and fixed-function state compiled ahead of a draw.
4. Shader cache — the compiled results kept for next time — an on-disk store of driver-compiled pipeline blobs keyed by hardware and driver version.
5. Serialization — turning live objects into bytes — writing state in a versioned, replayable form, and reading it back.
6. Atomic rename — the safe way to save — writing to a temporary file and renaming over the target so no partial file is ever visible.

45.14 Consoles versus PC

■ 45.14.1 PLAIN – in simple words

1. A PC is a different machine for every person. A console is the same machine for everybody.
2. That single difference is worth more than it sounds.
3. On a console the developer knows exactly how fast the processor is, exactly how much memory there is, exactly how fast the storage is, and exactly which graphics chip will run the shaders.
4. So the developer can tune to that machine, compile shaders in advance, use the memory to the last megabyte, and rely on a fixed loading speed.
5. On a PC the same code must work on thousands of combinations, through a driver that has to guess, with unknown amounts of memory, and with shaders compiled on your machine while you wait.
6. In exchange for that constraint, the console maker takes control: your game must pass their tests before it can be sold.
7. That is why a console game with weaker numbers on paper can look better than a PC game on stronger hardware.

■ 45.14.2 PLAIN – a picture in your head

1. Think of a tailor.
2. A bespoke suit is measured for one body. It fits perfectly and it fits nobody else. That is a console game.
3. Off-the-peg suits come in twelve sizes and must fit everybody roughly. They need more fabric in places, and they hang a little loose. That is a PC game.
4. The bespoke suit is not made of better cloth. It just wastes none.

Where this comparison breaks: a PC owner can buy far better cloth. A 1,500 dollar PC in 2026 genuinely outperforms any console, and gets modding, backwards compatibility and higher frame rates too. The console advantage is efficiency per unit of hardware, not raw capability.

■ 45.14.3 PLAIN – a worked example

1. The 2026 landscape, with United States prices as of August 2026. Note that prices in this generation went up rather than down, which is historically unusual.

Machine	Graphics	Price
PlayStation 5 (2020)	36 CU, 10.3 TFLOPS	649.99
PlayStation 5 Pro (2024)	60 CU, 16.7 TFLOPS	899.99
Xbox Series X (2020)	52 CU, 12.1 TFLOPS	649.99
Xbox Series S (2020)	20 CU, 4 TFLOPS	399.99
Nintendo Switch 2 (2025)	1,536 Ampere cores	449.99

2. PlayStation raised prices in August 2025 and again on 2 April 2026. Xbox raised prices in October 2025. The Nintendo Switch 2 launched at 449.99 on 5 June 2025 and has held that price.
3. Memory tells the same story as compute. The PlayStation 5 has 16 gigabytes of GDDR6 at 448 gigabytes per second, shared between processor and graphics chip. The Pro keeps 16 gigabytes but raises bandwidth to 576 gigabytes per second and adds 2 gigabytes of DDR5 for the system. The Switch 2 has 12 gigabytes of LPDDR5X at about 102 gigabytes per second docked.
4. Unified memory is the quiet advantage. On a PC, data must be copied across the PCI Express bus from system memory to video memory. On a console there is one pool and no copy.

■ 45.14.4 PLAIN – what is really happening inside

1. Certification is a checklist, not a review of whether the game is good.
2. Sony calls its list the Technical Requirements Checklist. Microsoft calls its list the Xbox Requirements. Nintendo's process is called Lotcheck.
3. The checks are behavioural. What happens if the controller battery dies mid-save. What happens if the network drops during a purchase. What happens if the user signs out. Does the game suspend and resume within the required time. Does it use the platform's exact button names. Does it declare its save data size correctly. Does it survive an eight-hour soak test.
4. A submission takes on the order of one to three weeks per platform per build, and a failure means fixing and resubmitting. Studios therefore lock content weeks before launch to leave room for one or two failures.
5. Those durations are studio experience rather than published figures, and they vary by platform, by title and by relationship.
6. Age ratings are a separate process again: ESRB in North America, PEGI in Europe, CERO in Japan, USK in Germany, and the IARC questionnaire for digital storefronts.

■ 45.14.5 TECHNICAL – the engineer's version

1. The concrete reasons a fixed target wins, in order of importance: precompiled shaders, so no run-time compilation and no first-run stutter; unified memory, so no bus copies; low-overhead graphics APIs closer to the hardware than the PC equivalents; a known memory budget minus a known system reservation; guaranteed storage bandwidth with hardware decompression; and a single optimization target, so every hour of tuning benefits every player.
2. The APIs differ: PlayStation uses its own GNM and GNMx; Xbox uses Direct3D 12 with console-specific extensions and a fixed driver; Nintendo Switch and Switch 2 use NVN. All three expose more control and less driver interpretation than desktop Direct3D 12 or Vulkan.
3. System reservations are real and published in developer documentation rather than in marketing: the Xbox Series X reserves about 2.5 gigabytes of its 16, and the Switch 2 reserves about 3 gigabytes of its 12 by reported figures, leaving the rest to the game.
4. Handhelds are the growth area. The Steam Deck, released 25 February 2022 with an OLED model in November 2023, uses an AMD APU with a 4-core Zen 2 processor and 8 RDNA 2 compute units,

about 1.6 teraflops, 16 gigabytes of LPDDR5, and a 1280 by 800 display, in a 4 to 15 watt power envelope.

5. SteamOS is Arch-based Linux, and Windows games do not run on Linux natively. **Proton** makes them run. It is not emulation: the processor instructions are native x86-64 and execute at full speed. Only the calls into Windows are translated.
6. Proton is Wine, the open reimplementation of the Windows API begun in 1993, plus DXVK which translates Direct3D 9, 10 and 11 into Vulkan, plus VKD3D-Proton which translates Direct3D 12 into Vulkan, plus FAudio for XAudio2, plus Steam-specific shims. Shader bytecode is translated too, from DXBC and DXIL into SPIR-V.
7. Typical overhead is 0 to 15 percent, and a minority of titles run faster than on Windows because of driver differences. The thing Proton cannot fix is kernel anti-cheat, which must be explicitly enabled for Linux by the game's developer.
8. Valve announced a **Steam Machine** in November 2025 for release in 2026: a small SteamOS box with a semi-custom 6-core AMD Zen 4 processor up to 4.8 GHz, an RDNA 3 graphics part, 16 gigabytes of system memory plus 8 gigabytes of dedicated graphics memory, running the same Proton stack. At the time of writing in August 2026 the price had not been announced.
9. The honest summary: consoles buy predictability and efficiency; PCs buy ceiling and freedom. Which is better depends entirely on whether you value a guaranteed experience or a configurable one, and reasonable people split on it.

■ 45.14.6 WORDS - remember these

1. Fixed platform — one machine for everyone — a single known hardware configuration allowing exact tuning and ahead-of-time compilation.
2. Certification — the platform holder's checklist — a technical requirements pass covering behaviour, terminology, storage and stability.
3. Unified memory — one pool shared by processor and graphics — no PCI Express copies between system and video memory.
4. System reservation — the slice the console keeps — memory and processor time reserved for the operating system and background features.
5. Compatibility layer — translating one platform's calls to another — Proton, which maps Windows and Direct3D calls to Linux and Vulkan without emulating the processor.
6. Lotcheck — Nintendo's certification — the platform's technical and content compliance review before release.

45.15 Emulation

■ 45.15.1 PLAIN – in simple words

1. An **emulator** is a program that pretends to be a different computer.
2. The game it runs was compiled for a processor your machine does not have, talking to chips your machine does not have.
3. So the emulator reads the old machine's instructions one at a time and does whatever they were supposed to do, using your machine's instructions.
4. It also pretends to be the old machine's graphics chip, sound chip, cartridge slot and controller ports.
5. There are two ways to run the instructions. **Interpretation** reads and acts on each instruction every time it is encountered. Simple, accurate, slow.
6. **Recompilation** translates a whole block of old instructions into new instructions once, keeps the translation, and reuses it. Complicated, much faster.
7. There is a third shortcut. Instead of emulating the old machine's system software, the emulator can spot a call to a known system function and do the equivalent thing natively. That is **high-level emulation**.

■ 45.15.2 PLAIN – a picture in your head

1. Interpretation is a live interpreter at a conference, translating sentence by sentence, every time, including sentences the speaker repeats.
2. Recompilation is having the speech translated once and printed, so the repeated parts are read from the page.
3. High-level emulation is noticing that the speaker just said a standard phrase, and saying the equivalent standard phrase in the target language rather than translating it word by word.
4. Accuracy is the trade in each case. The live interpreter catches every nuance. The printed version cannot adapt if the speaker goes off script.

Where this comparison breaks: a speech does not care about timing to the microsecond. Old consoles absolutely did, and many games depend on exactly when a chip responded, not just on what it returned.

■ 45.15.3 PLAIN – a worked example

1. Why emulating a slow machine can need a fast one.
2. The Super Nintendo ran at about 3.58 MHz. A modern processor runs at about 4 GHz, roughly 1,100 times faster in clock terms alone, and does far more per clock.
3. Yet a fully cycle-accurate SNES emulator such as byuu's bsnes and higan needed roughly a 3 GHz machine to reach full speed.
4. The reason is not the instructions. It is the synchronization. A cycle accurate emulator must interleave the processor, the picture processing unit, the sound processor and the cartridge coprocessors many times per emulated instruction, and each switch costs far more than the instruction itself.
5. A less accurate emulator that runs each chip in blocks and synchronizes rarely is ten to fifty times faster and breaks a small number of games that rely on exact timing.

Approach	Speed cost	Accuracy
Cycle-accurate interpreter	500 to 1500x	Highest

Approach	Speed cost	Accuracy
Block interpreter	20 to 100x	Good
Dynamic recompiler	2 to 10x	Varies
High-level API emulation	1 to 3x	Lowest

6. Those ratios are approximate and depend heavily on the console being emulated.

■ 45.15.4 PLAIN – what is really happening inside

1. An interpreter's inner loop is: read the instruction at the program counter, decode it, look up a handler, run the handler, update the registers and flags, advance the program counter, add the instruction's cycle cost to a counter, and check whether any hardware event is due.
2. That is 10 to 100 host instructions to do the work of one guest instruction.
3. A dynamic recompiler instead scans forward from the program counter until a branch, translates that whole block into host machine code once, stores it in a cache keyed by address, and jumps into it.
4. The block then runs at close to native speed on every later visit.
5. Self-modifying code and code overwritten by a memory bank switch force the cached block to be thrown away and retranslated, which is why emulating older machines with heavy bank switching is harder than it looks.
6. Emulating the graphics chip is where the biggest shortcut lives. If the emulator translates the old chip's drawing commands into modern graphics calls instead of simulating its pixel pipeline, it can also render at four or eight times the original resolution, which the original hardware could never do.

■ 45.15.5 TECHNICAL – the engineer's version

1. Terms, precisely. **Interpretation** decodes per execution. **Threaded interpretation** removes dispatch overhead by chaining handler addresses. **Dynamic binary translation**, also called dynarec or JIT, compiles per basic block or per trace. **Static recompilation** translates the whole binary ahead of time and mostly fails on general programs because indirect jumps make it impossible to tell code from data reliably, though per-title static recompilation projects have succeeded, notably for Nintendo 64 titles from around 2023.
2. **High-level emulation** replaces the guest system's own libraries with native implementations, which is essential when the firmware cannot legally be distributed. **Low-level emulation** runs the real firmware and is more accurate but requires the user to supply it.
3. Accuracy has axes: instruction accuracy, cycle accuracy, sub-instruction bus timing, sample-accurate audio, and scanline or dot accurate video. Choosing a lower point on any axis buys speed and breaks some titles.
4. The legal position, stated neutrally and without advice.
5. Writing an emulator has been upheld in United States courts. In *Sony Computer Entertainment v. Connectix*, decided by the Ninth Circuit in 2000, intermediate copying of the PlayStation BIOS for reverse engineering was held to be fair use. *Sony v. Bleem*, also 2000, held that using screenshots in comparative advertising was fair use.
6. Copying game data you do not own is copyright infringement essentially everywhere. Whether dumping a cartridge you do own is lawful varies by country, and in several jurisdictions the act of circumventing copy protection to make the dump is itself unlawful regardless of ownership, under the United States Digital Millennium Copyright Act of 1998 and the European Union Copyright Directive of 2001.

7. Firmware and BIOS images are copyrighted works in their own right; distributing them is infringement whatever the emulator's status.
8. Enforcement in practice: in March 2024 Nintendo settled with Tropic Haze, developer of the Switch emulator Yuzu, for 2.4 million United States dollars, and the project shut down. Nintendo's complaint centred on circumvention of encryption rather than on emulation as a concept.
9. Where people disagree: emulator authors and archivists argue the tool is lawful, general-purpose and necessary; rights holders argue that emulators of current hardware exist principally to enable piracy. Both claims can be true of different projects at the same time.
10. Preservation is the strongest argument, and it has numbers behind it. A study published in July 2023 by the Video Game History Foundation with the Software Preservation Network found that about 87 percent of video games released in the United States before 2010 are out of commercial circulation entirely.
11. The mechanisms of loss are concrete: digital storefronts close, as the Wii Shop Channel did in 2019 and the Nintendo 3DS and Wii U eShops did in March 2023; optical discs suffer disc rot; cartridge save batteries last ten to twenty years; and flash memory loses charge over decades.
12. Museums and libraries have argued for broader legal exemptions to preserve and provide access to games. Some exemptions exist for on-site preservation work; remote access for researchers remains contested.

■ 45.15.6 WORDS – remember these

1. Emulator — a program pretending to be another machine — software modelling a foreign instruction set and peripheral hardware.
2. Interpretation — decode every instruction every time — a fetch-decode- execute loop in software, simple and slow.
3. Dynamic recompilation — translate once, run many times — just-in-time compilation of guest basic blocks into host machine code.
4. High-level emulation — reimplement the system calls — replacing guest firmware routines with native host implementations.
5. Cycle accuracy — matching the original timing exactly — modelling per-clock behaviour including inter-chip contention.
6. ROM — a copy of the original game data — a dump of cartridge or disc contents, copyrighted material unless the rights holder permits otherwise.

45.16 Making your first game, practically

■ 45.16.1 PLAIN – in simple words

1. Build something tiny. Then build something slightly less tiny.
2. The reason is not that you cannot handle a big idea. It is that finishing is a separate skill from building, and it is the rarer one.
3. A tiny game teaches you the whole pipeline: input, a loop, collision, a win condition, a lose condition, sound, a menu, a build, and publishing.
4. A big game teaches you one slice of that and then dies.
5. The proven ladder is: Pong, then Breakout, then Snake, then Asteroids, then a one-level platformer, then something of your own.
6. Each of those should take days, not months. If it is taking months, the scope is wrong.
7. Then publish it. Publishing a bad small game teaches you more than not publishing a good big one.

■ 45.16.2 PLAIN – a picture in your head

1. Nobody learns to cook by attempting a five-course dinner for twenty.
2. You learn by making one dish, badly, then again, less badly.
3. The dinner party teaches you timing, which the single dish does not, so you do eventually need one. But you need it after ten dishes, not before.
4. A game jam is the dinner party: a fixed 48 hours, a theme announced at the start, and something submitted at the end regardless of quality.

Where this comparison breaks: a bad dish is eaten and forgotten. A published game stays on the internet under your name, which is exactly why some people never publish. Publish anyway. Nobody is looking as hard as you fear.

■ 45.16.3 PLAIN – a worked example

1. A thirty-day plan. It assumes about two hours a day, which is realistic alongside study or a job.

Days	Task	Deliverable
1 to 2	Engine, one tutorial	A window, a moving box
3 to 4	Core verb only	Move and jump feel good
5 to 7	One obstacle, win, lose	A 30-second playable loop
8 to 9	Playtest with 3 people	Written notes, a cut list
10 to 13	Fix the top three problems	The loop reads clearly
14 to 16	Add exactly one system	The game has some depth
17 to 18	Second playtest	Notes, cut list again
19 to 21	Sound and feedback pass	It feels good to touch
22 to 24	Five levels or a curve	Content, not features
25 to 26	Menu, pause, settings	Ship-shaped
27 to 28	Build, test on a clean PC	An installable build
29	Store page, screenshots	Page ready
30	Publish on itch.io	Released

2. Notice that only days 3 to 7 and 14 to 16 add features. Everything else is testing, fixing, content and shipping. That ratio is correct and it surprises everyone the first time.

■ 45.16.4 PLAIN – what is really happening inside

1. **Scope** is the number one killer of hobby projects, and the reason is arithmetic, not willpower.
2. Every feature costs its own build time plus its interaction with every other feature. The number of interacting pairs grows roughly as the square of the feature count.
3. Five features have ten pairs to make work together. Fifteen features have 105. That is why the second half of a project feels ten times harder than the first.
4. So the discipline is a **cut list**: when you have a new idea, write it down on a “version two” list, and carry on with what you were doing.
5. Rough multipliers for common additions, approximate but directionally right: multiplayer multiplies total work by about three; a save and load system by about 1.3; procedural generation by about two; a narrative mode by more than any of them.
6. The classic failure is choosing a massive online role-playing game or an open world as a first project. It has ended more hobby projects than any technical difficulty.
7. Prototype with untextured boxes. If a game is not fun as grey boxes, art will not save it. Art makes a good game feel better; it cannot make a boring game interesting.

8. Playtest by handing someone the controls and saying nothing. Every time you want to explain something, that is a design bug. Write it down instead of speaking.

■ 45.16.5 TECHNICAL – the engineer’s version

1. Choosing a tool by goal, as of August 2026:

Goal	Tool	Why
Understand the machinery	raylib or SDL3	No magic, all yours
Ship a 2D game quickly	Godot 4	Free, small, 2D-first
Reach mobile and consoles	Unity 6	Widest platform support
Highest-end 3D visuals	Unreal Engine 5	Best default look
Web game in a browser	Godot or a JS engine	HTML5 export

2. Code-first libraries worth knowing: SDL3 and raylib in C, LOVE in Lua, pygame in Python, MonoGame in C#, Bevy in Rust, and three.js in JavaScript. These give you a window, input, drawing and sound, and nothing else, which is exactly the point when learning.
3. Free asset sources with usable licences: Kenney’s public domain 2D and 3D packs; OpenGameArt; Poly Haven and AmbientCG for CC0 textures, models and environment maps; Quaternius for CC0 low-poly models; Adobe’s Mixamo for free rigged characters and animations; Freesound for Creative Commons audio; and Google Fonts. Read every licence and keep an attributions file from day one, because reconstructing it later is miserable.
4. “Juice” is the disproportionately effective polish layer: screen shake, a two to six frame hit pause, particles on impact, layered sound, tweened interface movement, and squash and stretch on jumps. The reference talk is “Juice It Or Lose It” by Martin Jonasson and Petri Purho from 2012.
5. Where to publish, with real numbers:

Platform	Cost to publish	Revenue share
itch.io	Free	You choose, 10% default
Steam	100 USD per game	30%, 25% over 10M
Epic Games Store	Free, curated	12%
Google Play	25 USD once	15% under 1M per year
Apple App Store	99 USD per year	15% under 1M per year

6. The Steam Direct fee of 100 United States dollars per title is refundable once the title reaches 1,000 dollars of adjusted gross revenue. Steam’s share drops to 25 percent above 10 million dollars of lifetime revenue and 20 percent above 50 million.
7. Game jams are the most reliable way to finish anything. Ludum Dare has run since 2002, Global Game Jam since 2009, and the GMTK Jam is now among the largest. A 48-hour deadline enforces scope better than any amount of personal discipline.
8. A practical technical checklist before publishing: test on a machine that has never had your development tools installed; check that the game runs from a path with a space and a non-English character in it; handle alt-tab, minimize and display resolution change; provide key rebinding; check it on a 16:10 and an ultrawide display; and make sure the game can be quit with the keyboard alone.

■ 45.16.6 WORDS - remember these

1. Scope — how big the thing is — the total feature and content set, and the dominant risk in any small project.
2. Cut list — the ideas you deliberately postpone — a written backlog that protects the current milestone from new ideas.
3. Prototype — the ugly playable test — a minimal implementation built to answer one design question, then usually discarded.
4. Playtest — watching someone else play — structured observation of a naive player without designer intervention.
5. Juice — cheap polish that feels expensive — screen shake, hit pause, particles and easing applied to feedback moments.
6. Game jam — a short deadline with a theme — a fixed-duration event, typically 48 to 72 hours, used to force completion.

45.98 Common wrong ideas

1. Wrong: games are made by one genius programmer. Right: a modern game is made by a team where roughly one person in five writes code, and the largest groups are artists and quality assurance. Even the famous solo games, such as *Stardew Valley*, took a single person four and a half years and still used other people's engine, tools and audio libraries.
2. Wrong: more polygons means better graphics. Right: past a certain density extra triangles are smaller than a pixel and cost performance for no visible gain. What actually makes an image look good is lighting, material response, texture quality, animation and art direction. A 2015 game with good art direction routinely looks better than a 2026 game without it.
3. Wrong: the engine makes the game. Right: the engine provides the machinery. Every game in the same engine can look and feel completely different, because the design, the art, the tuning and the content are the game. An engine can make a bad game easier to build; it cannot make it good.
4. Wrong: lag is always your internet connection. Right: what you feel as lag is the sum of your input device, your frame rate, your render queue depth, your display, your distance to the server, the server's tick rate, and the game's interpolation delay. A player with a perfect connection on a distant, low-tick server will feel worse than a player with a mediocre connection nearby.
5. Wrong: a higher average frame rate always feels smoother. Right: evenly paced frames feel smoother than unevenly paced ones at the same average. 112 frames per second average with one 100-millisecond hitch feels worse than a steady 90.
6. Wrong: game physics is real physics. Right: it is a stable, cheap approximation tuned for feel. Jump arcs, friction and gravity in most games are deliberately unphysical because physical values feel bad to play.
7. Wrong: game AI is machine learning. Right: shipped game AI is almost entirely hand-authored state machines, behaviour trees, utility scoring and pathfinding, deliberately weakened so it is fun to fight. Learned agents exist in research and beat humans, and are not what is in your game.
8. Wrong: emulators are illegal. Right: writing and using an emulator has been upheld as lawful in United States courts. Copying game data or firmware you do not own is what is unlawful, and the two questions are separate.
9. Wrong: kernel anti-cheat means the game is secure. Right: it raises the cost of software cheating, and it cannot see a direct-memory-access cheat on a second computer or a screen-reading cheat driving a hardware mouse. Server-side validation and not sending hidden data remain the only defences that cannot be bypassed on the client.

10. Wrong: consoles are just locked-down PCs. Right: the fixed target changes what is possible. Pre-compiled shaders, unified memory, a known memory budget and one optimization target let a console extract far more from the same silicon than a PC of identical specification.

45.99 Chapter summary in 20 lines

1. A game is a program that redraws the world on a clock, whether or not anything changed, unlike an application that redraws only on an event.
2. That single decision produces the frame budget: 16.67 ms at 60 frames per second, 8.33 ms at 120, 6.94 ms at 144.
3. The loop is input, update, render, present, and it never sleeps except when waiting for the display.
4. Physics needs a fixed timestep because integration is not step-size invariant; an accumulator collects real time and spends it in fixed steps.
5. Rendering interpolates between the last two simulation states using the leftover accumulator fraction, which is what makes 60 Hz physics look smooth at 144 frames per second.
6. Frame time is the real measurement; average frames per second hides stutter, which is why 1 percent lows are reported.
7. Games began as laboratory curiosities in 1958 and 1962, became wired logic in 1972, gained processors and cartridges in 1977, crashed in 1983, and were rebuilt around platform control from 1985.
8. Doom in 1993 and 3D acceleration from 1996 moved the bottleneck from pixel fill to triangle throughput, and then to per-pixel computation.
9. A modern AAA game costs 80 to 300 million dollars and employs 200 to 600 people, of whom fewer than a quarter write code; content, not code, is the cost.
10. Engines supply the reusable machinery and an editor. Unity, Unreal and Godot differ chiefly in language, licence and default strengths, and a licence is part of your technology stack, as 2023 demonstrated.
11. Entity-component-system layouts win on speed because contiguous component arrays match how caches and prefetchers work.
12. The asset pipeline converts editor formats into platform-specific runtime formats, a process Unreal calls cooking; shader permutations and lightmap baking are why builds take hours.
13. Physics is broad phase, narrow phase, and impulse-based resolution; momentum is conserved and restitution controls how much energy is lost.
14. Floating-point results are not reproducible across machines in general, which is why deterministic lockstep networking is hard.
15. Game AI is state machines, behaviour trees, utility scoring, planners and A-star pathfinding, deliberately weakened so that fighting it is fun.
16. A rendered frame is culling, batching, sorting, shadow passes, a forward or deferred lighting pass, transparency, post-processing, then interface.
17. Latency cannot be removed, only hidden: client-side prediction, server reconciliation, entity interpolation and lag compensation together explain why you get shot after reaching cover.
18. The client can never be trusted; server-side validation and not sending invisible data are the only defences that cannot be patched out.
19. Launch is loader, launcher, anti-cheat, device and swap chain creation, shader compilation, streaming and finally the loop, which is why the first run stutters and consoles do not.
20. Start tiny, cut ruthlessly, playtest silently, and publish. Scope, not skill, is what ends most projects.

Machine Learning From Scratch — Fitting, Loss, Gradients and Neural Networks

46.0 What this chapter gives you

1. You will be able to say exactly what machine learning is, in one sentence, without using the word “intelligence”, and explain how it differs from ordinary programming with a concrete example of both.
2. You will be able to tell the honest history: the perceptron, two winters, the support vector machine years, and why 2012 changed everything.
3. You will be able to fit a straight line to five points by hand, define what a parameter is, and compute the error of your fit two different ways.
4. You will be able to explain gradient descent to someone who has never seen a derivative, then work four steps of it on paper with real numbers.
5. You will be able to use the words sample, feature, label, epoch, batch, iteration and step correctly, and never confuse them again.
6. You will be able to read a training curve and say whether the model is underfitting, overfitting, or learning properly.
7. You will be able to name the main classical methods, say when each is the right tool, and explain why neural networks are not always the answer.
8. You will be able to describe one artificial neuron exactly, compute its output by hand, and prove in two lines why a network with no activation function is worthless.
9. You will be able to explain backpropagation in plain language as blame assignment, then do a complete backward pass through a small network with real numbers.
10. You will be able to say what a trained model physically is, and why training costs so much more than using the result.

46.1 What machine learning actually is

■ 46.1.1 PLAIN – in simple words

1. In ordinary programming you know the rule, and you write it down.
2. You want to convert Celsius to Fahrenheit, so you write: multiply by 1.8, then add 32. Done. The rule was in your head and now it is in the file.
3. Machine learning is for the other case: you do not know the rule, but you have a pile of examples of the rule working.
4. You have ten thousand emails, each already marked “spam” or “not spam”. You cannot write the rule that separates them. Nobody can.

5. So you do something different. You write down a **shape** for a rule, with blank spaces in it where numbers should go.
6. Then you write a procedure that fills in those numbers, by trying, checking against the examples, and adjusting.
7. When the procedure stops, the blanks are full. Those numbers are the rule.
8. Nobody wrote them. Nobody can read them. But they work on the examples, and usually on new cases too.
9. That is the whole of machine learning. A rule-shaped thing with adjustable numbers, plus a procedure that tunes the numbers to match examples.
10. At heart this is curve fitting: finding the settings that make a formula pass close to a set of points.
11. Saying “it is just curve fitting” is not dismissive. It is accurate, and the accuracy is what lets you reason about it.
12. Curve fitting in a space of a billion adjustable numbers, on data covering most of what humans have written, does astonishing things. It is still curve fitting.

■ 46.1.2 PLAIN – a picture in your head

1. Picture a sound mixing desk with a hundred sliders on it.
2. Each slider changes the sound a little. You do not know what any single one does, and no slider has a label.
3. Someone plays you a recording of how the finished mix should sound.
4. Your job is to move the sliders until what comes out of the speakers matches the recording.
5. You cannot solve this by thinking. You have to move sliders and listen.
6. So you make a small move, listen, and ask one question: closer or further?
7. If closer, keep going that way. If further, go back the other way.
8. Do this over and over, for all hundred sliders, thousands of times, and the mix creeps towards the target.
9. At the end you have a hundred slider positions that produce the right sound. You still cannot say what any one slider does.
10. The sliders are the parameters. The recording is the training data. The listening is the loss. The nudging is the optimizer.

Where this comparison breaks: a real sound engineer knows what each slider does, so they aim. Nothing here aims. Also, real learning does not move one slider and listen. It computes, in one shot, the direction every slider should move, all at once. That computation is called backpropagation and it is the single most important idea in the chapter. Finally, a mix only has to sound right once. A model has to work on sounds it has never heard, which is a much harder demand and the source of nearly every practical problem in the field.

■ 46.1.3 PLAIN – a worked example

1. Take spam detection. First, the hand-written way.

```
def is_spam_handwritten(email):
    subject = email.subject.lower()
    if "free" in subject and email.link_count > 3:
        return True
    if "viagra" in email.body.lower():
        return True
    if email.sender not in email.user_contacts:
        if email.exclamation_count > 5:
```

```

        return True
    return False

```

2. Every line of that was decided by a person. You can read it, argue with it, and fix it. Those are real advantages and they are often undervalued.
3. Now the failure. A spammer writes “FR33” instead of “free”. The rule misses.
4. You add a rule for “FR33”. They write “F.R.E.E”. You add another rule.
5. This is a race you lose, because there are more spellings than there are hours in your life.
6. Now the learned way. You do not write rules. You write a shape.
7. The shape: give every word a number, called its weight. Add up the weights of the words present. If the total is above zero, call it spam.
8. That shape has one blank per word in the vocabulary. Say 50,000 blanks.
9. You feed in 10,000 emails already marked spam or not, and let the tuning procedure fill the blanks. Afterwards the numbers look like this:

Word	Learned weight	Effect
viagra	+4.10	strong spam signal
unsubscribe	+1.35	mild spam signal
meeting	-2.60	strong not-spam
the	+0.01	says nothing
fr33	+3.80	learned, never typed

10. Nobody told the system about “fr33”. It appeared in spam in the training data, so it got a large positive weight automatically.
11. That is the real difference. The hand-written rule needed a human to notice each trick. The learned rule needs only examples containing the trick.
12. Test one email with the words “free”, “meeting” and “unsubscribe”, with weights +2.20, -2.60 and +1.35. Total: $2.20 - 2.60 + 1.35 = +0.95$.
13. Above zero, so it says spam. It is probably wrong, because “meeting” should have carried more. That is a failure of the training data, not of the idea.
14. Both approaches fail. The difference is how they fail and how you fix them. You fix the first with a code change. You fix the second with more data.

■ 46.1.4 PLAIN – what is really happening inside

1. Every machine learning system has exactly four pieces. Learn these four and nothing later will surprise you.
2. Piece one, the **model**: the shape of the rule, with blanks. A straight line, a tree of yes-or-no questions, or a network with a billion blanks.
3. Piece two, the **parameters**: the numbers that go in the blanks. Before training they are random or fixed. After training they are the answer.
4. Piece three, the **loss**: a single number saying how wrong the current parameters are on the examples. Lower is better. Zero would be perfect.
5. Piece four, the **optimizer**: the procedure that changes the parameters to make the loss smaller.
6. Training is a loop over these four. Predict with current parameters. Measure the loss. Work out which way each parameter should move. Move them a little. Repeat, often millions of times.
7. Notice what has been swapped. In ordinary programming, the logic is the thing you write and the data is what flows through it.

8. In machine learning, the data is the thing you provide and the logic is what comes out. The data has become the specification.
9. That single swap explains almost everything strange about the field. Bad data gives a bad model, in exactly the way a bad specification gives bad software, and for exactly the same reason.
10. It also explains why debugging feels so different. There is no line to step through. There is only a distribution of examples, and a number.

■ 46.1.5 TECHNICAL – the engineer’s version

1. The term was coined by Arthur Samuel of IBM, in his 1959 paper “Some Studies in Machine Learning Using the Game of Checkers”, in the IBM Journal of Research and Development. His program ran on an IBM 701.
2. The standard formal definition is Tom Mitchell’s, from his 1997 textbook Machine Learning: a program learns from experience E with respect to task T and performance measure P , if its performance at T , measured by P , improves with E .
3. Formally: choose a hypothesis class H , a set of functions parameterized by a vector θ . Choose a loss function L . Find θ that minimizes the average loss over the training data.
4. That last step is called **empirical risk minimization**. “Empirical” because you minimize measured loss on data you have, not true loss on data you do not have. The gap between the two is the whole subject of generalization.
5. The linear spam model above is logistic regression on a bag-of-words feature vector. It was the industry standard for spam filtering from the late 1990s, alongside naive Bayes, which Paul Graham popularized with his 2002 essay A Plan For Spam.
6. Side by side:

Aspect	Ordinary program	Learned model
You supply	logic	labelled examples
System supplies	output	logic (as numbers)
Debug by	reading code	inspecting data
Fails by	wrong branch	wrong distribution

7. Established fact: the “rule-shaped thing plus optimizer” description above is complete and correct for essentially every supervised learning system in production today, including the largest language models.
8. Marketing claim: that these systems reason, understand, or think. Those words have no agreed technical definition here, and vendors use them because they are unfalsifiable. Treat them as advertising until defined.
9. Active research: whether large models build internal structures that deserve to be called world models or algorithms rather than statistics. The field of mechanistic interpretability studies this. It is genuinely open, and serious researchers disagree, so do not let anyone tell you it is settled.

■ 46.1.6 WORDS – remember these

1. Machine learning — filling in blanks in a rule from examples — fitting the parameters of a hypothesis class by minimizing empirical risk.
2. Model — the shape of the rule, with blanks — the hypothesis class, a parameterized family of functions.
3. Parameter — a number the system may change during training — a component of the weight vector θ , learned by optimization.

4. Loss — one number saying how wrong you are — a scalar objective function measuring disagreement between prediction and target.
5. Optimizer — the procedure that changes the numbers — the algorithm that updates theta to reduce the loss, usually a gradient method.
6. Curve fitting — finding settings that make a formula pass near the points — function approximation from finite samples. An accurate description, not an insult.

46.2 A short honest history

■ 46.2.1 PLAIN - in simple words

1. This field is older than most people think, and it has failed publicly at least twice. Knowing that keeps you sane during the hype.
2. In 1943 two researchers, Warren McCulloch and Walter Pitts, wrote down a simple mathematical model of a nerve cell. That is where it starts.
3. In 1957 and 1958 Frank Rosenblatt built the **perceptron**, a machine that learned to tell simple pictures apart by adjusting numbers.
4. The press coverage was wild, and far ahead of the reality. That is a pattern you will see again in your lifetime.
5. In 1969 two respected researchers proved the perceptron could not do certain very simple things. Funding collapsed. This is called the first AI winter.
6. The fix, an algorithm for training networks with more layers, was invented several times between 1970 and 1974, and mostly ignored.
7. In 1986 it was published clearly, in a famous journal, and the field came back. Then it faded again in the early 1990s. Second winter.
8. Through the late 1990s and 2000s a different family of methods, based on clean mathematics rather than networks, did better in practice.
9. In 2012 a neural network won a big image contest by such a large margin that the argument ended in a single afternoon.
10. The thing that made 2012 possible was not a new idea. It was cheap parallel arithmetic hardware, plus a very large labelled dataset.

■ 46.2.2 PLAIN - a picture in your head

1. Think of a seed planted in soil that is too poor to grow it.
2. The seed is the idea of learning by adjusting numbers. It was planted in 1958 and it was a good seed.
3. The soil is three things: computing power, data, and algorithms.
4. In 1958 there was almost no computing power, almost no data, and only a one-layer algorithm. The seed sprouted and died.
5. In 1986 the algorithm arrived. Compute was better, data was still thin. The seed sprouted higher and died again.
6. By 2012 all three were rich at once: graphics chips gave the compute, the internet gave the data, and the 1986 algorithm was still sitting there unchanged. The seed grew into a tree.
7. Almost nothing about the seed changed across those fifty-four years.

Where this comparison breaks: the algorithms did improve, and pretending otherwise is unfair to a great deal of careful work. Better activation functions, better initialization, better normalization and better optimizers each moved the field, and without them the 2012 result would not have trained at all.

The honest version: compute and data were the necessary conditions, and a decade of unglamorous engineering was what turned “possible in principle” into “trains on a Tuesday”.

■ 46.2.3 PLAIN – a worked example

1. The overclaim of 1958, in detail, because it teaches you how to read news about this field.
2. Rosenblatt built the Mark I Perceptron at the Cornell Aeronautical Laboratory in Buffalo, New York, funded by the Office of Naval Research.
3. It had a 20 by 20 grid of 400 light sensors, so it saw a 400-pixel picture.
4. Its adjustable numbers were physical. They were potentiometers, small dials, turned by electric motors during training. You could watch the machine learn by watching the dials move.
5. It could learn to tell simple shapes apart. It genuinely worked, and that was a real achievement.
6. In July 1958 The New York Times reported the Navy’s expectation that the machine would be able to “walk, talk, see, write, reproduce itself and be conscious of its existence”.
7. It could sort simple shapes. The gap between those two sentences is the entire lesson of this section.
8. Eleven years later, Marvin Minsky and Seymour Papert published the book *Perceptrons*, in 1969, showing what one layer could not do.
9. Their killer example was XOR: output 1 if exactly one of two inputs is 1. Here is the whole problem.

x2			
1		1	0
0		0	1
	+	-----	
		0	1
			x1

1 means "should output 1"

A single straight line must put both 1s on one side.
No straight line can. That is the entire objection.

10. A one-layer perceptron can only draw a straight dividing line. XOR needs two lines, or a bent one. So one layer cannot do XOR.
11. That was mathematically correct and it was fatal in practice, because nobody yet had a working way to train two layers.
12. Minsky and Papert did say multi-layer networks were more capable. The reception of the book was harsher than its text, which is common.

■ 46.2.4 PLAIN – what is really happening inside

1. Why did the training method take so long to arrive, when the mathematics is just repeated use of the chain rule from school calculus.
2. Because nobody was looking for it in the place it was found. The reverse accumulation method was worked out for a completely different purpose.
3. In 1970 Seppo Linnainmaa, in his master’s thesis at the University of Helsinki, described how to compute the derivative of a whole computation efficiently by walking backwards through it.
4. His subject was rounding error in numerical algorithms. He was not thinking about learning at all. The algorithm was correct and general anyway.
5. In 1974 Paul Werbos, in his Harvard PhD thesis, applied that idea directly to training neural networks. Very few people read it.
6. In 1986 David Rumelhart, Geoffrey Hinton and Ronald Williams published “Learning representations by back-propagating errors” in *Nature*. Same idea, clearly written, in a journal everyone read, with results.

7. The lesson is not about mathematics. It is that an idea has to arrive in a readable form, in a place the right people look, at a moment when the hardware can demonstrate it.
8. The second winter came after 1987 for practical reasons: networks of the day were slow to train, needed careful hand-tuning, and were beaten on real tasks by simpler methods with better theory.
9. What broke the deadlock in 2012 was throughput. A graphics chip does the same arithmetic operation on thousands of numbers at once, which is exactly the shape of a neural network's work.

■ 46.2.5 TECHNICAL – the engineer's version

1. The timeline, with the facts you should be able to quote.

Year	Event	Why it mattered
1943	McCulloch and Pitts model	first formal neuron
1949	Hebb, Organization of Behavior	learning as weight change
1957	Rosenblatt perceptron report	first learning machine
1958	NYT overclaim	first hype cycle
1960	Widrow and Hoff ADALINE	least-mean-squares rule
1962	Novikoff convergence proof	perceptron theory
1969	Minsky and Papert book	XOR objection
1970	Linnainmaa thesis	reverse-mode derivatives
1973	Lighthill report, UK	funding cut
1974	Werbos thesis	backprop for networks
1980	Fukushima Neocognitron	ancestor of the CNN
1982	Hopfield networks	physics enters the field
1986	Rumelhart, Hinton, Williams	backprop reaches everyone
1989	LeCun, digits at Bell Labs	first real CNN application
1989	Cybenko approximation proof	one layer is enough, in theory
1995	Cortes and Vapnik, SVM	networks fall out of fashion
1997	Hochreiter and Schmidhuber	LSTM for sequences
1998	LeCun LeNet-5	cheque reading in production
2001	Breiman random forests	strong, simple, tabular
2006	Hinton deep belief nets	the name "deep learning"
2007	NVIDIA releases CUDA	general compute on GPUs
2009	ImageNet dataset published	a large labelled image corpus
2012	AlexNet wins ILSVRC	the argument ends
2014	GANs; Adam optimizer	generation; default optimizer
2015	ResNet; batch normalization	very deep networks train
2016	AlphaGo beats Lee Sedol	4-1, March 2016
2017	Attention Is All You Need	the transformer
2020	GPT-3; scaling laws	size as a strategy
2022	ChatGPT, 30 November	public arrival
2024	Nobel Prize in Physics	Hopfield and Hinton

2. The 2012 result, precisely. AlexNet, by Alex Krizhevsky, Ilya Sutskever and Geoffrey Hinton, won the ImageNet Large Scale Visual Recognition Challenge with a top-5 error rate of 15.3 percent. The second-placed entry, which did not use deep learning, scored 26.2 percent.
3. A gap of nearly 11 percentage points in a contest usually decided by one is why the field turned in a single day.

4. The training set was about 1.2 million images across 1,000 categories. The network had roughly 60 million parameters, most of them in its fully connected layers.
5. It was trained on two NVIDIA GTX 580 cards with 3 GB of memory each, for about five to six days. The 3 GB limit is why the network was split across two cards at all. A hardware constraint shaped the architecture.
6. Chapter 22 explained what a graphics chip is and why it multiplies matrices so quickly. The short version, without repeating it: these chips run thousands of identical arithmetic operations in parallel, and a neural network is thousands of identical arithmetic operations. The fit is exact and it was an accident of history.
7. ImageNet itself, led by Fei-Fei Li and published at CVPR in 2009, was arguably the more important contribution. Without a large, clean, labelled dataset there is nothing to fit.
8. The support vector machine era rests on Corinna Cortes and Vladimir Vapnik's 1995 paper "Support-Vector Networks", building on the kernel trick from Bernhard Boser, Isabelle Guyon and Vapnik in 1992. From roughly 1995 to 2010 these methods usually beat neural networks on the benchmarks of the day, and had far better theory.
9. Hinton, Yoshua Bengio and Yann LeCun shared the 2018 Turing Award, presented in 2019. In October 2024 John Hopfield and Geoffrey Hinton received the Nobel Prize in Physics for foundational discoveries enabling machine learning with artificial neural networks.
10. Historical note on naming: "backpropagation" is a shortening of "backward propagation of errors", from the 1986 Nature paper title.

■ 46.2.6 WORDS - remember these

1. Perceptron — the first machine that learned by adjusting dials — a single linear threshold unit with the 1958 update rule, convergent on linearly separable data.
2. AI winter — a period when funding and interest collapsed — the funding contractions of roughly 1974 to 1980 and 1987 to 1993.
3. XOR problem — the simple task one layer cannot do — a function that is not linearly separable, the core objection of Perceptrons, 1969.
4. Backpropagation — the way to find how each number should change — reverse-mode automatic differentiation applied to a layered network.
5. ImageNet — the giant labelled picture collection — the dataset of about 14 million images, and its annual challenge, ILSVRC, run from 2010.
6. AlexNet — the network that won in 2012 and ended the argument — an eight-layer CNN, 60 million parameters, 15.3 percent top-5 error.

46.3 Fitting a line, the foundation of everything

■ 46.3.1 PLAIN - in simple words

1. Everything in this chapter is an elaboration of one small task: draw the best straight line through some dots on a graph.
2. Understand this properly and the rest is bookkeeping.
3. You have pairs of numbers. For each one, an input and an output.
4. Hours studied and exam mark. Size of a flat and its rent. Anything.
5. Plot them. They do not lie on a perfect line, because reality is messy, but they lean in a direction.
6. You want the line that leans the same way and sits as close to all the dots as it can.
7. A straight line is described completely by two numbers. Just two.
8. The first is how steep it is. Call it w . If w is 2, then every step right makes the line go up two.

9. The second is how high it sits. Call it b . It is the height of the line where the input is zero.
10. So the line is: output equals w times input, plus b . Written short: $y = wx + b$.
11. Those two numbers, w and b , are the only things you are allowed to change.
12. A number the system is allowed to change to fit the data is called a **parameter**. This is the definition that carries through the whole book.
13. A straight-line model has two parameters. A large language model has hundreds of billions. There is no difference in kind, only in count.

■ 46.3.2 PLAIN – a picture in your head

1. Picture a long straight stick and a scattering of nails hammered into a board at different heights.
2. You must hold the stick against the board so it passes as close as possible to all the nails at once.
3. You have exactly two freedoms. You can slide the stick up and down, and you can tilt it.
4. Sliding up and down is b . Tilting is w . There is nothing else you can do to a straight stick.
5. Now the useful part. Suppose the nails clearly climb from left to right and your stick is flat. You can see immediately that tilting it will help.
6. Suppose the stick is at the right tilt but all the nails are above it. You can see that sliding it up will help.
7. That “you can see which way to move it” feeling is exactly the gradient. You already have the intuition. Later we just compute it instead of eyeballing.

Where this comparison breaks: with two freedoms you can see the whole board and judge both at once. With a million freedoms you cannot see anything. You can only ask, at your current position, which way is downhill, and take a step. Your entire view of the landscape is the slope under your feet.

■ 46.3.3 PLAIN – a worked example

1. Here is the dataset used for the whole of this chapter. Five points. Learn them, because they come back three more times.

x	y
1	2
2	4
3	5
4	4
5	5

2. Plotted, they rise, but not smoothly. The fourth point dips.

3. First, a guess. Try $w = 1$ and $b = 0$, the line $y = x$.
4. Predictions: 1, 2, 3, 4, 5. Actual values: 2, 4, 5, 4, 5.

5. It is too low at the start and too low in the middle. Not good.
6. Now do it properly. The best straight line under the usual error measure has a formula, and we work it by hand.
7. Average of the x values: $(1+2+3+4+5) / 5 = 15 / 5 = 3$.
8. Average of the y values: $(2+4+5+4+5) / 5 = 20 / 5 = 4$.
9. Now for each point, take x minus 3, and y minus 4, and multiply them.

x-3	y-4	product	(x-3) squared
-2	-2	4	4
-1	0	0	1
0	1	0	0
1	0	0	1
2	1	2	4

10. Sum of the products: $4 + 0 + 0 + 0 + 2 = 6$.
11. Sum of the squares: $4 + 1 + 0 + 1 + 4 = 10$.
12. The slope is the first divided by the second: $w = 6 / 10 = 0.6$.
13. The height is the average y minus w times the average x: $b = 4 - (0.6 \times 3) = 4 - 1.8 = 2.2$.
14. So the best line is $y = 0.6x + 2.2$. Those two numbers are the trained model. That is the whole model. Two numbers.
15. Its predictions on our five inputs: 2.8, 3.4, 4.0, 4.6, 5.2.
16. Compare to the actual values 2, 4, 5, 4, 5. Close, never exact. That is normal and expected.

■ 46.3.4 PLAIN - what is really happening inside

1. Notice what happened there. We did not search. We solved.
2. For a straight line under squared error, there is a formula that lands on the exact best answer in one calculation. No stepping, no guessing.
3. This is called a closed-form solution. It exists for this problem because the problem is simple enough to solve with algebra.
4. Here is the important fact: for almost every model you will ever use, no such formula exists.
5. Add a bend to the curve, add a threshold, add a second layer, and the algebra stops closing. There is no formula to solve.
6. When you cannot solve, you search. You start somewhere, look at which way is downhill, and step. That is section 46.5.
7. So the line is the perfect teaching example, precisely because you can check the search against the exact answer.
8. We know the truth is $w = 0.6$, $b = 2.2$. When gradient descent creeps towards 0.6 and 2.2 later in this chapter, you will know it is working.
9. One more thing to notice. The model has no memory of the five points. After training, all that is left is 0.6 and 2.2. The data is thrown away.
10. That is true of every trained model, from this line to the largest network. The data shaped the parameters and then went home.

■ 46.3.5 TECHNICAL - the engineer's version

1. The method is ordinary least squares. Adrien-Marie Legendre published it in 1805. Carl Friedrich Gauss published in 1809 and claimed use from 1795. The priority dispute is real and unresolved.

- The closed form for simple linear regression: w equals the sample covariance of x and y divided by the sample variance of x , and b equals the mean of y minus w times the mean of x .
- In matrix form for many features, the normal equation is θ equals the inverse of X -transpose- X , times X -transpose- y .
- Computing that inverse directly is a mistake in practice. Numerically stable implementations use a QR decomposition or a singular value decomposition. The function `numpy.linalg.lstsq` uses SVD.
- Cost: the normal equation is order n times d squared, where n is samples and d is features. At d equal to 100,000 features the d -squared term is fatal, which is one practical reason iterative methods win at scale.

```
import numpy as np
x = np.array([1, 2, 3, 4, 5], dtype=float)
y = np.array([2, 4, 5, 4, 5], dtype=float)
A = np.vstack([x, np.ones_like(x)]).T
w, b = np.linalg.lstsq(A, y, rcond=None)[0]
print(w, b)           # 0.6  2.2
```

- Terminology, and be careful here. In statistics these two numbers are “coefficients” and the model is a “regression”. In machine learning they are “weights” and “bias”, and the model is a “linear layer with one output”. Same equation, two vocabularies, two research communities.
- Parameter** has a precise meaning: a value learned from data by the optimization procedure. A **hyperparameter** is a value you choose before training, which the optimizer never touches. The learning rate is a hyperparameter. The slope is a parameter. Confusing these two is the single most common vocabulary error in the field.
- Scale check for intuition:

Model	Parameters	Fits on
Straight line	2	paper
LeNet-5, 1998	about 60,000	any laptop
ResNet-50, 2015	25.6 million	one GPU
GPT-2 XL, 2019	1.5 billion	one GPU
GPT-3, 2020	175 billion	a cluster

■ 46.3.6 WORDS – remember these

- Parameter — a number the system may change to fit the data — a learned component of θ , updated by the optimizer.
- Hyperparameter — a setting you choose before training starts — a value outside θ , fixed during optimization, tuned on validation data.
- Weight — how strongly an input pushes the output — the multiplicative coefficient applied to an input feature.
- Bias — the fixed offset added regardless of input — the additive intercept term, allowing the fit to leave the origin.
- Slope — how steep the line is — the first derivative of output with respect to input, constant for a linear model.
- Closed form — an exact answer from one formula — an analytic solution, such as the normal equation, available only for simple models.

46.4 Loss: how you measure being wrong

■ 46.4.1 PLAIN – in simple words

1. To improve something you must first be able to score it.
2. The score here is called the **loss**. It is one number. It says how badly the current parameters do on the examples.
3. Lower is better. Zero would mean perfect on every example.
4. The obvious idea is to add up how far each prediction is from the truth.
5. But there is a trap. If one prediction is 3 too high and another is 3 too low, they cancel to zero, and the model looks perfect when it is not.
6. So you must remove the sign before adding. There are two natural ways.
7. First way: square each miss. A miss of 3 becomes 9. Squares are never negative, so nothing cancels. Average the squares. That is **mean squared error**.
8. Second way: drop the minus sign on each miss. A miss of minus 3 becomes 3. Average those. That is **mean absolute error**.
9. Both are sensible. They are not the same, and the choice changes what the model learns.
10. Squaring punishes big misses much harder. A miss of 10 counts a hundred times more than a miss of 1, not ten times more.
11. So squared error makes the model terrified of large mistakes, and willing to accept many small ones to avoid one large one.
12. Absolute error treats a miss of 10 as exactly ten misses of 1. It does not panic about outliers.
13. The loss is not a description of reality. It is your statement of what you care about. The model will optimize exactly what you asked for, including the parts you did not mean.

■ 46.4.2 PLAIN – a picture in your head

1. Imagine you are a delivery company and you must score your drivers.
2. Scheme one: fine a driver the square of the minutes late. Five minutes late costs 25. Twenty minutes late costs 400.
3. Under that scheme a driver will do almost anything to avoid one very late delivery, and will happily be three minutes late on many.
4. Scheme two: fine one unit per minute late, always. Twenty minutes late costs 20, exactly four times what five minutes costs.
5. Under that scheme a driver optimizes total minutes and will let one delivery run very late if it saves a little time on several others.
6. Neither scheme is wrong. They encode different values.
7. And here is the point: the drivers are not cheating. They are doing exactly what you asked. If the result is bad, your scoring scheme was bad.

Where this comparison breaks: drivers understand the rule and plan around it. A model has no plan and no understanding. It only follows the slope of the number you defined. That is worse in one way, because it will exploit loopholes no honest person would notice, and better in another, because it is not trying to deceive you. The honest version: a model does not “game” the loss. The loss is its entire universe. There is nothing else to game.

■ 46.4.3 PLAIN – a worked example

1. Take the five points again and our fitted line $y = 0.6x + 2.2$.
2. Compute every step of the mean squared error.

Point (x, y)	predicted	error	squared
(1, 2)	2.8	+0.8	0.64
(2, 4)	3.4	-0.6	0.36
(3, 5)	4.0	-1.0	1.00
(4, 4)	4.6	+0.6	0.36
(5, 5)	5.2	+0.2	0.04

3. Error means predicted minus true. Sign kept for now.
4. Sum of the squared column: $0.64 + 0.36 + 1.00 + 0.36 + 0.04 = 2.40$.
5. Divide by the number of points: $2.40 / 5 = 0.48$.
6. Mean squared error is 0.48. Written as a formula:

$$\begin{aligned} \text{MSE} &= (1/n) * \text{sum over } i \text{ of } (w * x_i + b) - y_i)^2 \\ n &= 5 \\ &= (1/5) * (0.64 + 0.36 + 1.00 + 0.36 + 0.04) \\ &= (1/5) * 2.40 \\ &= 0.48 \end{aligned}$$

7. Now mean absolute error on the same fit. Drop the signs: 0.8, 0.6, 1.0, 0.6, 0.2. Sum is 3.2. Divide by 5: 0.64.
8. Note that the errors were not squared, so the answer is in the same units as
 - y. An MAE of 0.64 means “typically wrong by about 0.64 marks”. An MSE of 0.48 is in squared marks, which is not a unit anyone can feel.
9. Taking the square root of MSE gives 0.693, the root mean squared error, back in the original units. That is why people quote RMSE in reports.
10. Now the demonstration that the choice matters. Add a sixth point that is wildly wrong: $x = 6, y = 20$. Perhaps a data entry error.
11. Refit with squared error. The best line becomes $y = 2.629x - 2.533$.
12. The slope went from 0.6 to 2.63. One bad point out of six dragged the whole line more than four times steeper.
13. Refit with absolute error. The best line becomes $y = 1.5x + 0.5$.
14. Still moved, but far less. The absolute-error fit largely ignored the outlier while the squared-error fit chased it.
15. That is not a small technical detail. That is the loss deciding what the model believes.

■ 46.4.4 PLAIN – what is really happening inside

1. Now the idea that makes optimization possible: the **loss surface**.
2. The loss depends on the parameters. Change w , the loss changes. Change b , the loss changes.
3. So imagine a flat map. East-west is the value of w . North-south is the value of b . Every point on that map is one possible model.
4. At every point, compute the loss and use it as a height. Now you have a landscape.
5. High ground means bad parameters. Low ground means good ones.
6. Training is walking downhill on this landscape. That is the entire idea.

7. For our five points, here is the real landscape. Every number is a genuine mean squared error, computed for that pair of w and b .

	$w=0.0$	$w=0.3$	$w=0.6$	$w=0.9$	$w=1.2$
$b=4.4$	1.36	2.35	5.32	10.27	17.20
$b=3.3$	1.69	0.70	1.69	4.66	9.61
$b=2.2$	4.44	1.47	0.48*	1.47	4.44
$b=1.1$	9.61	4.66	1.69	0.70	1.69
$b=0.0$	17.20	10.27	5.32	2.35	1.36

* lowest point: $w=0.6$, $b=2.2$

8. Read it like a contour map. The 0.48 in the middle is the valley floor. That is exactly the answer we computed by formula in section 46.3.
9. Look at the diagonal. Going from top-left to bottom-right, the values stay small: 1.36, 0.70, 0.48, 0.70, 1.36. That is a long shallow trough.
10. Going the other diagonal, values shoot up fast: 1.36 to 17.20.
11. So this valley is not a round bowl. It is a long narrow ravine, steep across and shallow along. Remember that shape. It causes most of the pain in section 46.5.
12. The reason the ravine is tilted is that w and b are not independent here. Making the line steeper and lowering it can partly cancel out.

■ 46.4.5 TECHNICAL - the engineer's version

1. The standard losses, with the situation each belongs to.

Loss	Formula core	Used for
MSE / L2	mean of $(\text{pred} - y)^2$	regression, default
MAE / L1	mean of $\text{abs}(\text{pred} - y)$	regression, outliers
Huber	L2 near 0, L1 far out	robust regression
Binary cross-entropy	$-y \log p - (1-y) \log(1-p)$	two-class
Cross-entropy	$-\sum y_k \log p_k$	many-class

2. Mean squared error is the maximum likelihood estimator under the assumption that the errors are Gaussian with constant variance. That is where it comes from. It is not an arbitrary choice.
3. Mean absolute error is the maximum likelihood estimator under Laplace- distributed errors, and its minimizer is the conditional median rather than the conditional mean. That is exactly why it resists outliers.
4. MSE has a continuous derivative everywhere. MAE has a kink at zero where the derivative jumps from -1 to +1 and is undefined at the point itself. Implementations return 0 or a subgradient there. This is a real, if minor, optimization nuisance.
5. Huber loss, from Peter Huber's 1964 paper, is quadratic within a threshold δ of zero and linear outside it. It gets MSE's smooth gradients near the optimum and MAE's outlier resistance far away. In object detection the same idea appears as smooth L1 loss.
6. For classification you almost never use MSE. Cross-entropy is standard, because its gradient with respect to the pre-activation of a softmax output is simply predicted probability minus target, which is clean and does not saturate. MSE combined with a sigmoid output produces vanishing gradients when the model is confidently wrong, which is the worst possible time.
7. The loss surface of linear regression under MSE is a convex quadratic, so it has exactly one minimum and no local traps. Its Hessian for our five points is the matrix with rows $[22, 6]$ and $[6, 2]$.

8. That matrix has eigenvalues 23.66 and 0.338. The ratio, 70.0, is the condition number. It is the numerical measure of the ravine we saw above, and it directly bounds how fast gradient descent can converge.
9. Observation tools: log the loss every step and plot it. In PyTorch a scalar `loss.item()` per step written to TensorBoard, Weights and Biases, or a plain CSV is enough. Anyone who trains without a loss curve is guessing.

■ 46.4.6 WORDS – remember these

1. Loss — one number saying how wrong you are — a scalar objective evaluated on predictions and targets, to be minimized.
2. Mean squared error — average of the squared misses — the L2 loss, maximum likelihood under Gaussian noise, minimized by the conditional mean.
3. Mean absolute error — average of the misses, signs dropped — the L1 loss, minimized by the conditional median, robust to outliers.
4. Loss surface — the landscape of wrongness over parameter settings — the graph of the objective as a function of theta, in as many dimensions as there are parameters.
5. Outlier — a data point far from the rest — an observation with low probability under the assumed noise model, which dominates squared loss.
6. Cross-entropy — the standard score for choosing between categories — the negative log-likelihood of the correct class under the predicted distribution.

46.5 Gradient descent: walking downhill in fog

■ 46.5.1 PLAIN – in simple words

1. You are standing somewhere on a hillside. Thick fog. You can see nothing beyond your own boots.
2. You want to reach the lowest point in the valley.
3. You cannot see the valley. But you can feel the ground under your feet, and feel which way is downhill.
4. So you do the only sensible thing. You take a small step in the steepest downhill direction. Then you stop and feel again. Then step again.
5. Repeat a few thousand times and you will end up at the bottom of something.
6. That is gradient descent. That is the entire algorithm. Everything else in this section is detail.
7. Translate it. The hillside is the loss surface from section 46.4. Your position is the current values of the parameters.
8. “Feeling which way is downhill” means computing, for each parameter, whether increasing it makes the loss go up or down, and by how much.
9. That per-parameter answer is called the **gradient**. It is a list with one number per parameter.
10. The size of your step is called the **learning rate**. You choose it. It is a hyperparameter, and it matters enormously.
11. Every neural network you have heard of was trained this way. There is no more sophisticated principle hiding behind it.

■ 46.5.2 PLAIN – a picture in your head

1. Stay with the fog, but make the ground more interesting.
2. Suppose you are in a long narrow ravine, steep on the sides, almost flat along the bottom, running away into the fog.
3. You feel the ground. The steepest direction is across the ravine, not along it, because the sides are steep and the floor is nearly level.

4. So you step across. Now you are on the other side, slightly lower. You feel again. Steepest is back across.
5. You zig-zag from wall to wall, making painfully slow progress along the valley floor, which is where you actually needed to go.
6. That is the single most common failure of plain gradient descent, and our five-point problem has exactly this shape. Its condition number is 70, which means the ravine is seventy times steeper across than along.
7. The fixes all amount to remembering which way you were already going, so the zig-zags cancel and the along-valley movement adds up. That is momentum.

Where this comparison breaks: a real hiker can see their boots, feel the whole ground under them, and take a step of any size. A model computes the slope at exactly one point and then assumes the ground keeps that slope for the whole step. If the step is long and the ground curves, that assumption is wrong and you can land higher than you started. That is not a metaphor for divergence. It is literally what divergence is.

■ 46.5.3 PLAIN – a worked example

1. First, what “the slope” means for one parameter. Move w a tiny bit and see how much the loss moves.
2. At $w = 0.6$, $b = 2.2$, the loss is 0.48. At $w = 0.7$, $b = 2.2$, it is 0.58. The loss rose by 0.10 for a rise of 0.1 in w . So the slope is about +1.0.
3. Positive slope means increasing w increases the loss. So to reduce the loss, decrease w . Always move opposite to the slope. That is the rule.
4. The update rule, for every parameter:

$$\text{new value} = \text{old value} - (\text{learning rate}) * (\text{slope for it})$$

5. For mean squared error on a line, the two slopes have exact formulas:

$$\begin{aligned} \text{slope for } w &= (2/n) * \text{sum of } (w*x + b - y) * x \\ \text{slope for } b &= (2/n) * \text{sum of } (w*x + b - y) \end{aligned}$$

6. Now run it. Start at $w = 0$, $b = 0$, which is the flat line $y = 0$. Learning rate 0.02. Four full steps, all arithmetic shown.
7. Step 1. Predictions are all 0. Errors, predicted minus true, are -2, -4, -5, -4, -5.
8. Slope for w : $(2/5) \text{ times } [(-2)(1) + (-4)(2) + (-5)(3) + (-4)(4) + (-5)(5)] = (0.4) \text{ times } [-2 - 8 - 15 - 16 - 25] = 0.4 \text{ times } -66 = -26.4$.
9. Slope for b : $(2/5) \text{ times } [-2 - 4 - 5 - 4 - 5] = 0.4 \text{ times } -20 = -8.0$.
10. Update: $w = 0 - 0.02 \text{ times } (-26.4) = +0.528$. $b = 0 - 0.02 \text{ times } (-8.0) = +0.16$.
11. Both went up, which is right, because the line started far too low and far too flat.
12. Now the whole run in a table. Every number is exact.

Step	w	b	Loss
0	0.0000	0.0000	17.2000
1	0.5280	0.1600	5.5799
2	0.8045	0.2502	2.3494
3	0.9485	0.3037	1.4469
4	1.0227	0.3377	1.1904

13. The slopes computed at each of those positions were:

Step	Slope for w	Slope for b
0	-26.400	-8.000
1	-13.824	-4.512
2	-7.200	-2.673
3	-3.711	-1.702
4	-1.874	-1.188

14. Read the loss column. 17.20, then 5.58, then 2.35, then 1.45, then 1.19. It falls fast at first and then slows. That shape is normal and you will see it in every real training run.
15. Read the slope table. The slopes shrink towards zero. That is the ground flattening as you approach the valley floor.
16. But look at w. It has overshoot. It is 1.02 and the true answer is 0.6. And b is only 0.34 when the answer is 2.2.
17. That is the ravine. The optimizer raced along the steep w direction and is crawling along the shallow b direction.
18. Continue the run and it does get there, slowly:

Steps run	w	b	Loss
10	1.0870	0.4345	1.0471
100	0.8655	1.2416	0.6472
500	0.6176	2.1365	0.4807
2000	0.6000	2.2000	0.4800

19. Two thousand steps to find two numbers that a formula gave us instantly in section 46.3. That is the price of not having a formula. For any model worth training, there is no formula, so you pay it.
20. Notice also that the loss stops at 0.48 and does not reach zero. 0.48 is the best a straight line can do on this data. The remaining error is not a failure of the optimizer. The model simply is not a perfect description of the world, and no amount of training fixes that.

■ 46.5.4 PLAIN - what is really happening inside

1. Now the learning rate problem, with real numbers from the same dataset.
2. Too small: with a learning rate of 0.0001 instead of 0.02, every step is two hundred times shorter. You would need roughly 400,000 steps instead of 2,000. It works. It just wastes your week.
3. Too large: here is what happens at 0.09.

Step	w	b	Loss
0	0.000	0.000	17.20
1	2.376	0.720	21.60
2	-0.341	0.027	27.22
3	2.696	0.927	34.40
4	-0.766	0.024	43.58
5	3.114	1.154	55.30

4. The loss is going up, and it is going up faster each step. The parameters are flinging from one side of the ravine to the other, further each time.

5. This is **divergence**. Left alone it ends in numbers too large to represent, and the loss prints as nan, meaning not a number.
6. Seeing nan in a loss log means, in the overwhelming majority of cases, the learning rate was too high. Halve it and restart.
7. For this problem the exact boundary is computable: any learning rate below 0.0845 converges, and anything above diverges. At 0.02 we were safe. At 0.09 we were not.
8. Now a fact worth knowing. That boundary depends on how the input numbers are scaled. Our x values run 1 to 5, so their average is 3, far from zero.
9. Subtract 3 from every x, so they run -2 to +2 with an average of zero. Fit the same model. The condition number drops from 70 to 2, and the safe learning rate rises from 0.0845 to 0.5.
10. Nothing about the problem changed. We only recentred the inputs, and training became about thirty-five times easier.
11. That is why every practical guide tells you to normalize your inputs. It is not superstition. It reshapes the ravine into a bowl.
12. Finally, local minima. In a landscape with hills and dips, you might walk into a small dip that is not the true bottom, and get stuck.
13. In two dimensions this is a serious worry. In a million dimensions it is much less of one, and the reason is worth understanding.
14. To be a local minimum, the ground must curve upward in every single direction at once. With a million directions, that is like flipping a million coins and getting heads every time.
15. What you meet instead are saddle points: up in some directions, down in others. A saddle is not a trap. There is always a way out, though progress near one is slow.

■ 46.5.5 TECHNICAL - the engineer's version

1. The gradient of a scalar loss L with respect to a parameter vector θ is the vector of partial derivatives, written $\text{grad } L$. It points in the direction of steepest increase, so we step along its negative.
2. The update is θ at time $t+1$ equals θ at time t minus η times $\text{grad } L$, where η is the learning rate.
3. Convergence bound for a quadratic objective: plain gradient descent is stable if and only if η is less than 2 divided by the largest eigenvalue of the Hessian. For our five-point problem that is $2 / 23.66 = 0.0845$, which is exactly the boundary observed above.
4. The number of iterations to a fixed accuracy scales with the condition number, the ratio of largest to smallest eigenvalue. Ours was 70 raw and 2 after centring the inputs.
5. The three ways to choose how much data to use per step:

Variant	Data per step	Character
Batch (full)	all n samples	smooth, slow, exact
Stochastic (SGD)	1 sample	noisy, fast, jumpy
Mini-batch	32 to 8192	the practical default

6. Mini-batch is universal in practice. Batch sizes are usually powers of two, which is a convention rather than a requirement, chosen because it maps cleanly onto hardware. Common values are 32, 64, 128, 256.
7. The gradient noise from small batches is not purely harmful. It acts as a mild regularizer and helps escape sharp regions. Very large batches often generalize slightly worse unless the learning rate

is scaled up, an effect documented by Keskar and colleagues in 2017 and by Goyal and colleagues in the same year, whose linear scaling rule trained ImageNet in one hour.

8. The optimizer family, in order of invention:

Optimizer	Year	Core idea
Momentum	1964, Polyak	keep a velocity
Nesterov	1983	look ahead, then step
AdaGrad	2011, Duchi	per-parameter scaling
RMSProp	2012, Hinton	decaying squared average
Adam	2014, Kingma and Ba	momentum plus RMSProp
AdamW	2017, Loshchilov	Adam, decoupled decay

9. Momentum keeps a running velocity v : v becomes β times v plus the gradient, then θ moves by $-\eta$ times v . Typical β is 0.9, which means the step is roughly an average of the last ten gradients. In a ravine the across-valley components alternate in sign and cancel, while the along-valley components agree and accumulate.
10. RMSProp divides each parameter's step by the square root of a running average of that parameter's recent squared gradients. Parameters with consistently large gradients get shorter steps. Hinton introduced it in a 2012 Coursera lecture and never published it. It is cited as such.
11. Adam combines both: a running mean of the gradient, a running mean of the squared gradient, and a bias correction for the fact that both averages start at zero. Defaults from the paper: $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e-8$. These defaults are used almost unchanged a decade later.
12. AdamW, from Ilya Loshchilov and Frank Hutter, corrects how Adam applies weight decay. It is the standard for transformer training. Typical settings for large language model pretraining are $\beta_2 = 0.95$ and weight decay 0.1.
13. Practical starting learning rates, as of 2026, as rough guidance rather than law:

Setting	Optimizer	Typical rate
Small MLP or CNN	SGD + momentum	0.1 to 0.01
CNN fine-tuning	SGD + momentum	0.001
Transformer pretraining	AdamW	$1e-4$ to $3e-4$
Transformer fine-tuning	AdamW	$1e-5$ to $5e-5$

14. On saddle points: Dauphin and colleagues argued in 2014, in "Identifying and attacking the saddle point problem", that saddles rather than local minima are the dominant obstacle in high-dimensional non-convex optimization. This is the standard modern view, though the loss landscape of deep networks remains an area of active research rather than settled theory.

■ 46.5.6 WORDS – remember these

- Gradient — which way is uphill, and how steeply, for every parameter at once — the vector of partial derivatives of the loss with respect to θ .
- Gradient descent — repeatedly stepping downhill — iterative first-order minimization by moving against the gradient.
- Learning rate — how big a step you take — the scalar η multiplying the gradient in the update rule; a hyperparameter.
- Divergence — the loss climbing instead of falling — instability from a step size above 2 over the largest Hessian eigenvalue, usually ending in NaN.

5. Momentum — remembering the direction you were already going — an exponentially weighted moving average of past gradients, coefficient beta.
6. Adam — the optimizer most people use by default — adaptive moment estimation, combining momentum with per-parameter gradient scaling.
7. Saddle point — flat ground that is up one way and down another — a stationary point whose Hessian has both positive and negative eigenvalues.

46.6 The vocabulary of training

■ 46.6.1 PLAIN – in simple words

1. This field reuses ordinary words with narrow meanings, and half of all confusion comes from that. Fix the words now.
2. A **sample** is one example. One email. One photograph. One patient record. Also called an instance, an observation, or a row.
3. A **feature** is one measured property of a sample. The number of links in the email. The brightness of pixel 47. The patient's age.
4. A **label** is the right answer for that sample, provided by whoever made the data. "Spam". "Cat". "Recovered".
5. A **dataset** is all the samples together, with their labels.
6. Now the split, which is the most important habit in the field. You cut the dataset into three parts and treat them differently.
7. The **training set** is what the optimizer sees. The parameters are fitted to it. Usually 70 to 80 percent of the data.
8. The **validation set** is held back. You never train on it. You use it to choose between models and settings. Usually 10 to 15 percent.
9. The **test set** is held back even harder. You look at it once, at the very end, to report an honest number. Usually 10 to 15 percent.
10. Why three and not two? Because if you tune your settings by watching the validation score, you are indirectly fitting to it, so it stops being honest. The test set stays clean because you never used it to decide anything.
11. Now the counting words. An **epoch** is one complete pass through the whole training set.
12. A **batch** is a small group of samples processed together, typically 32 to 512 of them.
13. An **iteration**, also called a **step**, is one batch going through the model and producing one parameter update.
14. So: one step handles one batch, and one epoch is many steps.

■ 46.6.2 PLAIN – a picture in your head

1. A student is preparing for an exam and has a book of 500 practice questions with answers at the back.
2. Studying the questions is training. The 500 questions are the training set.
3. The real exam has different questions on the same subject. That is the test set. The student has never seen it.
4. Student A learns the ideas. On the exam, new questions, good marks. That is a model that generalizes.
5. Student B memorizes all 500 questions and their answers word for word. Perfect on practice, lost in the exam. That is **overfitting**.

6. Student C did not study enough and gets both the practice and the exam wrong. That is **under-fitting**.
7. The tell is the gap. A big gap between practice performance and exam performance means memorization, not learning.

Where this comparison breaks: a student who memorizes knows they are memorizing. A model cannot tell the difference between a real pattern and a coincidence in the data, and does not experience one as different from the other. Worse, the analogy suggests memorization is always bad. It is not that simple. Very large modern models memorize a great deal of their training data and still generalize well, which classical theory did not predict. That gap between theory and observation is real, and it is active research, not settled.

■ 46.6.3 PLAIN – a worked example

1. Take 50,000 labelled photographs. Split 80 / 10 / 10.
2. Training set: 40,000. Validation set: 5,000. Test set: 5,000.
3. Choose a batch size of 100.
4. Steps in one epoch: $40,000 / 100 = 400$.
5. Train for 20 epochs. Total steps: $20 \times 400 = 8,000$ parameter updates.
6. The model has seen each photograph 20 times, and the parameters have been changed 8,000 times.
7. Now read a real training curve. Both numbers are losses. Lower is better.

8. Epochs 0 to 10: both fall together. This is real learning. Nothing to do.
9. Epochs 10 to 18: training keeps falling, validation flattens. The model is starting to fit noise. Watch it.
10. Epoch 18 onwards: training still falls, validation rises. This is overfitting, and it is unambiguous.
11. The correct action is to stop at around epoch 18 and keep those parameters. That is **early stopping**, and it is the cheapest regularizer there is.
12. Here is the opposite picture, underfitting: both curves flatten early and high, at say 1.4 and 1.45, and stay there. Small gap, bad numbers.
13. That is not a stopping problem. That means the model is too simple, or the features carry no signal, or the learning rate is wrong.
14. Read the two symptoms as a pair. Big gap, low training loss: too much capacity, add regularization. Small gap, high loss on both: too little capacity, make the model bigger.

■ 46.6.4 PLAIN – what is really happening inside

1. Underneath the two symptoms sits one trade-off, and it has a name: **bias and variance**.
2. Bias, here, does not mean unfairness. It means systematic error from a model too simple to represent the truth.
3. A straight line fitted to data shaped like a curve has high bias. It is wrong in the same way every time, no matter how much data you give it.
4. Variance means sensitivity to the particular data you happened to get.
5. A very flexible model has low bias and high variance. Show it a slightly different sample of data and it produces a noticeably different answer.
6. Total error is roughly bias squared, plus variance, plus noise that nothing can remove.
7. Simple models sit at the high-bias end. Complex models sit at the high-variance end. Classically, the best model is somewhere in between.
8. **Regularization** is anything you do to push a flexible model back towards simplicity, so you get low bias without paying full variance.
9. The four you will actually use:
10. Weight decay, also called L2: add a penalty proportional to the sum of the squared weights. Big weights become expensive, so the model prefers small ones, and small weights make gentler, smoother functions.
11. L1: penalize the sum of the absolute weights instead. This drives many weights to exactly zero, which selects features and gives a sparse model you can read.
12. Dropout: during training, at every step, randomly switch off a fraction of the units, typically half. No unit can rely on any other being present, so the network cannot build fragile chains.
13. Early stopping: stop when validation loss stops improving, as in the curve above.
14. Separately from all of those, **data augmentation**: make more training data by altering what you have in ways that do not change the label. Flip the photograph left to right, crop it, rotate it slightly, change its brightness. A flipped cat is still a cat.
15. Augmentation is often the most effective of the lot, because the real problem is usually not enough data, and this is the cheapest way to get more.

■ 46.6.5 TECHNICAL – the engineer’s version

1. Precise definitions, so the words never slip again:

Term	Exact meaning
Sample	one row of the dataset
Feature	one input dimension
Label	the target value for a sample
Batch	samples in one forward pass
Iteration / step	one parameter update
Epoch	$n_{\text{train}} / \text{batch\_size}$ steps

2. Real scale: ImageNet’s ILSVRC training set is 1,281,167 images. At batch size 256 that is 5,004 iterations per epoch. The classic ResNet recipe runs 90 epochs, so about 450,000 parameter updates.
3. Splitting must respect structure. If several rows come from the same patient, the same user or the same day, they must not be split across train and test, or information leaks and your test number is a fantasy. Use grouped or time-based splits when the data has groups or an ordering.

4. K-fold cross-validation splits the data into k parts, trains k times with a different part held out each time, and averages. It gives a far more stable estimate on small datasets, at k times the cost. Common k is 5 or 10. It is rarely used for large deep networks purely because of cost.
5. L2 regularization adds λ times the sum of squared weights to the loss. Its gradient contribution is $2\lambda w$, so each step multiplies every weight by a factor slightly under one. With λ 0.01 and learning rate 0.02, that factor is 0.99960, and 1,000 steps of pure decay would shrink a weight of 0.6 to 0.402.
6. In Adam, adding L2 to the loss and applying weight decay directly are not equivalent, because Adam rescales the gradient per parameter. AdamW, from Loshchilov and Hutter in 2017, decouples them. This is why AdamW replaced Adam for transformer training, and it is a real bug fix, not a preference.
7. Dropout, from Srivastava, Hinton and colleagues, published in JMLR in 2014, with an earlier 2012 preprint. At training time each unit is kept with probability $1-p$. At inference nothing is dropped. Standard implementations use inverted dropout: divide activations by $1-p$ during training so the expected value matches, and inference needs no adjustment. Typical p is 0.5 for fully connected layers and 0.1 for transformer residual paths.
8. Batch normalization interacts with dropout badly, and modern convolutional networks often use batch normalization with little or no dropout.
9. Standard augmentations by field:

Field	Common augmentations
Images	flip, crop, colour jitter
Images, stronger	mixup, cutmix, RandAugment
Audio	time and frequency masking
Text	back-translation, dropout

10. The classical bias-variance curve is U-shaped: error falls, then rises with model size. Established fact for classical models.
11. Active research, and important: Belkin and colleagues showed in 2019 that for very over-parameterized models the test error falls again past the interpolation point. This is called **double descent**, and it means the classical U-shape is only the left half of the real picture. The theory is incomplete and the practical implications are still debated.
12. Practically, as of 2026, the standard recipe for very large models is not “find the sweet spot on the U”. It is “make the model large, train on far more data, regularize lightly, and stop before the data runs out”. That recipe is empirical, and it works.

■ 46.6.6 WORDS – remember these

1. Sample — one example — one row of the dataset, one point in feature space.
2. Feature — one measured property — one input dimension of the model.
3. Label — the right answer for a sample — the supervision target y .
4. Epoch — one full pass over the training data — $\text{ceil}(n / \text{batch size})$ optimizer steps.
5. Batch — the group processed together — the set of samples whose gradients are averaged into one update.
6. Overfitting — memorizing the practice questions — low training error with a large gap to validation error; fitting sample noise.
7. Underfitting — not learning enough — high error on both sets; insufficient model capacity or bad optimization.

8. Regularization — anything that pushes towards simpler solutions — a penalty or constraint that reduces effective capacity, trading bias for variance.
9. Data augmentation — making more examples by changing existing ones — label- preserving transformations that expand the effective training distribution.

46.7 Classical machine learning before neural networks

■ 46.7.1 PLAIN - in simple words

1. Neural networks are not the field. They are one family in it, and for a large amount of real work they are the wrong choice.
2. **Linear regression** predicts a number by adding up weighted inputs. That is section 46.3, with more than one input.
3. **Logistic regression** predicts a yes-or-no answer. It adds up weighted inputs the same way, then squashes the total into a probability between 0 and 1. Despite the name, it does classification.
4. A **decision tree** asks a series of yes-or-no questions and follows the answers to a leaf. “Is the income above 40,000? Then, is the age under 25?” You can read it out loud and a person will understand it.
5. One tree is easy to read and usually not very accurate. It clings to accidents in the data.
6. A **random forest** grows hundreds of different trees on different random parts of the data, and lets them vote. The mistakes are different, so they partly cancel.
7. **Gradient boosting** grows trees one after another, where each new tree is trained to fix the errors the current set makes. This is usually the most accurate method available for table-shaped data.
8. **k-nearest neighbours** does not train at all. To classify a new point, it finds the k most similar stored points and takes the majority answer.
9. **k-means clustering** takes unlabelled data and sorts it into k groups by similarity. No right answers are provided.
10. A **support vector machine** draws the dividing line that leaves the widest possible empty corridor between the two classes.
11. Every one of these is still in production somewhere, today, doing useful work.

■ 46.7.2 PLAIN - a picture in your head

1. Think of a toolbox with a hammer, a screwdriver, a spanner and a saw.
2. Linear regression is the tape measure. Cheap, fast, always the first thing you reach for, and it tells you a lot before you do anything clever.
3. A decision tree is a flowchart pinned to the wall. Anybody can follow it and anybody can argue with it.
4. A random forest is asking three hundred people the same question and taking the majority. No individual is reliable. The crowd is.
5. Gradient boosting is one person answering, then a second person who only corrects the first one’s mistakes, then a third who corrects what is left.
6. k-nearest neighbours is asking your five closest neighbours what they did.
7. A neural network is a machine tool. Enormously capable, expensive to set up, and absurd for hanging a picture.

Where this comparison breaks: real tools have obvious jobs and you can see when you are using the wrong one. Here you cannot, because every method returns a number for every input, and a badly chosen method still returns confident answers. The only way to know is to try several and measure

honestly on held- out data. The honest version: the choice is empirical, and anyone who tells you which method wins before seeing your data is guessing.

■ 46.7.3 PLAIN – a worked example

1. Logistic regression, worked fully. Predict whether a student passes, from hours studied.
2. The model is: $z = 0.8 \text{ times hours, minus } 1.2$. Then squash z with the sigmoid function, which is 1 divided by (1 plus e to the minus z).
3. Student studied 3 hours. $z = (0.8 \times 3) - 1.2 = 2.4 - 1.2 = 1.2$.
4. Sigmoid of 1.2 = $1 / (1 + e^{-1.2}) = 1 / (1 + 0.3012) = 0.7685$.
5. So the model says 76.85 percent chance of passing.
6. If the student did pass, the loss is minus the natural log of 0.7685, which is 0.263. Small loss, because the model was mostly right.
7. If the student failed, the loss is minus the log of $(1 - 0.7685) = \text{minus log of } 0.2315 = 1.463$. Much bigger loss. Correctly punished.
8. Now k-nearest neighbours, worked fully. New point at (3, 4). Five stored points with known classes:

Point	Class	Distance from (3,4)
(4, 4)	B	1.00
(2, 5)	B	1.41
(3, 6)	B	2.00
(1, 2)	A	2.83
(6, 1)	A	4.24

9. With $k = 3$, the three closest are all B, so the answer is B.
10. With $k = 5$, the vote is three B against two A, so still B, but less confidently.
11. Notice there was no training. The distances were computed at question time, against every stored point. That is why it is slow to use and instant to “train”.
12. Notice also that the distances mix the two axes as if they were comparable. If the first axis were rupees and the second were years, this would be nonsense. k-nearest neighbours demands that you scale your features first.

■ 46.7.4 PLAIN – what is really happening inside

1. Now the four kinds of learning, distinguished by what you give the system.
2. **Supervised learning:** every sample comes with the right answer. The system learns to map input to answer. Spam or not. Cat or dog. House price. This is most of the industry.
3. **Unsupervised learning:** no answers at all. The system finds structure in the data itself. Grouping customers. Compressing images. Spotting anomalies.
4. **Self-supervised learning:** the answers are generated automatically from the data by hiding part of it. Take a sentence, hide a word, and the label is the hidden word.
5. That last one deserves attention, because it is how every large language model is trained. Nobody labelled the internet. The data labels itself by the trick of prediction.
6. Self-supervised learning is why scale became possible. Human labelling costs money per example. Hiding a word costs nothing, so the amount of training data is limited only by how much text exists.
7. **Reinforcement learning:** no labels, only rewards. The system acts, receives a score, and must work out which of its actions caused the score.

8. The hard part of reinforcement learning is that the reward arrives late. You lose a game of chess at move 60. Which of the 60 moves was the bad one? That is the credit assignment problem, and it makes reinforcement learning far harder and far less stable than the other three.
9. One clean way to keep them straight: supervised has answers, unsupervised has none, self-supervised manufactures its own, reinforcement has only scores.

■ 46.7.5 TECHNICAL - the engineer's version

1. When each method is right:

Method	Best when	Weak when
Linear regression	few features, linear	curved relations
Logistic regression	need calibrated odds	complex boundaries
Decision tree	must explain decision	needs accuracy
Random forest	tabular, low tuning	wide sparse data
Gradient boosting	tabular, top accuracy	needs tuning
k-nearest neighbours	tiny data, odd shapes	many features
k-means	quick grouping	non-round clusters
SVM	small data, clear margin	over 100k samples
Neural network	images, audio, text	small tabular data

2. Origins, with dates: decision trees as CART, from Breiman, Friedman, Olshen and Stone in 1984, and ID3 from Ross Quinlan in 1986. Random forests from Leo Breiman in 2001. Gradient boosting from Jerome Friedman in 2001. k-means from Stuart Lloyd in 1957, published 1982, named by James MacQueen in 1967. k-nearest neighbours from Evelyn Fix and Joseph Hodges in 1951, with the classic analysis by Cover and Hart in 1967.
3. The practical boosting libraries: XGBoost, from Tianqi Chen and Carlos Guestrin in 2016; LightGBM from Microsoft in 2017; CatBoost from Yandex in 2017. Between them they won a very large share of Kaggle competitions on tabular data from 2016 onwards.
4. The honest note on tabular data, which is what most companies actually have. Established fact: for table-shaped data with mixed numeric and categorical columns, gradient-boosted trees have been the strongest default for a decade, and remain a leading choice in 2026. The 2022 paper by Grinsztajn, Oyallon and Varoquaux, "Why do tree-based models still outperform deep learning on typical tabular data", is the standard citation, and gives the reasons: trees handle uninformative features, irregular target functions and unnormalized columns well, and neural networks handle none of them well.
5. Active research, and genuinely moving: tabular foundation models, starting with TabPFN in 2022 and TabPFN v2 published in Nature in January 2025, are pretrained transformers that make predictions on a new small table without fitting it in the usual sense. On benchmarks of small datasets, roughly under a few tens of thousands of rows, they now often beat tuned gradient boosting. On larger tables and heavily categorical tables, boosted trees still generally lead. This boundary is moving, so check the current benchmarks rather than trusting a book on this point.
6. SVMs use the hinge loss and maximize the margin, the distance from the decision boundary to the closest points, which are the support vectors. The kernel trick, from Boser, Guyon and Vapnik in 1992, computes inner products in a high-dimensional space without ever building the coordinates. The radial basis function kernel is the usual default.

7. Cost matters: the standard SVM solver is between quadratic and cubic in the number of samples, which is why SVMs are rare above roughly 100,000 samples and were displaced partly for that reason.
8. k-means minimizes within-cluster sum of squares. Lloyd's algorithm is not guaranteed to find the global optimum, so you restart it several times. The k-means++ initialization of Arthur and Vassilvitskii, 2007, is the standard default and is what `sklearn.cluster.KMeans` uses.
9. Reinforcement learning landmarks: Q-learning from Chris Watkins in 1989, temporal difference learning from Richard Sutton in 1988, Deep Q-Networks from DeepMind in Nature in 2015, AlphaGo defeating Lee Sedol 4-1 in March 2016, and reinforcement learning from human feedback, which is how chat models are aligned after pretraining and is covered later in this book.

```
from sklearn.ensemble import GradientBoostingClassifier
from sklearn.model_selection import train_test_split

Xtr, Xte, ytr, yte = train_test_split(X, y, test_size=0.2,
                                     random_state=0)
clf = GradientBoostingClassifier(n_estimators=200,
                                learning_rate=0.05,
                                max_depth=3).fit(Xtr, ytr)

print(clf.score(Xte, yte))
```

10. Note the hyperparameters in that snippet: number of trees, learning rate and tree depth. Boosting has a learning rate too, for the same reason gradient descent does, and 0.05 with 200 trees is a reasonable default.

■ 46.7.6 WORDS - remember these

1. Logistic regression — a linear model that outputs a probability — a generalized linear model with a sigmoid link, fitted by minimizing binary cross-entropy.
2. Decision tree — a readable flowchart of yes-or-no questions — a recursive partition of feature space, split by information gain or Gini impurity.
3. Random forest — many different trees voting — bagged trees with random feature subsets at each split, reducing variance.
4. Gradient boosting — each new tree fixes the last one's mistakes — stage-wise additive modelling fitting each learner to the current negative gradient.
5. Support vector machine — the widest empty corridor between two classes — a maximum-margin classifier with hinge loss, optionally kernelized.
6. Supervised learning — learning from labelled answers — estimating a mapping from inputs to targets given paired examples.
7. Self-supervised learning — the data provides its own answers — training on a pretext task built by hiding part of the input, such as next-token prediction.
8. Reinforcement learning — learning from scores, not answers — optimizing a policy to maximize expected cumulative reward from delayed feedback.

46.8 The neuron

■ 46.8.1 PLAIN – in simple words

1. An artificial neuron is a tiny arithmetic unit. It does exactly three things and then it stops.
2. One: it takes several numbers in, and multiplies each by its own weight.
3. Two: it adds all those products together, then adds one more number called the bias.
4. Three: it passes that single total through a fixed non-straight function, and that answer is its output.
5. That is all. Multiply, add, bend. There is no memory, no decision, no state.
6. Steps one and two are just the line from section 46.3 with more inputs: $\text{output} = w_1 x_1 + w_2 x_2 + w_3 x_3 + b$.
7. Step three, the bend, is the only genuinely new part, and section 46.9 explains why it is essential.
8. A weight says how much that input matters, and in which direction. Large positive means “this pushes the answer up hard”. Negative means it pushes down. Near zero means the neuron ignores it.
9. The bias is the neuron’s own starting opinion, applied before any input is considered.
10. A network is thousands to billions of these, arranged in rows, each row feeding the next.

■ 46.8.2 PLAIN – a picture in your head

1. Picture a small committee vote where the members have unequal power.
2. Each member reports a number. Each member’s report is multiplied by their voting power, which is the weight.
3. The chair has a fixed opinion held before anyone speaks. That is the bias.
4. Everything is added into one total, and a rule converts the total into the committee’s answer. That rule is the activation function.
5. A member with a negative weight is one whose enthusiasm counts against the proposal. That is normal and useful.
6. A member with weight zero has been muted. Their report changes nothing.

Where this comparison breaks: committee members reason about the proposal and about each other. Nothing here does. The weights are fixed numbers that were tuned by an optimizer, not opinions held by anyone. And a real committee can deadlock or refuse to answer. A neuron always produces exactly one number, for every input, instantly, forever.

■ 46.8.3 PLAIN – a worked example

1. One neuron, three inputs. Weights 0.5, -0.2 and 0.1. Bias 0.3.
2. Inputs arrive: 2.0, 3.0 and -1.0.

$$\begin{array}{rcl}
 x_1 = 2.0 & \text{---} [w_1 = 0.5] & \text{---} \backslash \\
 x_2 = 3.0 & \text{---} [w_2 = -0.2] & \text{---} \rightarrow (+) \rightarrow z \rightarrow f(z) \rightarrow \text{output} \\
 x_3 = -1.0 & \text{---} [w_3 = 0.1] & \text{---} / \quad \quad \quad \wedge \\
 & & \quad \quad \quad | \\
 & & b = 0.3
 \end{array}$$

3. Multiply each input by its weight:
4. $2.0 \times 0.5 = 1.0$
5. $3.0 \times -0.2 = -0.6$
6. $-1.0 \times 0.1 = -0.1$
7. Add them: $1.0 - 0.6 - 0.1 = 0.3$
8. Add the bias: $0.3 + 0.3 = 0.6$. Call this z , the pre-activation.
9. Now apply the bend. Three common choices, all on the same $z = 0.6$:

Function	Output at $z = 0.6$
ReLU	0.600
Sigmoid	0.646
tanh	0.537

10. That is a complete neuron evaluation. Six multiplications and additions, then one function call.
11. Read the weights. Input one matters most and pushes up. Input two pushes down, less strongly. Input three barely matters at all.
12. And notice: input two had the largest raw value, 3.0, but contributed less than input one, because its weight was smaller. Size of input and importance of input are different things.

■ 46.8.4 PLAIN - what is really happening inside

1. Geometrically, the weighted sum plus bias defines a plane cutting through the input space.
2. The neuron is measuring which side of that plane the input lies on, and how far from it.
3. The weights set the direction the plane faces. The bias sets how far the plane sits from the origin.
4. So a single neuron with a threshold is a straight-line separator, and nothing more. It is exactly the 1958 perceptron.
5. This is why one neuron cannot do XOR: one plane, two regions, and XOR needs the two “1” corners on the same side, which no plane achieves.
6. Layers fix it, because the second layer separates a space that the first layer has already bent.
7. Now the honest part about the brain. A neuron in your head is a living cell. It fires discrete spikes whose timing carries information. It has thousands of synapses with their own chemistry, it changes its own structure, it is regulated by hormones, and it is affected by nearby cells that are not even neurons.
8. The artificial version is a weighted sum and a bend. It does not spike, has no timing, no chemistry and no internal state.
9. The name came from the 1943 McCulloch and Pitts paper, which was genuinely an attempt to model nerve cells. The name stuck long after the modelling ambition was dropped.
10. The honest version: the brain analogy is historical and, today, mostly marketing. Calling it a neuron tells you where the idea came from. It tells you nothing about how brains work, and nothing about how networks work. Real computational neuroscience uses far more detailed models and does not use these.

■ 46.8.5 TECHNICAL - the engineer's version

1. Formally, for input vector x in $\mathbb{R}^n$, weight vector w in $\mathbb{R}^n$ and bias b in $\mathbb{R}$: $z = w\text{-transpose } x + b$, and $a = f(z)$, where f is the activation.
2. z is the pre-activation or logit. a is the activation or unit output.
3. Cost per neuron: n multiply-accumulate operations, counted as $2n$ floating-point operations, plus one activation evaluation.
4. Storage per neuron: $n + 1$ parameters. In float32 that is $4(n+1)$ bytes; in bfloat16, $2(n+1)$ bytes.
5. The set of points where z equals zero is a hyperplane of dimension $n-1$. The vector w is its normal, and the perpendicular distance from the origin is the absolute value of b divided by the Euclidean norm of w .
6. The original 1958 perceptron used the Heaviside step as f , which has a derivative of zero everywhere it is defined and is undefined at zero. That is precisely why perceptrons could not be trained by gradient descent, and why the switch to smooth activations mattered so much.
7. Biological comparison, with real figures:

Property	Biological neuron	Artificial unit
Signal	timed voltage spikes	one real number
Inputs	~1,000 to 10,000	as designed
Firing rate	up to ~200 Hz	not applicable
State	membrane potential	none

- The human brain has roughly 86 billion neurons, a figure from Suzana Herculano-Houzel's 2009 work, with of the order of 100 trillion synapses. Parameter counts of large models are sometimes compared to synapse counts. That comparison is not meaningful, because the units are not comparable, and you should treat it as a marketing claim.
- Spiking neural networks and neuromorphic hardware, such as Intel's Loihi 2 and IBM's TrueNorth, do model timing and spikes. They are active research and are not what runs any deployed large model today.

■ 46.8.6 WORDS - remember these

- Neuron / unit — a weighted sum followed by a bend — a parameterized affine map composed with a fixed non-linearity.
- Weight — how much an input matters and in which direction — a learned coefficient in the affine map.
- Bias — the unit's fixed starting offset — the additive constant, shifting the hyperplane off the origin.
- Pre-activation — the total before the bend — z , the logit; the affine output before f is applied.
- Activation — the neuron's final output — $a = f(z)$, the value passed to the next layer.
- Hyperplane — the flat surface a neuron measures distance from — the set where w -transpose $x + b$ equals zero, of dimension $n-1$.

46.9 Activation functions

■ 46.9.1 PLAIN - in simple words

- Every neuron ends with a bend, and without the bend the whole network is worthless. Here is the proof, in two lines of algebra.
- Take two layers with no bend. Layer one computes $W_1 x + b_1$. Layer two takes that and computes $W_2 (W_1 x + b_1) + b_2$.
- Multiply out: $W_2 W_1 x + W_2 b_1 + b_2$. Now let W' be $W_2 W_1$ and let b' be $W_2 b_1 + b_2$. Both are just fixed matrices of numbers.
- The result is $W' x + b'$. That is one single layer.
- So a hundred layers with no bend collapse into one layer. Depth buys nothing at all. Not less than expected. Exactly nothing.
- The bend is what stops the collapse. Once you put a non-straight function between the layers, the multiplication cannot be folded up, and the second layer sees a genuinely reshaped space.
- The function that provides the bend is called the **activation function**.
- There are only a handful in common use, and almost all of modern practice is one of them: ReLU, which is "if the number is negative, make it zero; otherwise leave it alone".
- That is genuinely the whole of ReLU. One comparison and one selection.

■ 46.9.2 PLAIN – a picture in your head

1. Picture folding a flat sheet of paper.
2. A linear layer stretches, rotates and slides the sheet. However many times you do that, the sheet stays flat, and you could have done it in one move.
3. ReLU folds it. Everything below the crease is flattened onto the crease line, and everything above is untouched.
4. Fold, stretch, fold, stretch, twenty times, and the sheet is a complicated crumpled shape that no single stretch could produce.
5. Now a straight cut through the crumpled sheet is, when you unfold it, a complicated curved boundary in the original space.
6. That is exactly what a deep network with ReLU is: many folds, then one straight cut at the end.

Where this comparison breaks: paper folds along a line you choose by hand. Here the crease positions are the weights and biases, and they are learned. Also, paper is two-dimensional, so you can see the folds. In 512 dimensions with thousands of folds there is nothing to see, and the intuition stops helping long before the mathematics does.

■ 46.9.3 PLAIN – a worked example

1. The same input z , through four different activations.

z	sigmoid	tanh
-2.0	0.1192	-0.9640
-1.0	0.2689	-0.7616
0.0	0.5000	0.0000
1.0	0.7311	0.7616
2.0	0.8808	0.9640

z	ReLU	GELU
-2.0	0.00	-0.0455
-1.0	0.00	-0.1587
0.0	0.00	0.0000
1.0	1.00	0.8413
2.0	2.00	1.9545

2. Notice sigmoid never leaves the range 0 to 1, and tanh never leaves -1 to 1. Both are squashers.
3. Notice ReLU has no upper limit. Feed it 1000 and it returns 1000.
4. Notice GELU is almost ReLU for large inputs but is smooth near zero and allows a small negative output. That smoothness is why it is preferred in transformers.
5. Now the vanishing gradient, worked with numbers. The steepness of sigmoid at any point is s times $(1 - s)$, where s is its output.
6. At $z = 0$, $s = 0.5$, so the steepness is $0.5 \times 0.5 = 0.25$. That is the maximum it ever reaches.
7. At $z = 6$, $s = 0.9975$, so the steepness is $0.9975 \times 0.0025 = 0.0025$. A hundred times flatter.
8. Now recall that backpropagation multiplies these steepness values together, once per layer. Best case, every layer contributes 0.25.

Layers of sigmoid	Best-case gradient factor
1	0.25
3	0.0156
5	0.00098
10	0.00000095

- After ten sigmoid layers, the gradient reaching the first layer is at best about one millionth of the gradient at the output, and in practice far less.
- So the early layers barely move. They are effectively frozen at their random starting values. The network trains its last two layers and nothing else.
- That is the vanishing gradient problem, and it is the single technical reason deep networks did not work before roughly 2010.
- ReLU's steepness is exactly 1 for every positive input. Multiply 1 by itself fifty times and you still have 1. The problem disappears.

■ 46.9.4 PLAIN – what is really happening inside

- So why did ReLU win, when it looks crude next to a smooth curve?
- Reason one, the gradient. Slope of exactly 1 on the positive side, so gradients pass through many layers undamaged.
- Reason two, speed. ReLU is one comparison. Sigmoid needs an exponential, which is many times more expensive, and it is evaluated billions of times.
- Reason three, sparsity. Roughly half the units output exactly zero for a given input. Zeros propagate nothing and cost nothing, and the resulting sparse representations seem to help.
- ReLU has one real failure, called the dying ReLU. If a unit's weights land such that its pre-activation is negative for every input in the data, its output is always zero, its gradient is always zero, and it can never recover. It is dead for the rest of training.
- Leaky ReLU fixes this by giving the negative side a small slope, typically 0.01, instead of zero. A dead unit still receives a trickle of gradient.
- In practice, plain ReLU with sensible initialization dies rarely enough that leaky ReLU is optional rather than standard, which is a somewhat surprising empirical result.
- GELU and SiLU are the modern smooth alternatives. Both look like ReLU from a distance, but curve gently through zero and dip slightly negative just below it.
- There is no strong theory for why that small dip helps. The honest answer is that it measured better on transformer benchmarks and the field adopted it.

■ 46.9.5 TECHNICAL – the engineer's version

- The reference table:

Name	Definition	Range
Sigmoid	$1/(1+e^{-z})$	(0, 1)
Tanh	$(e^{z-e}-z)/(e^{z+e}-z)$	(-1, 1)
ReLU	$\max(0, z)$	[0, inf)
Leaky ReLU	$\max(0.01z, z)$	(-inf, inf)
GELU	$z * \Phi(z)$	(-0.17, inf)
SiLU / Swish	$z * \text{sigmoid}(z)$	(-0.28, inf)
Softmax	$e^{z_i} / \sum e^{z_j}$	(0, 1), sums to 1

2. Where each is used today, as of 2026:

Activation	Typical use
ReLU	CNNs, most MLPs
GELU	BERT, GPT-2, GPT-3
SiLU / SwiGLU	Llama, Mistral, Qwen
Sigmoid	binary output layer only
Tanh	LSTM gates, some RL heads
Softmax	multi-class output layer

- Derivatives, which is what backpropagation actually needs. Sigmoid: $s(1-s)$, maximum 0.25 at $z = 0$. Tanh: $1 - \tanh^2$, maximum 1.0 at $z = 0$. ReLU: 1 for z above 0, 0 below, undefined at exactly 0, where implementations return 0 by convention.
- Tanh's maximum derivative of 1.0 versus sigmoid's 0.25 is why tanh was preferred over sigmoid through the 1990s and 2000s. It is zero-centred, which also keeps the mean activation near zero. It still saturates at both ends, so it only postpones the problem.
- GELU, from Dan Hendrycks and Kevin Gimpel in 2016, is z times the standard normal cumulative distribution function. The common tanh approximation is $0.5z(1 + \tanh(\sqrt{2/\pi})(z + 0.044715z^3))$. Both forms are shipped in PyTorch, selected by the `approximate` argument.
- SiLU, also called Swish, appeared in Elfwing, Uchibe and Doya in 2017 and in Ramachandran, Zoph and Le's neural architecture search paper the same year.
- SwiGLU, from Noam Shazeer in 2020, is a gated variant using SiLU. It is the feedforward activation in the Llama family and much of the current open model ecosystem. It uses three weight matrices rather than two, so implementations shrink the hidden dimension to keep the parameter count equal.
- Softmax is not a per-neuron activation. It operates on a whole output vector, turning logits into a probability distribution. Implementations always subtract the maximum logit before exponentiating, to avoid overflow. This is called the log-sum-exp trick and it is an implementation detail every library handles for you.
- The vanishing gradient problem was identified in Sepp Hochreiter's 1991 diploma thesis and analysed by Bengio, Simard and Frasconi in 1994. The move to ReLU came through Nair and Hinton in 2010 and Glorot, Bordes and Bengio in 2011, and reached everyone through AlexNet in 2012.

■ 46.9.6 WORDS – remember these

- Activation function — the bend after the weighted sum — the elementwise non-linearity f applied to the pre-activation.
- ReLU — negative becomes zero, positive passes through — the rectified linear unit, $\max(0, z)$, with derivative 1 on the positive side.
- Vanishing gradient — the learning signal fading out before it reaches the early layers — the product of many derivatives below 1 decaying towards zero exponentially in depth.
- Saturation — the region where a squashing function stops responding — where the derivative is near zero because the input is far from zero.
- Dying ReLU — a unit stuck outputting zero forever — a unit whose pre-activation is negative across the entire data distribution, so its gradient is permanently zero.
- Softmax — turning scores into probabilities that add to one — the normalized exponential over a logit vector, used with cross-entropy.

46.10 Layers and depth

■ 46.10.1 PLAIN – in simple words

1. A **layer** is a row of neurons that all look at the same inputs and all produce outputs at the same time.
2. Neurons in one layer do not talk to each other. They work in parallel, which is exactly why this runs so well on the hardware from Chapter 22.
3. Stack layers so each one's outputs are the next one's inputs, and you have a network.
4. The **input layer** is not really a layer of neurons. It is just the numbers you feed in. Counting it is a convention some books follow and some do not.
5. **Hidden layers** are the middle ones. They are called hidden because nothing outside the network ever sees their values.
6. The **output layer** is the last one, and its size is set by the task. One unit for a single number. Ten units for ten categories.
7. **Width** is how many neurons are in a layer. **Depth** is how many layers there are.
8. "Deep learning" means, roughly, more than two or three hidden layers. There is no official threshold. It is a marketing term that stuck.
9. What depth actually buys you is composition. Early layers find simple patterns, later layers combine those into complicated ones.
10. In a picture network, the first layer finds edges, the third finds corners and textures, the tenth finds eyes and wheels, the last finds faces and cars. Nobody designed that. It emerges from training.

■ 46.10.2 PLAIN – a picture in your head

1. Think of a factory production line rather than one craftsman.
2. Station one takes raw metal and cuts flat pieces. That is all it does, and it does it to everything.
3. Station two takes flat pieces and bends them into brackets.
4. Station three joins brackets into frames. Station four fits frames into cabinets.
5. No station understands the cabinet. Each does one narrow transformation of whatever arrives.
6. Depth is the number of stations. Width is how many workers stand at each station doing that station's job in parallel.
7. Adding stations lets you build more complicated products. Adding workers per station lets you build more different things at each stage.

Where this comparison breaks: a factory line is designed, and someone knows what each station is for. Here nobody assigns jobs. The stations arrive at their own division of labour during training, and often it does not decompose neatly at all. Some units respond to combinations of things that have no name. The tidy edges-to-faces story is real for convolutional image networks and was demonstrated by visualization work in the 2010s, but it is a summary of typical behaviour, not a law.

■ 46.10.3 PLAIN – a worked example

1. A network for handwritten digits. Input is a 28 by 28 greyscale image, which is 784 numbers. Output is 10 scores, one per digit.
2. Shape: 784 inputs, then a hidden layer of 128, then a hidden layer of 64, then 10 outputs.

3. Parameter count, layer by layer. Each layer has (inputs x outputs) weights plus (outputs) biases.

4. Layer 1: $784 \times 128 = 100,352$ weights, plus 128 biases = 100,480.
5. Layer 2: $128 \times 64 = 8,192$ weights, plus 64 biases = 8,256.
6. Layer 3: $64 \times 10 = 640$ weights, plus 10 biases = 650.
7. Total: $100,480 + 8,256 + 650 = 109,386$ parameters.
8. Note how lopsided that is. The first layer holds 92 percent of the parameters, purely because 784 inputs is a lot to connect to.
9. This is a real network. Trained for a few minutes it reaches roughly 97 to 98 percent accuracy on the MNIST test set.
10. Now change the shape and see the trade. Width 512 in one hidden layer: $784 \times 512 + 512$, then $512 \times 10 + 10 = 401,920 + 5,130 = 407,050$ parameters.
11. Four times the parameters, one layer fewer, and typically slightly worse accuracy on this task. Depth is usually the more efficient way to spend parameters, though not without limit.

■ 46.10.4 PLAIN – what is really happening inside

1. The **universal approximation theorem** is the famous result here, and it is almost always quoted wrongly. Here it is stated correctly.
2. A feedforward network with a single hidden layer, containing enough neurons, and a suitable non-polynomial activation, can approximate any continuous function on a closed bounded region, to any accuracy you like.
3. Read the conditions again. Continuous. Closed and bounded. Any accuracy you like, but “enough neurons” is not bounded.
4. Now the three things it does not say, which is where the misuse happens.
5. It does not say how many neurons. “Enough” can mean exponentially many in the number of inputs. The theorem is silent on the count.
6. It does not say you can find those weights. It proves such weights exist. It gives no procedure, and gradient descent may never reach them.
7. It does not say anything about new data. Approximating a function on the region you sampled says nothing about behaviour outside it.
8. So the theorem is an existence result. It tells you the model family is rich enough. It does not tell you the model is learnable, efficient or useful.
9. The practical answer to why we use depth at all: for many functions, a deep network needs exponentially fewer units than a shallow one to reach the same accuracy. Depth is about efficiency, not possibility.
10. That is not folklore. There are proven separation results, for example Telgarsky in 2016, exhibiting functions a deep network represents with few units that any shallow network needs exponentially many units to match.

■ 46.10.5 TECHNICAL – the engineer’s version

1. A fully connected layer with n inputs and m outputs has $n \times m$ weights and m biases, and costs $2nm$ floating-point operations per sample.
2. Layer terminology in code: `nn.Linear(in, out)` in PyTorch, `Dense(units)` in Keras, `nn.Dense(features)` in Flax. All the same object.
3. Depth in real architectures, with dates:

Model	Year	Depth
LeNet-5	1998	7 layers
AlexNet	2012	8 layers

Model	Year	Depth
VGG-19	2014	19 layers
GoogLeNet	2014	22 layers
ResNet-152	2015	152 layers
GPT-3	2020	96 blocks
Llama 3 70B	2024	80 blocks

- Depth beyond about 20 plain layers did not train at all before residual connections. ResNet, from Kaiming He and colleagues at Microsoft Research in 2015, adds the input of a block to its output, so the block only has to learn a correction. That single change took usable depth from about 20 to over 1,000 and is the most important architectural idea of the decade.
- Approximation theory: George Cybenko proved the sigmoid case in 1989. Kurt Hornik generalized it in 1991, showing that the multilayer structure, not the choice of activation, is what gives universality. Leshno and colleagues showed in 1993 that a non-polynomial activation is the precise condition.
- There are also dual results for width. Lu and colleagues showed in 2017 that networks of bounded width and unbounded depth are universal, with a width threshold around the input dimension plus four.
- Established fact: depth gives exponential representational efficiency for some function classes, and residual connections make great depth trainable.
- Active research: exactly why depth helps optimization, not just representation, and why over-parameterized networks generalize at all. There is no complete theory. Anyone claiming otherwise is overselling.

■ 46.10.6 WORDS - remember these

- Layer — a row of neurons computed together — an affine transform followed by an elementwise non-linearity.
- Hidden layer — a middle layer nothing outside ever sees — any layer that is neither the input nor the output.
- Width — how many neurons in one layer — the output dimension of that layer.
- Depth — how many layers deep the network is — the number of composed non-linear transformations.
- Universal approximation theorem — one wide layer can copy any smooth function — for any continuous f on a compact set and any epsilon, a sufficiently wide single-hidden-layer network exists within epsilon. An existence result only.
- Residual connection — adding a block's input to its output — a skip connection giving gradients a direct path, from ResNet in 2015.

46.11 The forward pass as matrix multiplication

■ 46.11.1 PLAIN - in simple words

- Running a network on an input is called the **forward pass**. Numbers go in at one end and come out the other.
- Doing it one neuron at a time, as in section 46.8, is correct but slow to describe and slower to compute.
- Every neuron in a layer does the same thing to the same inputs, with different weights. That is exactly what a matrix multiplication is.

4. So stack the weights of all the neurons in a layer as rows of a grid. Then one grid-times-list operation computes the whole layer at once.
5. That grid is the **weight matrix**. Its height is the number of neurons and its width is the number of inputs.
6. The whole forward pass becomes: multiply by a matrix, add a bias list, apply the bend. Repeat once per layer. That is all a network is.
7. Chapter 22 explained the matrix multiplication and the chip that does it. This is the same operation, unchanged, on bigger grids.
8. That is not a coincidence or an analogy. It is the same arithmetic, and it is the entire reason graphics hardware runs this field.

■ 46.11.2 PLAIN – a picture in your head

1. Imagine a spreadsheet where a whole column of results is computed by one formula dragged down.
2. You do not calculate each cell separately. You describe the pattern once and the machine fills the column.
3. A matrix multiplication is that idea in two directions at once, and on hardware built to do thousands of the multiplications simultaneously.

Where this comparison breaks: a spreadsheet computes cells one after another and just hides it from you. A graphics chip genuinely computes thousands at the same instant, in separate arithmetic units. The parallelism is real, not presentational, and that difference is worth roughly a thousandfold in speed.

■ 46.11.3 PLAIN – a worked example

1. A two-layer network. Two inputs, three hidden units with ReLU, one output.
2. Input $x = [1.0, 2.0]$.
3. Layer 1 weight matrix $W1$, three rows of two, and bias $b1$:

$$\begin{array}{|l} W1 = \begin{bmatrix} 0.5 & -0.2 \\ 0.3 & 0.8 \\ -0.4 & 0.1 \end{bmatrix} \quad b1 = \begin{bmatrix} 0.1 \\ -0.1 \\ 0.2 \end{bmatrix} \end{array}$$

4. Multiply row by row. Row 1: $(0.5 \times 1.0) + (-0.2 \times 2.0) = 0.5 - 0.4 = 0.1$. Add bias 0.1, giving 0.2.
5. Row 2: $(0.3 \times 1.0) + (0.8 \times 2.0) = 0.3 + 1.6 = 1.9$. Add bias -0.1, giving 1.8.
6. Row 3: $(-0.4 \times 1.0) + (0.1 \times 2.0) = -0.4 + 0.2 = -0.2$. Add bias 0.2, giving 0.0.
7. So $z1 = [0.2, 1.8, 0.0]$. Apply ReLU: nothing is negative, so $a1$ is unchanged at $[0.2, 1.8, 0.0]$.
8. Layer 2 is one row of three: $W2 = [1.0, -0.5, 0.25]$, and $b2 = [0.05]$.
9. Multiply: $(1.0 \times 0.2) + (-0.5 \times 1.8) + (0.25 \times 0.0) = 0.2 - 0.9 + 0 = -0.7$. Add bias: $-0.7 + 0.05 = -0.65$.
10. Output is -0.65. If this were a two-class problem, apply sigmoid: 0.343, so 34.3 percent.
11. Total parameters: $(3 \times 2 + 3) + (1 \times 3 + 1) = 9 + 4 = 13$. Total arithmetic: 9 multiply-adds. That is the whole network.
12. Written compactly, the entire forward pass is two lines:

$$\begin{array}{|l} a1 = \text{ReLU}(W1 @ x + b1) \\ out = \text{sigmoid}(W2 @ a1 + b2) \end{array}$$

■ 46.11.4 PLAIN – what is really happening inside

1. Now count the work for a real network: the 784 to 128 to 64 to 10 digit classifier from section 46.10.
2. Each weight is used exactly once per input, in one multiply and one add. So count multiply-accumulate operations, then double for floating-point operations.

Layer	Multiply-adds	FLOPs
784 → 128	100,352	200,704
128 → 64	8,192	16,384
64 → 10	640	1,280
Total	109,184	218,368

3. About 218,000 floating-point operations to classify one digit. A modern laptop core does billions per second, so this takes microseconds.
4. Useful rule to memorize: a forward pass costs roughly two floating-point operations per parameter. Here, 218,368 divided by 109,386 is 1.996.
5. That rule holds for dense layers and for transformers, so it lets you estimate the cost of any model you know the size of.
6. Now batching. Instead of one input vector, stack 64 inputs as columns of a matrix. One matrix-times-matrix computes all 64 forward passes.
7. Same total arithmetic, 64 times 218,368 which is about 14 million operations, but each weight is loaded from memory once and used 64 times.
8. Chapter 22 made the point that memory bandwidth, not arithmetic, is usually the limit. Batching is how you escape it, and it is why batch size is a performance knob and not only a statistical one.

■ 46.11.5 TECHNICAL – the engineer’s version

1. For a layer with weight matrix W of shape (m, n) , input X of shape (n, B) where B is the batch size, and bias b of shape $(m, 1)$: $Z = W X + b$, broadcast over the batch dimension, then $A = f(Z)$.
2. This is a GEMM, a general matrix-matrix multiply, the operation every BLAS library optimizes above all others. On NVIDIA hardware it runs through cuBLAS or CUTLASS, and on tensor cores where precision allows.
3. Cost: $2 m n B$ FLOPs. Memory traffic if unbatched and uncached: $m n$ reads for the weights per sample. The arithmetic intensity, operations per byte, rises linearly with B until the compute units saturate.
4. Convention warning: mathematics texts write $W x$ with x as a column vector. PyTorch’s `nn.Linear` stores weight of shape $(\text{out\_features}, \text{in\_features})$ but computes $x @ W.T + b$ with x of shape $(\text{batch}, \text{in\_features})$, so the batch dimension is first. Both conventions are in daily use and mixing them up is a common source of shape errors.
5. Real forward-pass costs, per single sample:

Model	Parameters	FLOPs per forward
MNIST MLP above	109 thousand	0.22 million
ResNet-50, 224px	25.6 million	about 8.2 billion
GPT-3, per token	175 billion	about 350 billion

6. Note ResNet-50 breaks the two-FLOPs-per-parameter rule badly, at about 320 FLOPs per parameter. That is because convolution reuses each weight at every spatial position. The rule applies to dense layers, and transformers are mostly dense layers, which is why it works there.

7. The training-cost rule of thumb, from Kaplan and colleagues in 2020, is about $6ND$ floating-point operations to train a model of N parameters on D tokens: roughly $2N$ for the forward pass and $4N$ for the backward pass.
8. Precision matters enormously here, and Chapter 22 gave the per-chip figures. The short summary without repeating them: halving the bits per number roughly doubles the achievable rate on the same silicon, which is why training moved from FP32 to mixed BF16 and inference is moving to FP8 and 4-bit integers.

■ 46.11.6 WORDS – remember these

1. Forward pass — running the input through to the output — evaluating the composed function, layer by layer, with no gradient computation.
2. Weight matrix — the grid holding a layer's weights — a matrix of shape (out_features, in_features).
3. GEMM — the matrix multiply that dominates the work — general matrix-matrix multiply, the core BLAS level-3 routine.
4. Batch dimension — many inputs processed at once — the axis over which samples are stacked to raise arithmetic intensity.
5. FLOP — one floating-point operation — one multiply or one add; a forward pass through dense layers costs about 2 per parameter.

46.12 Backpropagation

■ 46.12.1 PLAIN – in simple words

1. The network produced an answer. The answer was wrong by some amount. Now what?
2. Every weight in the network contributed something to that wrong answer. Some contributed a lot. Some contributed almost nothing. Some pushed in the right direction and were outvoted.
3. What we need is, for each weight, its share of the blame: if this one weight were slightly larger, would the error get better or worse, and by how much?
4. **Backpropagation** is the procedure that works out every weight's share.
5. It works backwards. It starts at the output, where the error is directly measurable, and moves towards the input, one layer at a time.
6. At the output layer, the blame is obvious. Each output weight fed directly into the answer, so its share is easy to compute.
7. Then the trick. Having computed how much blame belongs to each unit in the last hidden layer, that blame is passed further back, split among the weights that fed those units, in proportion to how strongly each fed them.
8. Repeat until you reach the input. Now every weight in the network has a number attached: its share of the error.
9. Then every weight is nudged a little, against its share. Weights that made things worse move down. Weights that helped move up.
10. That is it. Compute forwards, assign blame backwards, nudge everything. Millions of times.
11. The reason this matters so much is efficiency. It computes the share for every weight in one backward sweep, costing about twice one forward pass, regardless of how many weights there are.

■ 46.12.2 PLAIN – a picture in your head

1. A large company delivers a project three weeks late. The chief executive wants to know who is responsible.
2. She does not interview every one of ten thousand employees. That would take longer than the project.
3. Instead she asks four department heads: how much of the delay came through your department? They can answer, because they sit right next to the outcome.
4. Manufacturing says 60 percent, logistics 30 percent, design 10 percent.
5. Now each head asks their own team leads the same question, splitting only their own share. The manufacturing head splits her 60 percent among five teams.
6. Each team lead splits their portion among their engineers. In four rounds, every one of ten thousand employees has a number.
7. Four conversations per level, not ten thousand interviews. The saving is the whole point.
8. And the blame is proportional to influence. Someone whose work barely touched the delivery date receives a share near zero automatically.

Where this comparison breaks, and it matters. First, blame in a company is a judgement, and people argue. Here it is an exact derivative with a single correct value. Second, real blame implies fault. Here a “share” can be negative, which simply means that increasing that weight would reduce the error, so the weight should grow. Third, and most important, the shares are only valid for a tiny nudge. They tell you the effect of changing one weight by a hair while everything else stays fixed. Change all the weights at once by a large amount and the shares no longer describe reality. That is exactly why the learning rate must be small.

■ 46.12.3 PLAIN – a worked example

1. Now the chain rule, which is the exact rule behind the blame splitting.
2. If a affects b, and b affects c, then the effect of a on c is the effect of a on b multiplied by the effect of b on c.
3. If turning a dial doubles a pressure, and doubling the pressure triples a flow, then turning the dial multiplies the flow by six. Effects along a chain multiply.
4. A network is a long chain, so a weight’s effect on the loss is the product of the effects at every step between that weight and the loss.
5. Here is the network we will do completely. Two inputs, two hidden units with sigmoid, one output unit with sigmoid, and the loss is half the squared error.

```
x1=0.5 --w11=0.8--> h1 --v1=0.5--\
      \--w21=0.2-> h2 --v2=-0.3--> out -> loss
x2=-1.0-/w12=-0.4, w22=0.6/
biases: b1=0.1, b2=-0.2, c=0.2      target y = 1.0
```

6. Forward pass. Hidden unit 1: $z = (0.8 \times 0.5) + (-0.4 \times -1.0) + 0.1 = 0.4 + 0.4 + 0.1 = 0.9$. Sigmoid of 0.9 = 0.710950.
7. Hidden unit 2: $z = (0.2 \times 0.5) + (0.6 \times -1.0) + (-0.2) = 0.1 - 0.6 - 0.2 = -0.7$. Sigmoid of -0.7 = 0.331812.
8. Output: $z = (0.5 \times 0.710950) + (-0.3 \times 0.331812) + 0.2 = 0.355475 - 0.099544 + 0.2 = 0.455931$. Sigmoid = 0.612048.
9. Loss = $0.5 \times (0.612048 - 1.0)^2 = 0.5 \times 0.150506 = 0.075253$.
10. Backward pass, output layer first.
11. Effect of the output on the loss: predicted minus target = $0.612048 - 1.0 = -0.387952$.

12. Effect of the pre-activation on the output, which is the sigmoid derivative: $0.612048 \times (1 - 0.612048) = 0.237445$.
13. Multiply them. This product is the output unit's blame share, called delta: $-0.387952 \times 0.237445 = -0.092117$.
14. Now each output weight's share is that delta times the activation it multiplied:
15. Share for $v1 = -0.092117 \times 0.710950 = -0.065491$.
16. Share for $v2 = -0.092117 \times 0.331812 = -0.030566$.
17. Share for the output bias $c = -0.092117$, because a bias multiplies 1.
18. Now push the blame back to the hidden units. Each hidden unit's blame is the output delta times the weight connecting them, times that unit's own sigmoid derivative.
19. Hidden unit 1: $-0.092117 \times 0.5 = -0.046059$. Its sigmoid derivative is $0.710950 \times 0.289050 = 0.205500$. Product: -0.009465 .
20. Hidden unit 2: $-0.092117 \times -0.3 = +0.027635$. Its sigmoid derivative is $0.331812 \times 0.668188 = 0.221713$. Product: $+0.006127$.
21. Note that hidden unit 2 got a positive share while unit 1 got a negative one, because its outgoing weight was negative. The sign carried through the multiplication automatically.
22. Now the input weights. Each is its unit's delta times the input it multiplied:
23. $w11 = -0.009465 \times 0.5 = -0.004733$. $w12 = -0.009465 \times -1.0 = +0.009465$.
24. $w21 = +0.006127 \times 0.5 = +0.003064$. $w22 = +0.006127 \times -1.0 = -0.006127$.
25. Biases $b1 = -0.009465$ and $b2 = +0.006127$.
26. Every parameter now has a share. Update with a learning rate of 0.5, using new value = old value minus rate times share:

Parameter	Old	Share	New
$v1$	0.5	-0.065491	0.532745
$v2$	-0.3	-0.030566	-0.284717
c	0.2	-0.092117	0.246059
$w11$	0.8	-0.004733	0.802366
$w12$	-0.4	+0.009465	-0.404733
$w21$	0.2	+0.003064	0.198468
$w22$	0.6	-0.006127	0.603064

27. Run the forward pass again with the new numbers. Output is now 0.629935, up from 0.612048, and the loss is 0.068474, down from 0.075253.
28. It moved towards the target of 1.0. One step, and it worked.
29. Continue: after 5 steps the output is 0.688, after 20 steps 0.801, after 50 steps 0.874. Loss falls from 0.0753 to 0.0079.
30. That is training. Everything else is this, at scale.

■ 46.12.4 PLAIN – what is really happening inside

1. Notice something about the arithmetic above. The value 0.710950 was used twice: once going forward, and once coming back.
2. That is the reason the forward pass stores its intermediate values. Every activation computed on the way in is kept, because the backward pass needs it.
3. This is why training uses far more memory than inference. Inference can discard each layer's output as soon as the next layer has consumed it. Training cannot discard anything until the backward pass has been.

4. For large models this stored activation memory frequently exceeds the memory taken by the weights themselves.
5. The other thing to notice: at no point did anyone write down a derivative formula for the whole network.
6. Each small step knew only its own local rule. The sigmoid knows its own derivative. Multiplication knows its own. Addition knows its own.
7. The overall answer came from chaining those local rules together, mechanically.
8. That mechanical chaining is called **automatic differentiation**, and it is what PyTorch, JAX and TensorFlow actually implement. Backpropagation is one specific use of it.
9. Here is how the frameworks do it. As the forward pass runs, every operation records itself and its inputs onto a graph. Multiply here, add there, ReLU there. That is the **computation graph**.
10. When you ask for gradients, the framework walks that graph backwards. At each node it applies that operation's known local derivative rule and multiplies it into what arrived from downstream.
11. The graph is built while the code runs, so an `if` statement or a loop in your model creates a different graph on different inputs, and it still works. That style is called define-by-run, and PyTorch popularized it.
12. So you never write a gradient. You write the forward computation in ordinary code, call `.backward()`, and every parameter's share appears in its `.grad` field.

■ 46.12.5 TECHNICAL – the engineer's version

1. Notation for a network of L layers, with z the pre-activation, a the activation, and δ the error signal at a layer.
2. Output layer: $\delta_L = \text{grad}_a L$, elementwise times $f'(z_L)$. For the common pairing of softmax with cross-entropy, this simplifies exactly to predicted probability minus one-hot target, with no activation derivative left over.
3. Recurrence for earlier layers: $\delta_l = (W_{l+1})^T \delta_{l+1}$, elementwise times $f'(z_l)$.
4. Parameter gradients: $dL/dW_l = \delta_l a_{l-1}^T$, and $dL/db_l = \delta_l$. Summed over the batch.
5. Read those four lines again. The forward pass multiplies by W . The backward pass multiplies by W^T . That is the whole structural symmetry, and it is why backward costs about the same as forward.
6. Cost: the backward pass is about twice the forward, because each layer computes both the gradient with respect to its input and the gradient with respect to its weights. Total training step is about three times a forward pass, giving the $2N$ forward plus $4N$ backward that produces the $6ND$ rule.
7. Memory: activations for all L layers must be retained. Gradient checkpointing, from Chen and colleagues in 2016, stores only some layers and recomputes the rest during the backward pass, trading roughly 30 percent more compute for a large memory saving. It is standard for large models.
8. Automatic differentiation has two modes. Reverse mode, used here, costs one sweep per output and is efficient when outputs are few and inputs are many. Forward mode costs one sweep per input and is efficient in the opposite case. Training has one scalar loss and billions of parameters, so reverse mode wins by an enormous margin.
9. Reverse mode is Linnainmaa's 1970 result. Applying it to networks is Werbos in 1974 and Rumelhart, Hinton and Williams in 1986.
10. Backpropagation is not finite differences. Nudging each weight and re-running would cost one

forward pass per parameter, so 175 billion forward passes for GPT-3 instead of one backward pass. It is also not symbolic differentiation, which would produce an expression that grows explosively with depth. Automatic differentiation is a third thing: numerically exact, and linear in the size of the computation.

```
import torch
x = torch.tensor([0.5, -1.0])
W1 = torch.tensor([[0.8, -0.4], [0.2, 0.6]], requires_grad=True)
b1 = torch.tensor([0.1, -0.2], requires_grad=True)
h = torch.sigmoid(W1 @ x + b1)
v = torch.tensor([0.5, -0.3], requires_grad=True)
c = torch.tensor(0.2, requires_grad=True)
out = torch.sigmoid(v @ h + c)
loss = 0.5 * (out - 1.0) ** 2
loss.backward()
print(v.grad)      # tensor([-0.0655, -0.0306])
print(W1.grad)     # tensor([[ -0.0047,  0.0095], [ 0.0031, -0.0061]])
```

11. Those printed gradients are exactly the shares computed by hand above. The hand calculation and the framework agree to the digits shown.
12. Practical detail: gradients accumulate by default in PyTorch, so `optimizer.zero_grad()` must be called each step. Forgetting it is one of the most common bugs in the field, and it shows up as training that starts fine and then degrades.

■ 46.12.6 WORDS - remember these

1. Backpropagation — passing the blame backwards through the layers — reverse- mode automatic differentiation applied to a layered network.
2. Chain rule — effects along a chain multiply — the derivative of a composition is the product of the derivatives of its parts.
3. Delta / error signal — one unit's share of the blame — the partial derivative of the loss with respect to that unit's pre-activation.
4. Computation graph — the record of every operation performed — a directed acyclic graph of operations and tensors, built during the forward pass.
5. Automatic differentiation — chaining known local derivative rules mechanically — exact derivative evaluation at machine precision, linear in the cost of the original computation.
6. Gradient checkpointing — recomputing instead of storing — trading extra forward compute for reduced activation memory during backpropagation.

46.13 Training in practice

■ 46.13.1 PLAIN - in simple words

1. The theory so far says: start somewhere, compute gradients, step downhill. In practice, five extra things decide whether it works at all.
2. **Initialization:** what the weights are before training starts. They cannot all be zero, because then every neuron in a layer computes the same thing, gets the same gradient, and stays identical forever. Symmetry must be broken by randomness.
3. But the random numbers cannot be any size. Too large and each layer amplifies its input, so after twenty layers the numbers explode. Too small and each layer shrinks its input, so after twenty layers the signal is gone.
4. The fix is to scale the random numbers by the size of the layer, so each layer roughly preserves the scale of what passes through it.

5. **Input normalization:** rescale your input data so each feature has an average near zero and a similar spread. Section 46.5 showed this making the safe learning rate thirty-five times larger on a two-parameter problem.
6. **Normalization inside the network:** do the same rescaling to the values flowing between layers, not just at the entrance.
7. **Gradient clipping:** if the gradient is enormous, shrink it before taking the step, so one bad batch cannot destroy the model.
8. **Learning rate schedules:** do not use one step size for the whole run. Start small, grow, then shrink towards the end.
9. None of these change what the model can represent. All of them change whether you can find the weights.

■ 46.13.2 PLAIN – a picture in your head

1. Think of a chain of loudspeakers, each feeding the next one's microphone.
2. If every stage amplifies by 1.5, then after twenty stages the signal is 3,300 times louder and everything clips into noise.
3. If every stage attenuates by 0.7, after twenty stages the signal is one thousandth of its original size and is lost in the hiss.
4. What you want is every stage having a gain of almost exactly 1, so the signal arrives at the end intact.
5. Careful initialization is setting each amplifier's gain to about 1 at the start. Normalization layers are automatic gain control, resetting the level at each stage while the system runs.

Where this comparison breaks: an audio chain carries one signal and the right gain is obviously 1. A network carries hundreds of dimensions, and the useful quantity is the variance across them, not the level of one. Also, the gradient flows in the opposite direction to the signal, and it has its own gain that can explode or vanish independently. Initialization schemes have to compromise between keeping the forward pass and the backward pass both well scaled, and in general you cannot have both exactly.

■ 46.13.3 PLAIN – a worked example

1. Xavier initialization, from Glorot and Bengio in 2010: draw weights from a distribution with standard deviation equal to the square root of 2 divided by (inputs plus outputs).
2. He initialization, from He and colleagues in 2015: standard deviation equal to the square root of 2 divided by inputs. It is larger, to compensate for ReLU throwing away half the signal.

Layer shape	Xavier std	He std
784 -> 128	0.0468	0.0505
128 -> 64	0.1021	0.1250
512 -> 512	0.0442	0.0625

3. Rule: Xavier with tanh or sigmoid, He with ReLU and its relatives. Both ship in every framework and are usually the default already.
4. Gradient clipping by norm, worked. Suppose three parameters have gradients 3.0, 4.0 and 12.0.
5. The norm is the square root of $(9 + 16 + 144) = \text{square root of } 169 = 13.0$.
6. Clip threshold is 1.0. Since 13.0 exceeds 1.0, multiply every component by $1.0 / 13.0 = 0.07692$.
7. New gradients: 0.2308, 0.3077, 0.9231. Their norm is exactly 1.0.

8. The direction is unchanged. Only the length was cut. That is the point: you still step the right way, just not off a cliff.
9. A warmup-plus-cosine schedule, with peak rate $3e-4$, 2,000 warmup steps and 100,000 total steps:

Step	Learning rate
0	0
1,000	$1.5e-4$
2,000	$3.0e-4$ (peak)
10,000	$2.95e-4$
50,000	$1.55e-4$
100,000	0

10. Warmup exists because at step zero the weights are random, the gradients are large and meaningless, and a full-size step would throw the model somewhere useless before it has learned anything. Starting from zero and ramping up avoids that.

■ 46.13.4 PLAIN – what is really happening inside

1. The two normalization layers, and exactly what each normalizes. People confuse these constantly.
2. **Batch normalization**, from Ioffe and Szegedy in 2015: for each feature, compute the average and spread across all the samples in the batch, then rescale that feature so it has mean 0 and variance 1.
3. It normalizes down the batch. Sample 5's value for feature 3 depends on what samples 1 to 64 happened to be.
4. That has a strange consequence: a sample's output depends on which other samples it travelled with. At inference you have no batch, so batch norm keeps a running average from training and uses that instead. This train versus inference difference is a genuine source of bugs.
5. **Layer normalization**, from Ba, Kiros and Hinton in 2016: for each sample, compute the average and spread across that sample's own features, then rescale.
6. It normalizes across the features. Each sample is handled entirely alone, so the batch size does not matter and training and inference behave identically.
7. That independence is why layer normalization won in transformers and sequence models, where sequences have different lengths and batch statistics are unreliable. Batch normalization remains standard in convolutional image networks.
8. One sentence to remember: batch norm normalizes each feature over the batch; layer norm normalizes each sample over its features.
9. Both add two learned parameters per feature, a scale and a shift, so the network can undo the normalization where it is unhelpful.

■ 46.13.5 TECHNICAL – the engineer's version

1. Troubleshooting, which is the most useful table in this chapter:

Symptom	Likely cause	Action
Loss is NaN	learning rate too high	halve it, add clipping
Loss flat from step 0	rate too low, or dead net	raise rate 10x, check init
Loss falls then explodes	rate too high late	add warmup and decay
Train falls, val rises	overfitting	augment, regularize, stop
Both flat and high	underfitting	bigger model, more steps

Symptom	Likely cause	Action
Loss spikes then recovers	bad batch or outlier	clip gradients, shuffle
Val loss very noisy	val set too small	enlarge it, use EMA
Works on 1 batch, not all	data pipeline bug	overfit 1 batch first
Slower each epoch	memory leak	check retained graphs

2. The single best debugging habit: take one batch of eight samples and train until the loss reaches near zero. If a model cannot memorize eight examples, the bug is in your code, not your hyperparameters. This takes two minutes and saves days.
3. Schedules in common use: step decay, which multiplies by 0.1 at fixed epochs, the classic ImageNet recipe; cosine annealing, from Loshchilov and Hutter in 2016, now the default for transformers; and inverse square root, used in the original 2017 transformer paper with 4,000 warmup steps.
4. Typical warmup lengths for large language models are 1 to 2 percent of total steps, or a fixed 2,000 steps. This is a convention, not a standard.
5. Gradient clipping: clip by global norm, not per-parameter, so the update direction is preserved. A threshold of 1.0 is the near-universal default for transformer training.
6. Mixed precision is standard practice: keep a master copy of weights in FP32, compute in BF16 or FP16, and with FP16 scale the loss up before the backward pass to stop small gradients underflowing to zero. BF16 has the same exponent range as FP32 so it usually needs no loss scaling, which is why it is preferred on hardware that supports it.
7. Observation tools: TensorBoard or Weights and Biases for curves, `torch.cuda.max_memory_allocated()` for memory, `nvidia-smi` for utilization, and `torch.profiler` or Nsight Systems for finding the real bottleneck. Low GPU utilization almost always means the data loader, not the model.
8. Reproducibility caveat: seeding with `torch.manual_seed` is not sufficient for bit-identical runs, because some GPU kernels are non-deterministic by design. `torch.use_deterministic_algorithms(True)` forces determinism where possible, at some cost in speed.

■ 46.13.6 WORDS - remember these

1. Initialization — the random starting values of the weights — a distribution chosen to keep activation and gradient variance stable across depth.
2. Xavier / Glorot initialization — scaling by inputs plus outputs — variance $2/(\text{fan\_in} + \text{fan\_out})$, suited to tanh and sigmoid.
3. He initialization — scaling by inputs only, larger — variance $2/\text{fan\_in}$, compensating for ReLU zeroing half its input.
4. Batch normalization — rescaling each feature across the batch — normalizing over the batch dimension, with running statistics used at inference.
5. Layer normalization — rescaling each sample across its own features — normalizing over the feature dimension, identical in training and inference.
6. Gradient clipping — cutting the step length without changing direction — rescaling the gradient vector when its global norm exceeds a threshold.
7. Warmup — starting with tiny steps and ramping up — a linear increase of the learning rate over the first steps, before the main decay schedule.

46.14 The families of neural network

■ 46.14.1 PLAIN – in simple words

1. Everything so far described the **feedforward** network: layers in a line, every unit connected to every unit in the next layer. It is the default and the fallback.
2. Its weakness is that it treats every input as unrelated to every other. Move a picture one pixel to the right and it is a completely different input.
3. A **convolutional network** fixes this for images. Instead of one weight per pixel, it learns a small patch of weights and slides that same patch over the whole image.
4. So a pattern learned in one corner is recognized everywhere, and the number of weights collapses.
5. A **recurrent network** handles sequences, such as words or sound. It reads one item at a time and keeps a running summary of what it has read.
6. An **autoencoder** learns to squeeze data into a small representation and rebuild it. Useful for compression, denoising and finding structure.
7. A **generative adversarial network** trains two networks against each other: one makes fakes, one detects fakes, and both improve.
8. A **diffusion model** learns to remove noise, and generates by starting from pure noise and removing it repeatedly until an image appears.
9. A **graph neural network** works on data with connections, such as molecules or social networks, by passing messages along the edges.
10. The **transformer** replaced recurrent networks for almost all sequence work after 2017. Chapter 48 covers it properly.

■ 46.14.2 PLAIN – a picture in your head

1. Think of a rubber stamp and an ink pad.
2. A convolutional filter is a stamp with a small pattern cut into it. You press it at every position on the page and record how well the pattern matched there.
3. One stamp finds one thing: a vertical edge, a spot of red, a diagonal line.
4. A layer has many stamps, so you get many maps of where each pattern occurred.
5. The next layer stamps patterns onto those maps, so it finds combinations of patterns. A corner is where a vertical edge map and a horizontal edge map both light up.
6. Layer after layer, the patterns become larger and more specific.

Where this comparison breaks: a stamp is a fixed pattern you carved. These are learned from data, and typically nobody can say in words what most of them detect. The early ones do look like edge detectors and colour blobs, reliably and across independently trained networks, which is a genuine and repeatable finding. The middle ones are much harder to describe, and the neat story that each unit detects one nameable thing is often false.

■ 46.14.3 PLAIN – a worked example

1. One convolution, worked completely. A 5 by 5 image with a vertical edge in it: two dark columns then three bright ones.

image	kernel (vertical edge)		
0 0 10 10 10	-1	0	+1
0 0 10 10 10	-2	0	+2
0 0 10 10 10	-1	0	+1
0 0 10 10 10			
0 0 10 10 10			

2. The kernel is 3 by 3, so it fits in the image at $3 \times 3 = 9$ positions.
3. Take the top-left position. The window covers rows 1 to 3, columns 1 to 3: all values are 0, 0, 10 on each row.
4. Multiply each window value by the kernel value in the same place and add:
5. Row 1: $(0 \times -1) + (0 \times 0) + (10 \times +1) = 10$.
6. Row 2: $(0 \times -2) + (0 \times 0) + (10 \times +2) = 20$.
7. Row 3: $(0 \times -1) + (0 \times 0) + (10 \times +1) = 10$.
8. Total: $10 + 20 + 10 = 40$. That is one output value.
9. Slide right by one and repeat. Do this for all nine positions:

```
output (3x3)
 40 40 0
 40 40 0
 40 40 0
```

10. Read it. The left columns are strongly positive, marking the edge. The right column is exactly 0, because that window was uniformly bright, and a uniform region produces no edge response.
11. Nine parameters found a vertical edge anywhere in the image. A fully connected layer would have needed 25 weights per output unit and would have had to learn the pattern separately at every position.
12. Now **pooling**, which shrinks the map. Take a 4 by 4 grid and keep the largest value in each 2 by 2 block:

```
 1  3 | 2  4          max-pool 2x2, stride 2
 5  6 | 1  2  ---->    6  4
-----+-----        7  9
 7  2 | 8  0
 1  4 | 3  9
```

13. The result is half the size in each direction, so a quarter of the values. It keeps the strongest response and discards where exactly it occurred, which makes the network tolerant of small shifts.

■ 46.14.4 PLAIN - what is really happening inside

1. Recurrent networks and their fundamental limit, which is worth understanding properly because it explains why transformers exist.
2. A recurrent network reads word one, updates a hidden summary, reads word two, updates it again, and so on. The same weights are used at every step.
3. So the summary after 50 words has been through 50 multiplications by the same matrix.
4. If that matrix shrinks things slightly, the influence of word one is multiplied by a number below 1 fifty times and vanishes. If it grows things slightly, the influence explodes.
5. That is the vanishing and exploding gradient problem again, this time through time rather than through layers, and it is why plain recurrent networks cannot remember much past about ten steps.
6. The **LSTM**, from Hochreiter and Schmidhuber in 1997, fixes it with a separate memory line that information can travel along unchanged, plus three learned gates that decide what to write, what to keep and what to read. That memory path is additive rather than multiplicative, so gradients survive along it. LSTMs handle hundreds of steps.
7. But there is a second limit that no gate fixes: a recurrent network must process step 1 before step 2. It is sequential by construction.
8. That means it cannot use the parallel hardware from Chapter 22 across the sequence. Doubling your chips does not halve your training time.

9. The transformer's central trick is to let every position look at every other position at once, in one matrix multiplication, with no sequential dependency. That is why it took over. Chapter 48 explains how.
10. Established fact: transformers replaced recurrent networks for nearly all language work from about 2018 onwards. Active research: state-space models such as Mamba, from 2023, revisit the recurrent idea with a formulation that can be parallelized during training. Whether they displace attention at scale is genuinely open as of 2026.

■ 46.14.5 TECHNICAL – the engineer's version

1. Summary of the families:

Family	Best for	Key idea
Feedforward MLP	tabular, final heads	dense layers
Convolutional	images, spectrograms	shared local filters
Recurrent / LSTM	short sequences, streams	carried hidden state
Transformer	text, and now most things	all-pairs attention
Autoencoder	compression, anomalies	bottleneck plus rebuild
GAN	fast image synthesis	generator versus critic
Diffusion	high-quality generation	learned denoising
Graph network	molecules, networks	message passing on edges

2. Convolution parameter count: a layer with C_{in} input channels, C_{out} output channels and a k by k kernel has $C_{in} \times C_{out} \times k \times k$ weights plus C_{out} biases, independent of image size. A 3×3 layer with 64 in and 128 out has 73,728 weights and is applied at every spatial position.
3. Convolution FLOPs: $2 \times H_{out} \times W_{out} \times C_{in} \times C_{out} \times k \times k$. This is why ResNet-50 costs about 8.2 billion operations per 224 by 224 image with only 25.6 million parameters. Weights are reused, not multiplied.
4. Convolutional milestones: Fukushima's Neocognitron in 1980, LeCun's backpropagation-trained digit network at Bell Labs in 1989, LeNet-5 in 1998 reading cheques in production, AlexNet in 2012, VGG and GoogLeNet in 2014, ResNet in 2015.
5. What is actually implemented: most convolutional layers are lowered to a matrix multiply, either by the im2col transformation or by an implicit GEMM in cuDNN, so the underlying arithmetic is the same GEMM from Chapter 22. Winograd algorithms are used for small kernels to cut the multiply count.
6. Autoencoders: an encoder maps to a bottleneck of lower dimension, a decoder rebuilds, and the loss is reconstruction error. The variational autoencoder, from Kingma and Welling in 2013, adds a probabilistic latent distribution and enables generation. Autoencoder latents are used inside modern image diffusion models to work in a compressed space rather than pixel space.
7. GANs, from Ian Goodfellow and colleagues in 2014, train a generator and a discriminator in a minimax game. They produce images in a single forward pass, which is fast, but training is notoriously unstable and can collapse to producing a few outputs repeatedly. Diffusion models displaced them for quality from about 2021.
8. Diffusion models come from Sohl-Dickstein and colleagues in 2015, made practical by Ho, Jain and Abbeel's denoising diffusion probabilistic models in 2020. A forward process adds Gaussian noise in steps; a network learns to predict and remove it; generation runs the process backwards from noise. Sampling originally took hundreds of steps; distilled and flow-matching variants now reach single-digit steps. This area is moving fast.

9. Graph neural networks aggregate each node's neighbours' features, transform the result, and repeat. Message passing was formalized by Gilmer and colleagues in 2017. They are used in molecular property prediction, and AlphaFold 2 in 2021 combined graph-like reasoning with attention.

■ 46.14.6 WORDS - remember these

1. Convolution — sliding one small pattern over the whole image — a shared, local, translation-equivariant linear operator, implemented as a GEMM.
2. Kernel / filter — the small patch of learned weights — the k by k by C_{in} tensor slid across the input.
3. Pooling — shrinking the map by keeping the strongest response — a downsampling operation, usually 2×2 max or average with stride 2.
4. Feature hierarchy — edges first, objects later — successive layers representing progressively larger and more abstract patterns.
5. Recurrent network — reading a sequence while keeping a running summary — a network applying shared weights over time steps with a carried hidden state.
6. LSTM — a recurrent unit with a protected memory line — long short-term memory, with input, forget and output gates over an additive cell state.
7. Autoencoder — squeeze it small, then rebuild it — an encoder-decoder trained on reconstruction loss through a bottleneck.
8. Diffusion model — generating by repeatedly removing noise — a model trained to reverse a gradual noising process.

46.15 What a trained model physically is

■ 46.15.1 PLAIN - in simple words

1. After all the training, what do you actually have? A file.
2. The file contains numbers. Nothing else. No code, no logic, no rules you could read.
3. It is a long list of the weights and biases, in a known order, with a small index at the front saying which block of numbers belongs to which layer.
4. To use the model you need two things: this file, and the code that knows the architecture, so it can put each block of numbers in the right place.
5. Neither is useful alone. The file without the architecture is noise. The architecture without the file is an untrained network that outputs rubbish.
6. **Training** is the expensive process of producing the file. **Inference** is the cheap process of using it to answer one question.
7. Training happens once, on a cluster, for weeks. Inference happens billions of times, on one machine, in milliseconds.
8. The asymmetry between those two is the single most important economic fact about this field. Chapter 49 goes into what is inside the file in detail.

■ 46.15.2 PLAIN - a picture in your head

1. Think of a printed dictionary.
2. Compiling it took a team of lexicographers many years, with arguments, revisions and enormous cost.
3. Looking up one word takes you four seconds and costs nothing.
4. The book is the model file. The compilation is training. The lookup is inference.
5. And note: you cannot recover the arguments, the drafts or the sources from the finished book. It contains the conclusions and nothing else.

Where this comparison breaks: a dictionary can be read by a person and checked entry by entry. A model file cannot. There is no entry for anything. The knowledge, if that word even applies, is spread across all the numbers at once, and no single number means anything on its own. That property is called distributed representation, and it is why interpreting these models is hard research rather than an afternoon of reading.

■ 46.15.3 PLAIN – a worked example

1. File sizes, computed directly. Multiply the parameter count by the bytes per number.

Model	Parameters	Precision	File size
MNIST MLP	109,386	FP32	0.44 MB
ResNet-50	25.6 million	FP32	102 MB
Llama-class 8B	8 billion	BF16	16 GB
Llama-class 70B	70 billion	BF16	140 GB
Same 70B, 4-bit	70 billion	INT4	35 GB

2. The arithmetic is simply: FP32 is 4 bytes per number, BF16 and FP16 are 2, INT8 is 1, INT4 is half a byte.
3. That last row is why quantization matters. The same model drops from 140 GB to 35 GB, which is the difference between needing several datacentre cards and fitting on one.
4. Now the compute asymmetry, with the standard estimates. Training cost is about 6 times parameters times training tokens.
5. For an 8-billion-parameter model trained on 15 trillion tokens: $6 \times 8e9 \times 15e12 = 7.2e23$ floating-point operations.
6. Inference cost for one token is about 2 times parameters: $2 \times 8e9 = 1.6e10$ operations.
7. The ratio is $4.5e13$. Training that model costs about as much arithmetic as generating 45 trillion tokens with it.
8. So if the model serves a billion tokens a day, the training cost is repaid in arithmetic terms after about 45,000 days of service.
9. That is why nobody trains their own foundation model unless they are selling access to it, and why fine-tuning an existing file is the normal path.

■ 46.15.4 PLAIN – what is really happening inside

1. Inside the file, the layout is boring by design.
2. A header holds the metadata: the name of each tensor, its shape, its data type, and the byte range where its numbers start and end.
3. Then a single long region of raw numbers, laid out so a program can memory-map the file and read a tensor without copying it.
4. The safetensors format, now the default for published models, is exactly that: a JSON header giving names, shapes and offsets, then raw bytes.
5. It replaced Python's pickle format for a security reason. A pickle file can execute arbitrary code when loaded, so downloading a model was equivalent to running a stranger's program. safetensors cannot execute anything.
6. What is not in the file: the training data, the optimizer state, the code, or any record of how the numbers were reached.
7. The optimizer state is worth noting. During training, Adam keeps two extra numbers per parameter, so the training checkpoint is roughly three times the size of the final model, or four if a master FP32 copy is kept. Those extra numbers are discarded before publication.

8. Inference needs the weights and one small activation buffer. Training needs the weights, the gradients, the optimizer state, and every stored activation. That is why a model you can run on one card may need eight cards to fine-tune.

■ 46.15.5 TECHNICAL – the engineer’s version

1. Memory required, per billion parameters, as a planning table:

Purpose	Precision	Memory per 1B
Inference weights	INT4	0.5 GB
Inference weights	BF16	2 GB
Training weights	FP32 master	4 GB
Adam state	FP32, 2 moments	8 GB
Gradients	BF16	2 GB

2. So full fine-tuning at 1 billion parameters needs roughly 16 GB before activations, against 2 GB to run it. A factor of eight, and this is exactly why parameter-efficient methods such as LoRA, from Hu and colleagues in 2021, exist.
3. Formats you will meet: safetensors for published weights, ONNX for framework-portable graphs, GGUF for quantized local inference in the llama.cpp ecosystem, and TensorRT engines for compiled NVIDIA deployment.
4. Established fact: a trained model is a fixed function. Given identical inputs, identical settings and deterministic kernels, it returns identical outputs. Chat models appear to vary because a random sampler is applied to their output distribution, not because the model changed.
5. Established fact: the model does not learn from your conversation. Its weights are read-only at inference. Anything that looks like learning within a session is context, not weight change.
6. Marketing claim: that a deployed model “improves as you use it”. In almost all cases the file is static and improvements arrive as a new file, trained separately, on data that may include logged interactions. That is a different and much slower loop, and it is worth insisting on the distinction.

■ 46.15.6 WORDS – remember these

1. Model file / checkpoint — the file of trained numbers — a serialized tensor dictionary mapping parameter names to arrays.
2. Inference — using the trained model to answer — a forward pass only, with no gradients, activations discarded as soon as they are consumed.
3. Training — producing the numbers in the first place — repeated forward passes, backward passes and optimizer updates over a dataset.
4. Quantization — storing the numbers in fewer bits — reducing weight precision to INT8 or INT4 to cut memory and bandwidth, at some accuracy cost.
5. Safetensors — the safe modern weight file format — a JSON header of names, shapes and offsets over a raw tensor region, with no code execution.
6. Optimizer state — the extra numbers training needs — momentum and variance estimates, roughly two extra values per parameter for Adam.

46.98 Common wrong ideas

1. Wrong: the network understands what it is doing. Right: it computes a function. Weighted sums and bends, repeated. “Understanding” has no agreed technical definition here, and using the word imports assumptions nobody has earned. Whether internal structures deserve richer descriptions is active research, not a settled fact.
2. Wrong: more layers is always better. Right: past a point, deeper networks get harder to optimize, overfit more and cost more, without gaining accuracy. Plain networks beyond about 20 layers did not train at all until residual connections in 2015, and even now the right depth is chosen by measurement, not by adding more.
3. Wrong: it learned by itself. Right: a person chose the architecture, the loss, the optimizer, the learning rate, the schedule, the regularization, the data and when to stop. The only thing the machine did was solve, by repeated small steps, the exact optimization problem it was handed.
4. Wrong: neural networks work like brains. Right: the resemblance stopped at the 1943 model of a neuron. Real neurons spike, have timing, chemistry and internal state, and change their own structure. An artificial unit is a weighted sum and a bend. The name is historical, and today it is mostly marketing.
5. Wrong: AI is just a big pile of if-statements. Right: there are no branches at all in a dense network’s forward pass. It is a fixed sequence of multiplications, additions and one elementwise function, executed in the same order for every input. That is the opposite of branching.
6. Wrong: training finds the best possible weights. Right: it finds some set of weights where the gradient is near zero, reached from where it started. A different random start gives different weights and often similar accuracy. There is no guarantee of optimality for any non-convex model.
7. Wrong: a lower training loss means a better model. Right: training loss can always be driven down by memorizing. The only number that means anything is performance on data the model has never seen and that you never used to make a decision.
8. Wrong: the model stores its training data, so it can be asked to recall it. Right: the data shaped the parameters and was then discarded. Verbatim recall of some training examples does happen, and is a real privacy concern, but it is a side effect of over-fitting particular sequences, not a lookup mechanism.
9. Wrong: bigger datasets always help. Right: more of the same distribution has diminishing returns, and more badly labelled data actively hurts. Data quality, coverage and correct labelling usually beat raw volume.
10. Wrong: gradient descent gets stuck in local minima all the time. Right: in very high dimensions the common stationary points are saddles, not minima, because a minimum requires upward curvature in every direction at once. The practical obstacles are ill-conditioning, poor scaling and bad learning rates far more often than local minima.

46.99 Chapter summary in 20 lines

1. Machine learning writes a rule-shaped thing with adjustable numbers, and a procedure that tunes those numbers until outputs match examples.
2. It is curve fitting at heart, and saying so is accurate rather than dismissive; it is what lets you reason about the system.
3. The four pieces are always the same: a model, its parameters, a loss, and an optimizer that reduces the loss.
4. The history has two public failures. The perceptron of 1957 to 1958 was overclaimed, limited by Minsky and Papert in 1969, and funding collapsed.

5. Backpropagation existed from Linnainmaa in 1970 and Werbos in 1974 and was ignored until Rumelhart, Hinton and Williams published it in Nature in 1986.
6. In 2012 AlexNet won ImageNet with 15.3 percent top-5 error against 26.2 percent, trained on two consumer graphics cards, and the argument ended.
7. A parameter is a number the system may change; a hyperparameter is one you choose. Fitting $y = wx + b$ to five points has exactly two parameters.
8. Loss is one number saying how wrong you are. Squared error punishes large misses hardest; absolute error resists outliers. The choice changes the fit.
9. The loss surface is a landscape over the parameters, and training is walking downhill on it in fog, feeling only the slope under your feet.
10. Gradient descent steps against the gradient by a learning rate. Too small crawls; too large diverges to NaN. Normalizing inputs reshapes the ravine.
11. Momentum, RMSProp and Adam all exist to fix the same problem: plain descent zig-zags across narrow valleys instead of running along them.
12. Split your data into training, validation and test sets, and decide nothing using the test set. A widening gap between training and validation loss is overfitting, and the cure is early stopping, regularization or more data.
13. Classical methods are not obsolete. Gradient-boosted trees remain a leading choice for table-shaped data in 2026, though tabular foundation models are now competitive on small datasets and the boundary is moving.
14. One neuron is a weighted sum plus a bias, then a non-linear bend. It is not a brain cell and the analogy is historical.
15. Without the bend, stacked layers collapse algebraically into a single layer, so depth would buy exactly nothing. ReLU won because its slope is 1.
16. A forward pass is a matrix multiply, a bias add and a bend, once per layer. It is the same matrix multiply as Chapter 22, which is why GPUs run this field.
17. Backpropagation assigns each weight its share of the error by passing blame backwards layer by layer, then nudges every weight against its share.
18. That is the chain rule applied mechanically, which frameworks implement as reverse-mode automatic differentiation over a recorded computation graph.
19. Convolutional networks share small filters across an image, recurrent networks carry a running summary and cannot be parallelized over time, and the transformer of 2017 replaced them for sequences. See Chapter 48.
20. A trained model is a file of numbers, useless without the architecture that reads it. Training costs roughly $6 N D$ operations once; inference costs about $2 N$ per token, forever. See Chapter 49.

Parameters, Tokens and Embeddings

47.0 What this chapter gives you

1. You will be able to say exactly what one parameter is: a single number in a single position of a single table inside the model.
2. You will be able to take an architecture description and compute the parameter count by hand, and say which parts of the model hold the billions.
3. You will be able to tell parameters apart from hyperparameters, activations, context and tokens, and use all five words correctly in one sentence.
4. You will be able to turn a parameter count into a memory figure, for inference and for training, and explain the gap between them.
5. You will be able to explain quantization, name the common formats, and work out whether a given model fits on a given machine.
6. You will be able to say honestly why parameter count is a weak predictor of how useful a model is, and cite the evidence for that.
7. You will be able to explain byte-pair encoding by working it through by hand on a tiny corpus, and name the three other tokenizer families.
8. You will be able to predict roughly how many tokens a piece of text costs, and explain why Hindi costs several times more than English for one meaning.
9. You will be able to explain why a model cannot count the letters in a word, and why it fails at arithmetic on long numbers, from tokenization alone.
10. You will be able to explain what an embedding is, what similarity between embeddings means, and what a context window really limits.

47.1 What a parameter actually IS in a language model

■ 47.1.1 PLAIN - in simple words

1. A language model is, on the inside, a very large pile of numbers.
2. Nothing else. No sentences stored. No facts written down as text. Numbers.
3. One of those numbers is called a **parameter**.
4. Chapter 46 fitted a straight line to five points. That line had exactly two parameters: a slope and an intercept, both found by gradient descent, which is the process of nudging numbers downhill until the error stops falling.
5. A language model is the same idea with the count raised enormously. Two parameters becomes eight billion, and the shape of the thing being fitted becomes a network of layers instead of a line.
6. Everything else in this section is that one sentence unpacked.
7. So a parameter is not a setting you choose. It is not an option in a menu.

8. It is one plain number, like -0.0113 or 0.0392, sitting in one fixed slot.
9. The slots are arranged in rectangles, called matrices. Rows and columns.
10. A parameter has an address: this matrix, this row, this column.
11. When the model was trained, every one of those numbers was slowly adjusted until the model got good at predicting the next piece of text.
12. When training finished, the numbers were frozen and written to a file.
13. Every time you use the model, it reads the same frozen numbers.
14. Your question does not change them. Your conversation does not change them.
15. When somebody says a model has 7 billion parameters, they mean the file contains 7 billion such numbers.
16. That is the whole idea. A parameter is one learned number in one slot.

■ 47.1.2 PLAIN - a picture in your head

1. Picture an enormous sound mixing desk, the kind in a recording studio.
2. A mixing desk has knobs. Each knob controls how loudly one thing is heard.
3. Turn one knob and the guitar gets louder. Turn another and the drums fade.
4. Now imagine a desk with seven billion knobs instead of forty.
5. Each knob is set to some exact position, like 0.0392 out of a range.
6. Training was a very long process of nudging every knob a tiny amount, over and over, until the whole desk produced a good sound.
7. Shipping the model means writing down every knob position in a file.
8. Loading the model means setting all seven billion knobs back to those exact positions.
9. Running the model means pushing sound through the desk without touching a single knob.

Where this comparison breaks: on a real mixing desk, a human knows what each knob does, and there is a label under it. In a model, almost no single parameter has a meaning you can name. Its effect only exists in combination with millions of others. Also, a mixing desk has knobs a person turns during a performance. Model parameters are never turned during use. They are turned only during training, and then never again unless the model is retrained.

■ 47.1.3 PLAIN - a worked example

1. Here is a genuine kind of object from inside a model: a weight matrix.
2. This is a four-by-four corner of one, with values rounded for printing.

A 4 x 4 corner of one weight matrix, values rounded

	col 0	col 1	col 2	col 3
row 0	-0.0113	0.0271	-0.0004	0.0158
row 1	0.0392	-0.0087	0.0221	-0.0310
row 2	-0.0056	0.0143	0.0079	0.0002
row 3	0.0018	-0.0225	-0.0166	0.0407

3. Look at row 1, column 2. The value there is 0.0221.
4. That is a parameter. That one number. Not the row. Not the matrix. That.
5. Its full address inside a real model would be something like: layer 7, the query projection matrix, row 1, column 2.
6. There are 16 parameters in this little corner, because it is 4 rows times 4 columns.
7. The real matrix this corner came from would be 4096 by 4096.
8. That is $4096 \times 4096 = 16,777,216$ parameters in that one matrix alone.
9. A model of this size has hundreds of matrices like it.

10. Every one of those numbers started as a random value before training, and ended up at its final value because training pushed it there.
11. Nobody chose 0.0221. Nobody can explain 0.0221 on its own.

■ 47.1.4 PLAIN - what is really happening inside

1. The model's job at each step is to turn a list of numbers into another list of numbers.
2. The main operation it uses is multiply-and-add, done many times at once.
3. Take an incoming list of 4096 numbers. Call it the input vector.
4. Take one column of the weight matrix, also 4096 numbers.
5. Multiply them pairwise and add the results up. That gives one output number.
6. Repeat for every column. That gives the whole output vector.
7. So each parameter is a multiplier. It says how much one incoming number contributes to one outgoing number.
8. The parameter at row 1, column 2 says: take input number 1, multiply it by 0.0221, and add that into output number 2.
9. That is literally all a weight does. It is a multiplier in one cell of a giant multiply-and-add.
10. There is a second, smaller kind of parameter called a **bias**.
11. A bias is added rather than multiplied. It shifts an output up or down by a fixed amount regardless of the input.
12. Biases are also learned during training, and are also parameters.
13. Some model families use biases everywhere, some use almost none.
14. When the model runs, it walks through layer after layer doing this. The parameters never move. Only the numbers flowing through them change.

■ 47.1.5 TECHNICAL - the engineer's version

1. A **parameter** is one scalar element of a learnable tensor, updated by the optimizer during training and fixed at inference time.
2. In PyTorch terms, a parameter is one element of a tensor wrapped in `torch.nn.Parameter`, which is a tensor with `requires_grad=True` that is registered in the module's parameter list.
3. The words **weight** and **parameter** are used interchangeably in practice, and in almost every sentence you will read they mean the same thing.
4. The precise distinction is that a **weight** is a multiplicative parameter in a linear map, while a **bias** is an additive parameter. Both are parameters. So all weights are parameters, but not all parameters are weights.
5. Normalization scale and shift terms, often called gamma and beta, are also parameters. So are learned position embeddings where a model uses them.
6. In a decoder-only transformer of the Llama family, the linear layers carry no bias terms at all, and RMSNorm carries a scale but no shift. In GPT-2 the linear layers do carry biases and LayerNorm carries both scale and shift.
7. That difference is tiny in count. In GPT-2 small, all biases and all normalization parameters together are 121,344 out of 124,439,808 parameters, which is 0.098 per cent of the model.
8. Parameters are stored in the model's state dictionary under dotted names. Real names from a Llama-family checkpoint look like this:

```
model.embed_tokens.weight      [128256, 4096]
model.layers.0.self_attn.q_proj.weight [4096, 4096]
model.layers.0.self_attn.k_proj.weight [1024, 4096]
model.layers.0.mlp.gate_proj.weight [14336, 4096]
```

```
model.layers.0.input_layernorm.weight      [4096]
lm_head.weight                             [128256, 4096]
```

9. The bracketed pair is the tensor shape. The number of parameters in a tensor is the product of its dimensions.
10. Counting them in PyTorch is one line: `sum(p.numel() for p in model.parameters())`. Counting trainable ones only adds `if p.requires_grad`.
11. For a file on disk, safetensors stores a JSON header listing every tensor name, dtype and shape, so the count can be read without loading the model. For GGUF files, `gguf-dump` prints the same information.
12. Terminology note, and it is a standard one: in statistics a “parameter” is a quantity of a distribution, and in software a “parameter” is a function argument. Neither meaning applies here. The machine learning meaning is the one in this chapter.

Kind of parameter	Operation	Typical share
Linear layer weight	Multiply	Over 99 per cent
Bias	Add	Under 0.1 per cent
Norm scale (gamma)	Multiply	Under 0.01 per cent
Embedding row	Lookup	0.5 to 25 per cent

■ 47.1.6 WORDS – remember these

1. Parameter — one learned number in the model — one scalar element of a learnable tensor, updated by the optimizer, frozen at inference.
2. Weight — a number that multiplies something — a multiplicative parameter in a linear map, stored as an element of a weight matrix.
3. Bias — a number that is added on — an additive parameter applied after a linear map, one per output dimension.
4. Matrix — a rectangle of numbers — a rank-2 tensor with shape `[out_features, in_features]` for a linear layer.
5. Tensor — a box of numbers with a shape — an n-dimensional array with a dtype and a shape tuple.
6. State dictionary — the list of all the model’s numbers with names — an ordered mapping from parameter name to tensor, saved to disk.
7. Checkpoint — the saved file of a model — a serialized state dictionary, in formats such as safetensors, PyTorch .pt or GGUF.
8. Frozen — not changing any more — parameters with `requires_grad=False`, or any parameter during inference.

47.2 What 7B, 70B and 405B actually count

■ 47.2.1 PLAIN – in simple words

1. The B in 7B means billion. It is a count of parameters.
2. A 7B model contains about seven thousand million individual numbers.
3. A 405B model contains about four hundred and five thousand million of them.
4. Nothing else is being counted. Not files. Not facts. Not words known.
5. To get the total you add up the size of every matrix in the model.
6. Every matrix size is just rows times columns.

7. So the whole count is a long sum of simple multiplications.
8. The numbers are not round because the shapes are not round.
9. A model called “8B” often turns out to hold 8,030,261,248 parameters exactly.
10. The advertised name is rounded. The real count is exact and computable.
11. Once you know four or five shape numbers about a model, you can compute the total yourself in a few minutes.
12. That is what this section does, all the way through, for a real model.

■ 47.2.2 PLAIN – a picture in your head

1. Imagine a large office block with 126 identical floors.
2. Every floor has exactly the same furniture plan: seven big filing cabinets.
3. Some cabinets are wide, some are narrow, but every floor gets the same set.
4. To count the drawers in the whole building you do not walk every floor.
5. You count the drawers on one floor, then multiply by 126.
6. Then you add the reception desk at the bottom and the roof office at the top, because those exist only once.
7. That is exactly how a transformer parameter count works.
8. The floors are the layers. The identical furniture is the same set of matrices repeated in every layer.
9. The reception desk is the embedding table. The roof office is the output layer. Both exist once, not once per floor.

Where this comparison breaks: real buildings sometimes have odd floors. In most transformer models every layer genuinely is the same shape, which is why the multiply-by-number-of-layers trick works exactly. But some newer designs break this on purpose: mixture-of-experts models have layers with many parallel expert blocks, and only some are used per token, so the total count and the count actually used per token stop being the same number.

■ 47.2.3 PLAIN – a worked example

1. Let us count a real model completely: Llama 3.1 8B, released by Meta on 23 July 2024.
2. Five shape numbers describe it, and they are published:

Setting	Value
Layers	32
Hidden size (d)	4096
Feed-forward size	14336
Attention heads	32
Key-value heads	8
Vocabulary size	128256

3. Head size is hidden size divided by heads: $4096 / 32 = 128$.
4. Now count one layer. Attention first, four matrices:

```

q_proj  4096 x 4096  = 16,777,216
k_proj  4096 x 1024  =  4,194,304
v_proj  4096 x 1024  =  4,194,304
o_proj  4096 x 4096  = 16,777,216
attention total per layer = 41,943,040

```

5. The k and v matrices are narrower because of grouped-query attention: only 8 key-value heads, so $8 \times 128 = 1024$ columns instead of 4096.

6. Now the feed-forward part, three matrices:

```
gate_proj    4096 x 14336 = 58,720,256
up_proj      4096 x 14336 = 58,720,256
down_proj    14336 x 4096 = 58,720,256
feed-forward total per layer = 176,160,768
```

7. Two normalization vectors of 4096 each add 8,192 more.

8. One layer therefore holds $41,943,040 + 176,160,768 + 8,192 = 218,112,000$.

9. There are 32 layers: $32 \times 218,112,000 = 6,979,584,000$.

10. The embedding table is vocabulary times hidden size: $128,256 \times 4,096 = 525,336,576$.

11. The output layer is the same shape again: 525,336,576.

12. The final normalization adds 4,096.

13. Add them all: $6,979,584,000 + 525,336,576 + 525,336,576 + 4,096 = 8,030,261,248$.

14. That is 8.03 billion. The model is sold as “8B”. The arithmetic closes.

■ 47.2.4 PLAIN - what is really happening inside

1. Here is the whole 8B model drawn as a structure, with the parameter count written next to every piece.

2. Look at where that total came from and a clear pattern appears.
3. The feed-forward matrices are the biggest single item, by a wide margin.
4. In the 8B model, feed-forward is 70 per cent of all parameters.
5. Attention is about 17 per cent.
6. The embedding and output tables together are about 13 per cent.
7. Normalization is a rounding error: three thousandths of one per cent.
8. Now scale the model up and watch the shares move.
9. In the 70B model, feed-forward rises to 80 per cent and embeddings fall to 3 per cent, because the vocabulary stays the same size while the layers grow.
10. In the 405B model, feed-forward is 81 per cent and embeddings are 1 per cent.
11. So the honest one-line answer to “where do the billions live” is: in the feed-forward blocks, repeated once per layer.
12. That matters practically. When people compress models, they attack the feed-forward matrices first, because that is where the mass is.
13. It also explains why small models feel embedding-heavy. In GPT-2 small, the embedding table alone is 25 per cent of the whole model.

■ 47.2.5 TECHNICAL – the engineer’s version

1. The general formula for a decoder-only transformer with grouped-query attention, SwiGLU feed-forward and RMSNorm, with untied embeddings, is:

```

per_layer = 2*d*d          (q_proj and o_proj)
            + 2*d*n_kv*head_dim (k_proj and v_proj)
            + 3*d*d_ff      (gate, up, down)
            + 2*d          (two RMSNorm scales)

total = V*d                (input embedding)
       + L*per_layer       (all layers)
       + d                 (final RMSNorm)
       + V*d               (output head, if untied)

```

2. Here d is hidden size, d_{ff} feed-forward size, L layers, V vocabulary size, n_{kv} the number of key-value heads and $head\_dim$ the per-head width.
3. Applying it to the three published Llama 3.1 configurations gives exact totals that match the marketing names:

Model	Layers x d x d_{ff}	Computed total
Llama 3.1 8B	32 x 4096 x 14336	8,030,261,248
Llama 3.1 70B	80 x 8192 x 28672	70,553,706,496
Llama 3.1 405B	126 x 16384 x 53248	405,853,388,800

4. All three use vocabulary 128,256, head dimension 128, and 8 key-value heads. The 405B model has 128 query heads, which is why its k and v projections are only 16384×1024 while q and o are 16384×16384 .
5. Where the parameters sit, as a percentage of the total:

Block	8B	70B	405B
Feed-forward	70.20%	79.90%	81.25%
Attention	16.71%	17.12%	17.71%

Block	8B	70B	405B
Input embedding	6.54%	1.49%	0.52%
Output head	6.54%	1.49%	0.52%

- Norm parameters are 0.0033 per cent for 8B, 0.0019 per cent for 70B and 0.0010 per cent for 405B, and are omitted from the table above for width.
- Tied embeddings** are an implementation choice, not a standard: the output projection reuses the transposed input embedding matrix, saving $V \times d$ parameters. GPT-2 ties them. Llama 3.1 8B, 70B and 405B do not. Several small models such as Gemma tie them, which is why their embedding share is larger than you would guess.
- Verifying GPT-2 small the same way, including biases, gives exactly 124,439,808 parameters: 38,597,376 token embeddings, 786,432 learned position embeddings, 12 layers of 7,087,872 and a final LayerNorm of 1,536. The commonly quoted “117M” for GPT-2 small comes from an older count that excluded the position embeddings and some terms; 124M is the count that matches the released checkpoint.
- For mixture-of-experts models the count splits in two. Report the **total** parameter count and the **active** parameter count separately, because only a few experts run per token. A model with 8 experts of which 2 run has roughly a quarter of its feed-forward parameters active at any moment. Quoting only the total for such a model is a marketing choice, not a technical one.
- Tools: `sum(p.numel() for p in model.parameters())` in PyTorch, `model.num_parameters()` in Hugging Face transformers, the safetensors index JSON header, and `gguf-dump --no-tensors file.gguf` for GGUF metadata.

■ 47.2.6 WORDS - remember these

- Hidden size — how wide the model is — `d_model`, the width of the residual stream carried between layers, commonly 4096 or 8192.
- Feed-forward size — the width of the wide middle part — `d_ff`, usually between 2.7 and 4 times `d_model` in modern designs.
- Layer — one repeat of the model’s standard block — one transformer block containing attention, feed-forward and two normalizations.
- Vocabulary size — how many different tokens exist — the number of rows in the embedding matrix, for example 128,256 in Llama 3.1.
- Grouped-query attention — sharing key and value work across heads — GQA, where `n_kv` is smaller than `n_heads`, shrinking `k` and `v` projections and the key-value cache.
- Tied embeddings — reusing the input table as the output table — weight tying between `embed_tokens` and `lm_head`, saving $V \times d$ parameters.
- Active parameters — the ones that actually run for a token — in a mixture-of-experts model, the subset routed to per token, as against the total stored.

47.3 Parameters versus the four things they get confused with

■ 47.3.1 PLAIN - in simple words

- Five words get mixed up constantly. Here they are, one line each.
- Parameters** are the learned numbers inside the model, frozen after training.
- Hyperparameters** are the choices a human made before training started. They are not learned. Nobody trained them.

4. **Activations** are the temporary numbers created while the model runs on one input, and thrown away as soon as the answer is produced.
5. **Context** is the text you are giving the model right now. It is data.
6. **Tokens** are the small pieces that text is chopped into. Also data.
7. Now the sharp test. Which of these are in the model file on disk?
8. Only the parameters. The other four are not in the file.
9. Hyperparameters are recorded next to the file, in a small configuration note, so the loader knows what shape to build. But they were not learned.
10. Activations exist only for a moment while a request is being answered.
11. Context and tokens are whatever you happen to be asking about today.
12. So: parameters are what the model is. The rest is how it was built, what it is thinking about right now, and what you asked.

■ 47.3.2 PLAIN – a picture in your head

1. Think of a bakery.
2. The **recipe decisions** are the hyperparameters: oven temperature, tin size, how long to bake. A person chose these before any baking started.
3. The **baker's learned skill** is the parameters: the exact feel for how long to knead, built up over years and now fixed in the baker's hands.
4. The **ingredients on the counter today** are the context: this flour, this water, this order for a birthday cake.
5. The **individual scoops and spoonfuls** are the tokens: the units the ingredients get measured into.
6. The **half-made dough at each stage** is the activations: sticky, temporary, real, and gone the moment the bread is out.
7. Now the useful part. Changing the oven temperature is changing a hyperparameter, and you have to re-train the baker to suit it. Giving new ingredients is changing the context, and needs no re-training at all.

Where this comparison breaks: a baker learns a little from every loaf. A deployed model does not. Its parameters are identical after your millionth message and after your first. Any apparent learning inside a conversation is the context being carried along, not the parameters changing.

■ 47.3.3 PLAIN – a worked example

1. Here is one scenario with all five words used correctly in it.
2. A team trains a model. They choose 32 layers, hidden size 4096, learning rate 0.0003 and batch size 4 million tokens. Those are **hyperparameters**.
3. Training runs for weeks and produces 8,030,261,248 **parameters**, which are saved to a file of about 16 gigabytes.
4. A user types "Summarize this contract" and pastes 3,000 words of contract. That whole thing is the **context**.
5. The tokenizer chops that context into 4,182 **tokens**, each an integer.
6. The model runs. As those 4,182 tokens flow through 32 layers, it creates millions of temporary numbers at every layer. Those are **activations**, and they are discarded when the answer is finished.
7. Now the one-sentence version the reader asked for, all five in one line:
8. "The 8B model's frozen parameters were produced by a training run whose hyperparameters fixed 32 layers and a learning rate of 0.0003; at inference the 4,182 tokens of the user's context are turned into activations that flow through those parameters and are then thrown away."
9. Read it twice. Every one of the five words is doing a different job.

■ 47.3.4 PLAIN – what is really happening inside

1. Trace the lifetime of each of the five things, in order of when it exists.
2. Hyperparameters exist first, before there is a model at all. A human writes them into a configuration file.
3. The training program reads them and builds an empty model of that shape, filled with random numbers.
4. Training begins. The parameters change, millions of times, over weeks.
5. Training ends. The parameters are written to disk and never change again.
6. Later, somebody loads the file. Now the parameters are in memory.
7. A user sends text. That is the context. The tokenizer converts it to tokens.
8. The tokens flow in. At every layer the model computes new temporary numbers. Those are activations.
9. The activations are what carries the meaning of your specific question. The parameters are what does the transforming.
10. When the reply is finished, the activations are freed. The parameters are still sitting there, byte for byte identical.
11. This is why inference needs more memory than the model file size. The activations, and the cached keys and values for the conversation so far, need room too.
12. And it is why a longer conversation costs more memory but does not make the model bigger. The model is exactly as big as it was.

■ 47.3.5 TECHNICAL – the engineer's version

Thing	Learned?	Lives where
Parameter	Yes, by optimizer	Checkpoint, then GPU
Hyperparameter	No, chosen by human	config.json, run script
Activation	No, computed	Transient GPU buffers
Context	No, supplied	Request payload
Token	No, derived	Integer array

1. **Hyperparameters** split into two families that people wrongly lump together. Architectural hyperparameters fix the shape and therefore fix the parameter count: number of layers, hidden size, feed-forward size, head count, vocabulary size, maximum position count. Optimization hyperparameters do not change the count at all: learning rate, warmup steps, weight decay, batch size, dropout rate, gradient clipping threshold, number of epochs.
2. Sampling settings supplied per request, such as temperature, top-p, top-k and repetition penalty, are sometimes loosely called hyperparameters. They are inference settings. They change decoding, not the model.
3. **Activations** are the intermediate tensors of the forward pass. During inference with no gradient tracking, most are freed as soon as the next layer consumes them, so peak activation memory is a few hundred megabytes for a single sequence, not gigabytes.
4. During training the picture inverts. Activations must be retained for the backward pass. Using the accounting from the 2022 NVIDIA paper Reducing Activation Recomputation in Large Transformer Models, activation memory per layer per sample is about $sbh(34 + 5a*s/h)$ bytes in 16-bit, where s is sequence length, b batch, h hidden size and a head count.
5. For a 7B-class model at sequence length 2048 and batch 1 that is about 912 MiB per layer, so about 28.5 GiB across 32 layers for a single sample, before any recomputation is applied. Gradient checkpointing trades compute for memory to cut that sharply.

6. The **key-value cache** is a special, persistent kind of activation. It is the only activation deliberately kept across decoding steps, and it grows linearly with context length. It is covered with numbers in section 47.4.
7. **Context** is data on the request path. It has no gradient, no persistence and no effect on any stored parameter. This is the technical reason a model cannot “learn from your chat” unless a separate fine-tuning job is run.
8. **Tokens** are integers in the range 0 to V-1. They index rows of the embedding matrix. They are not parameters; the rows they select are.
9. Observing them: `config.json` and `generation_config.json` hold hyperparameters, `nvidia-smi` and `torch.cuda.max_memory_allocated()` show activation and cache growth, and any tokenizer’s `encode` returns the tokens.

■ 47.3.6 WORDS – remember these

1. Hyperparameter — a choice made before training — a configuration value not updated by gradient descent, either architectural or optimization-related.
2. Activation — a temporary number inside the model while it runs — an intermediate tensor of the forward pass, freed unless retained for backward.
3. Context — the text being processed right now — the input token sequence supplied per request, including any system prompt and history.
4. Key-value cache — the model’s notes on the conversation so far — cached per-layer key and value tensors reused across decoding steps.
5. Inference — using the model — a forward pass with no gradient computation and no parameter update.
6. Forward pass — pushing data through the model once — computing outputs layer by layer from inputs.
7. Gradient checkpointing — recomputing instead of storing — discarding activations during forward and recomputing them during backward to save memory at the cost of extra compute.

47.4 Parameters, memory and precision

■ 47.4.1 PLAIN – in simple words

1. Every parameter has to be stored somewhere, and storage takes space.
2. So the memory a model needs is a simple multiplication.
3. Memory = number of parameters x bytes used per parameter.
4. That is the whole rule. There is no magic in it.
5. How many bytes per parameter? That is your choice, and it is a trade.
6. Four bytes stores a number very accurately. Two bytes stores it less accurately but takes half the space.
7. One byte is less accurate still. Half a byte, which means four bits, is cruder again.
8. A 7 billion parameter model at two bytes each needs about 14 gigabytes.
9. The same model at half a byte each needs about 3.5 gigabytes.
10. Same model. Same parameters. Different amount of detail kept per number.
11. But the weights are not the only thing in memory when the model runs.
12. There is also the model’s running notes on your conversation, the temporary numbers, and the software’s own overhead.
13. And training is far worse again, because training keeps several extra copies of every parameter. We will work that out too.

■ 47.4.2 PLAIN – a picture in your head

1. Think of writing down the price of something.
2. You could write 12.345678. That is very precise and takes many characters.
3. You could write 12.35. Less precise, fewer characters.
4. You could write 12. Cruder still, fewest characters.
5. If you have to write down seven billion prices, the choice matters enormously for how much paper you need.
6. And for most purposes 12.35 is good enough. Nobody notices the missing digits when you are adding up a shopping basket.
7. That is exactly the precision trade in a model. Fewer digits per number, much less memory, slightly less exact answers.
8. Now the training part. To train, you do not only need the current prices.
9. You also need, for every price, a note of which direction to move it, and two running averages of how it has been moving lately.
10. So training needs about four to five sheets of paper for every one sheet that using the finished model needs.

Where this comparison breaks: numbers in a computer are not stored as decimal digits. They are stored in a floating point format with a sign, an exponent and a fraction, and the loss of accuracy is not a clean chopping of digits. It is a coarser grid of representable values, and the grid spacing changes with magnitude.

■ 47.4.3 PLAIN – a worked example

1. Take the same models at four different precisions. Here is the arithmetic for weights only, using 1 GiB = 1,073,741,824 bytes.
2. 7 billion × 4 bytes = 28,000,000,000 bytes = 26.1 GiB.
3. 7 billion × 2 bytes = 14,000,000,000 bytes = 13.0 GiB.
4. 7 billion × 1 byte = 7,000,000,000 bytes = 6.5 GiB.
5. 7 billion × 0.5 bytes = 3,500,000,000 bytes = 3.3 GiB.
6. Repeat for the other sizes and the full table falls out:

Model	fp32 GiB	fp16 GiB
7B	26.1	13.0
13B	48.4	24.2
70B (70.55B)	262.8	131.4
405B (405.85B)	1511.9	756.0

Model	int8 GiB	int4 GiB
7B	6.5	3.3
13B	12.1	6.1
70B (70.55B)	65.7	32.9
405B (405.85B)	378.0	189.0

7. Sanity check against reality: the published fp16 file for Llama 3.1 70B is about 141 GB in decimal gigabytes, which is 131 GiB. The arithmetic matches the real file.
8. Now add what inference needs beyond the weights.

9. The key-value cache for Llama 3.1 70B is 320 KiB per token. At 8,000 tokens that is 2.5 GiB. At 32,000 tokens it is 10 GiB.
10. Temporary activations for one sequence are roughly 0.5 to 1 GiB.
11. The framework's own overhead, buffers and fragmentation is another 1 to 2 GiB in practice.
12. So a realistic total for 70B at fp16 with an 8,000 token context is $131.4 + 2.5 + 1.0 + 2.0 =$ about 137 GiB, not 131.

■ 47.4.4 PLAIN – what is really happening inside

1. Training memory is a different story, and much bigger, for a simple reason.
2. Training must keep, for every single parameter, four extra things.
3. First, the parameter itself, usually kept twice: a fast low-precision copy used for the maths and an accurate master copy used for the update.
4. Second, the gradient, which is one number per parameter saying which way to nudge it.
5. Third and fourth, the optimizer's two running averages. The standard optimizer, called Adam, keeps a running average of recent gradients and a running average of recent squared gradients.
6. That is what "Adam's two moments" means: two extra numbers per parameter.
7. Count the bytes for the common mixed-precision recipe:

16-bit working weights	2 bytes
32-bit master weights	4 bytes
gradients	4 bytes
Adam first moment (m)	4 bytes
Adam second moment (v)	4 bytes

total	18 bytes per parameter

8. For a 7B model: $7,000,000,000 \times 18 = 126,000,000,000$ bytes = 117 GiB.
9. That is before a single activation is stored.
10. Add training activations, which for a 7B-class model at sequence length 2048 come to roughly 28 GiB per sample without recomputation.
11. So training a 7B model is a 150 GiB-plus problem, not a 14 GiB problem.
12. That is why a model you can happily run on one 24 GiB graphics card cannot be fully fine-tuned on it. Using needs weights. Training needs weights plus four more copies plus history.
13. It is also why techniques that train only a small extra set of parameters, which Chapter 50 covers, exist at all.

■ 47.4.5 TECHNICAL – the engineer's version

1. The precision formats, with their real layouts:

Format	Bits	Layout (sign/exp/frac)
fp32	32	1 / 8 / 23
fp16	16	1 / 5 / 10
bf16	16	1 / 8 / 7
fp8 E4M3	8	1 / 4 / 3

2. bfloat16 was introduced by Google for its Tensor Processing Units and keeps fp32's 8-bit exponent, so it has the same dynamic range as fp32 with far fewer fraction bits. That is why bf16 training rarely needs loss scaling while fp16 training usually does.
3. fp16 has a maximum finite value of 65504 and underflows below about $6e-8$, which is why gradients in fp16 are scaled up before the backward pass and scaled down afterwards.

- fp8 in the E4M3 and E5M2 variants was standardized across NVIDIA, Arm and Intel in a 2022 joint proposal, and is supported in hardware from NVIDIA's Hopper generation, announced March 2022. NVIDIA's Blackwell generation, announced 18 March 2024, added hardware support for 4-bit floating point.

- Key-value cache size per token is exact and worth memorizing:

```
| kv_bytes_per_token = 2 * L * n_kv * head_dim * bytes_per_element
```

- The leading 2 is for keys and values. Real figures at fp16:

Config	Per token	32k ctx	128k ctx
Llama 3.1 8B (GQA 8)	128 KiB	4.0 GiB	16.0 GiB
Llama 3.1 70B (GQA 8)	320 KiB	10.0 GiB	40.0 GiB
Llama 3.1 405B (GQA 8)	504 KiB	15.8 GiB	63.0 GiB
70B-shape without GQA	2560 KiB	80.0 GiB	320.0 GiB

- That last row is the point of grouped-query attention. Cutting key-value heads from 64 to 8 cuts the cache by a factor of 8, which is what makes long contexts affordable at all.
- Full-fine-tuning memory in bytes per parameter, by optimizer:

Optimizer state	Bytes/param	7B total
Adam, mixed precision	18	117 GiB
Adam, pure fp32	16	104 GiB
SGD with momentum	12	78 GiB
Inference, fp16	2	13 GiB

- Adam was published by Diederik Kingma and Jimmy Ba in 2014 as Adam: A Method for Stochastic Optimization; AdamW, the decoupled weight decay variant used by almost every modern language model, came from Ilya Loshchilov and Frank Hutter in 2017. Both keep two moment estimates per parameter, which is the source of the 8 bytes.
- ZeRO, from the 2019 Microsoft paper ZeRO: Memory Optimizations Toward Training Trillion Parameter Models, shards optimizer states, gradients and parameters across data-parallel ranks in three stages, so the per-device cost falls roughly by the number of devices. It does not reduce the total.
- Practical observation commands: `nvidia-smi --query-gpu=memory.used --format=csv`, `torch.cuda.memory_summary()`, and for serving, vLLM's reported KV cache blocks and `--gpu-memory-utilization` setting.

■ 47.4.6 WORDS - remember these

- Precision — how many digits are kept per number — the numeric format's bit width and its split between exponent and fraction.
- fp32 — the accurate, expensive format — IEEE 754 single precision, 4 bytes, 24 bits of significand including the implicit bit.
- bf16 — the training-friendly 16-bit format — brain floating point, fp32's exponent range with 8 bits of significand.
- Key-value cache — the model's stored notes on tokens seen so far — cached K and V tensors per layer, sized $2 \times L \times n_{kv} \times \text{head\_dim}$ per token.

5. Optimizer state — the extra bookkeeping training needs — Adam’s first and second moment estimates, one of each per parameter.
6. Mixed precision — computing in 16-bit, updating in 32-bit — a training recipe with a low-precision working copy and an fp32 master copy.
7. GiB versus GB — two different gigabytes — $2^{30} = 1,073,741,824$ bytes versus 10^9 bytes; file sizes are usually quoted in the decimal form and memory in the binary form, and confusing them costs you 7 per cent.

47.5 Quantization

■ 47.5.1 PLAIN - in simple words

1. **Quantization** means storing each of the model’s numbers using fewer bits.
2. That is the whole idea in one line. Fewer bits per number, smaller model.
3. The trained numbers are typically stored in 16 bits each.
4. Quantization rewrites them into 8 bits, or 4 bits, or sometimes fewer.
5. Nothing about the model’s shape changes. It still has 70 billion parameters.
6. Each of those 70 billion is just written down more roughly.
7. To do it you need a trick, because a 4-bit slot holds only 16 different values, and the real weights are spread over a wide range.
8. The trick is to store a small group of weights together with one shared scaling number.
9. The 4-bit value says “which of my 16 steps”, and the shared scale says “and here is how big a step is”.
10. Multiply them back together at load time or on the fly, and you get an approximation of the original number.
11. The approximation is not exact. The question is whether the error matters.
12. Mostly, at 8 bits and 5 bits, it barely does. At 4 bits it is small. Below that it starts to hurt in ways you can measure.

■ 47.5.2 PLAIN - a picture in your head

1. Imagine a shop that must label 10,000 items with prices.
2. The prices range from 1 rupee to 3,000 rupees.
3. The labels only have room for a single digit, 0 to 9.
4. That looks impossible, until you split the shop into departments.
5. In the pencil department, prices run 1 to 10 rupees, so you write on the department sign: “each step on the label = 1 rupee”.
6. In the furniture department, prices run 1,000 to 3,000, so that sign says “each step on the label = 200 rupees”.
7. Now a label reading 7 means 7 rupees in one department and 1,400 in the other, and one digit is enough everywhere.
8. The department sign is the **scale**. The department is the **group**.
9. Smaller departments mean more accurate prices but more signs to store.
10. That is the entire design space of quantization: how small the groups are, and how much extra you pay to store the signs.

Where this comparison breaks: real quantization also needs a **zero point** when the values are not centred on zero, so the label’s 0 does not have to mean a value of 0. And unlike a shop, a badly chosen department boundary does not just annoy a customer; it puts an outlier weight far outside the range and distorts every weight in the group with it.

■ 47.5.3 PLAIN – a worked example

1. Take eight real-looking weights and quantize them by hand.
2. The values: 0.42, -1.13, 0.05, 2.31, -0.77, 1.02, -2.90, 0.66.
3. Symmetric 8-bit first. Find the largest absolute value: 2.90.
4. Scale = $2.90 / 127 = 0.022835$.
5. Divide each value by the scale and round:

value	/scale	rounded int8
0.42	18.39	18
-1.13	-49.49	-49
0.05	2.19	2
2.31	101.16	101
-0.77	-33.72	-34
1.02	44.67	45
-2.90	-127.00	-127
0.66	28.90	29

6. To use them, multiply back by the scale. $18 \times 0.022835 = 0.4110$.
7. Original 0.42, recovered 0.4110. Error 0.0090.
8. Across all eight, the largest error is 0.0111. Small.
9. Now 4-bit, asymmetric, using minimum and maximum instead of absolute maximum.
10. Minimum -2.90, maximum 2.31. Scale = $(2.31 - (-2.90)) / 15 = 0.347333$.
11. Zero point = $\text{round}(2.90 / 0.347333) = 8$. So the stored code 8 means 0.
12. Quantized codes: 9, 5, 8, 15, 6, 11, 0, 10.
13. Recovered values: 0.3473, -1.0420, 0.0000, 2.4313, -0.6947, 1.0420, -2.7787, 0.6947.
14. Largest error now 0.1213, about eleven times worse than 8-bit. That is the price of four bits instead of eight.
15. Note the storage cost of the scale itself. If one 16-bit scale and one 16-bit zero point cover a group of 64 weights, the real cost is $4 + 32/64 = 4.5$ bits per weight, not 4.

■ 47.5.4 PLAIN – what is really happening inside

1. There are three levels of granularity, and they are the main design choice.
2. **Per-tensor**: one scale for an entire matrix. Cheapest to store, worst accuracy, because one outlier anywhere ruins the scale for everything.
3. **Per-channel**: one scale per row or per column. Much better, because a badly behaved output channel no longer poisons its neighbours.
4. **Per-group**: one scale for every fixed run of weights, typically 32, 64, 128 or 256 of them. Best accuracy, most scales to store.
5. Then there is the question of when you quantize.
6. **Post-training quantization** takes a finished model and compresses it. Fast, needs no training run, sometimes needs a few hundred sample texts to calibrate the scales.
7. **Quantization-aware training** simulates the rounding during training, so the model learns weights that survive rounding well. Much more expensive, better results at very low bit widths.
8. Finally: not everything gets squeezed equally.
9. The embedding table and the output layer are often kept at higher precision, because errors there hit every token directly and there is no later layer to absorb the damage.
10. Normalization scales, which are a tiny fraction of parameters, are almost always left at 16 or 32 bits.
11. Some formats keep specific matrices, such as the attention value projection and the feed-forward down projection, at a higher bit width because measurements showed those layers are the most

sensitive.

- And the key-value cache is a separate decision. You can run 4-bit weights with a 16-bit cache, or quantize the cache too.

■ 47.5.5 TECHNICAL - the engineer's version

- The affine quantization map, which is the standard, is:

```
q = clamp(round(x / s) + z, qmin, qmax)
x_hat = (q - z) * s
```

- Symmetric quantization fixes $z = 0$ and sets $s = \max|x| / q_{\max}$. Asymmetric quantization derives s from the range and z from the offset. Symmetric is cheaper at run time because the zero point drops out of the arithmetic.
- The named methods, with correct attribution:

Method	Year	One-line idea
LLM.int8()	2022	Split out outlier channels
GPTQ	2022	Second-order error correction
AWQ	2023	Protect salient weights
NF4 (QLoRA)	2023	Normal-distribution 4-bit

- LLM.int8(), by Tim Dettmers and colleagues in 2022, observed that a small number of feature dimensions carry extreme magnitudes and must stay in 16 bits, while the rest go to int8. This is mixed-precision decomposition.
- GPTQ, by Elias Frantar, Saleh Ashkboos, Torsten Hoefer and Dan Alistarh, posted October 2022 and published at ICLR 2023, quantizes weights column by column and uses approximate second-order information from a small calibration set to adjust the not-yet-quantized weights to compensate for the error just introduced.
- AWQ, Activation-aware Weight Quantization, by Ji Lin and colleagues at MIT, posted June 2023 and awarded Best Paper at MLSys 2024, observes that protecting roughly 1 per cent of weights, chosen by activation magnitude rather than weight magnitude, recovers most of the loss, and implements the protection by per-channel scaling rather than by keeping mixed precision.
- NF4, NormalFloat4, comes from the QLoRA paper by Tim Dettmers, Artidoro Pagnoni, Ari Holtzman and Luke Zettlemoyer, May 2023. Its 16 levels are placed at the quantiles of a normal distribution rather than evenly, because trained weights are approximately normally distributed. QLoRA also applies double quantization, quantizing the scales themselves, saving about 0.37 bits per parameter.
- GGUF is the file format used by llama.cpp, introduced on 21 August 2023 as the successor to GGML, GGUF and GGJT. Its k-quant types use a super-block of 256 weights subdivided into blocks of 32. Exact sizes, read from the ggml header:

Type	Bytes per 256	Bits per weight
Q2_K	84	2.625
Q3_K	110	3.4375
Q4_K	144	4.5
Q5_K	176	5.5
Q6_K	210	6.5625

9. The suffixes S and M mean small and medium mixes. Q4_K_M keeps the attention value projections and the feed-forward down projections at Q6_K in part of the network, so its measured average is about 4.8 bits per weight rather than 4.5. Checking against real published files: Llama 3.1 8B at Q4_K_M is 4.9 GB, and $8.03e9 \times 4.83 / 8 = 4.85e9$ bytes. The published 405B Q4_K_M file is 243 GB, and $405.85e9 \times 4.79 / 8 = 243e9$. The arithmetic closes both ways.
10. Quality cost, measured. From a January 2026 evaluation of llama.cpp quantization on Llama-3.1-8B-Instruct, WikiText-2 perplexity, lower better:

Format	Perplexity	Size cut
fp16 baseline	7.32	0%
Q8_0	7.33	46.9%
Q6_K	7.35	59.0%
Q5_K_M	7.40	64.4%
Q4_K_M	7.56	69.4%
Q3_K_M	7.96	75.0%
Q3_K_S	8.96	77.2%

11. Read that table honestly. Q8_0 costs 0.01 perplexity, which is noise. Q4_K_M costs 0.24, about 3.3 per cent relative, for a 69 per cent size cut. Q3_K_S costs 1.64, about 22 per cent relative, and that is a real degradation you will notice.
12. The same study reported that on aggregate downstream scores across GSM8K, HellaSwag, IFEval, MMLU and TruthfulQA, several quantized variants scored within noise of the fp16 baseline, and Q5_0 scored marginally above it. That last result is a reminder that benchmark noise at these margins is larger than the quantization effect, not evidence that quantizing helps.
13. Now the laptop arithmetic the question asks for. Assume about 75 per cent of installed memory is usable for the model, the rest going to the operating system and everything else.

Machine with 64 GiB, about 48 GiB usable:

```
70B at fp16  131.4 GiB weights -> does not fit
70B at int8   65.7 GiB weights -> does not fit
70B at Q4_K_M 39.7 GiB weights
              + 2.5 GiB KV at 8k
              + 2.5 GiB other   -> 44.7 GiB, fits
```

Machine with 16 GiB, about 12 GiB usable:

```
8B at fp16   15.0 GiB weights -> does not fit
8B at int8    7.5 GiB weights
              + 1.0 GiB KV at 8k
              + 1.3 GiB other   -> 9.8 GiB, fits
8B at Q4_K_M  4.5 GiB weights -> 6.8 GiB total, fits easily
70B at Q4_K_M 39.7 GiB weights -> does not fit
```

14. So the honest answer to “why can a 70B model run on a laptop at 4-bit but not at 16-bit” is: 131.4 GiB does not fit in 48 GiB and 39.7 GiB does, and that is the entire reason. Note the 64 GiB case only works with a modest context. Raise the context to 32,000 tokens and the cache alone adds 10 GiB, taking the total to about 52 GiB, which no longer fits.
15. On Apple silicon the calculation uses unified memory, and the default cap on how much the GPU may claim is around 65 to 75 per cent of installed RAM depending on machine and macOS version, which is where the 75 per cent rule of thumb above comes from.

16. Speed, separately from memory: at batch size 1, generation is memory bandwidth bound, so halving the bytes per weight roughly doubles tokens per second. That is often a bigger practical win than the memory saving.
17. Tools: llama-quantize in llama.cpp, AutoGPTQ and GPTQModel, autoawq, bitsandbytes for NF4 and int8, llm-compressor for vLLM-targeted formats, and optimum-quanto in the Hugging Face stack.

■ 47.5.6 WORDS - remember these

1. Quantization — storing each number in fewer bits — mapping high-precision weights onto a small integer grid with a scale and optional zero point.
2. Scale — how big one step of the integer grid is — the multiplier s in $\hat{x} = (q - z) * s$.
3. Zero point — where the integer grid's zero sits — the offset z that lets an asymmetric range be represented.
4. Group size — how many weights share one scale — commonly 32, 64 or 128; smaller means more accurate and more metadata.
5. Post-training quantization — squeezing a finished model — PTQ, applied to trained weights with at most a small calibration set.
6. Quantization-aware training — training with the rounding simulated — QAT, with fake quantization in the forward pass and straight-through gradients.
7. Perplexity — how surprised the model is by real text — the exponential of the mean negative log-likelihood per token; lower is better, and only comparable between models sharing a tokenizer.
8. Outlier channel — a feature dimension with extreme values — a dimension whose magnitude forces a bad scale for everything grouped with it.

47.6 Why capability does not scale linearly with parameter count

■ 47.6.1 PLAIN - in simple words

1. Bigger models are, on average, better. That much is true.
2. But parameter count is a weak way to guess how good a model is.
3. A model is the product of at least five things, not one.
4. How many parameters it has. How much text it was trained on. How good that text was. How much computing time was spent. What was done to it afterwards.
5. Get any one of those badly wrong and a huge model performs poorly.
6. Get them all right and a small model can beat a much larger one.
7. This is not a rare exception. It happens constantly.
8. In 2022 a 70 billion parameter model called Chinchilla beat a 280 billion parameter model called Gopher, using the same computing budget.
9. It won by being smaller and reading four times as much text.
10. That result changed how the whole field trains models.
11. So when a company says its model has more parameters than a rival's, that is a fact about the file size, not a claim about usefulness that you should accept without evidence.
12. The honest position: parameter count sets a ceiling. It does not tell you how close to that ceiling the model got.

■ 47.6.2 PLAIN - a picture in your head

1. Think of a student preparing for an exam.
2. Parameter count is how much the student could remember if they studied. Call it brain capacity.
3. Training data is how many books they read.

4. Data quality is whether the books were good ones or nonsense from the internet.
5. Training compute is how many hours they actually spent studying.
6. The stages after training are the coaching: practice papers, feedback on answers, learning how to lay out a solution clearly.
7. Now: a student with enormous capacity who read three books and never practised will fail.
8. A student with ordinary capacity who read widely, studied hard and got good coaching will do well.
9. Everyone knows this about students. The same thing is true about models, and the industry spent years talking as though only capacity mattered.

Where this comparison breaks: a student's capacity is fixed and unknown; a model's is chosen and exactly known. And a model has no motivation, no sleep and no forgetting, so the analogy tells you nothing about the training dynamics. It only tells you that one input out of five does not determine the output.

■ 47.6.3 PLAIN – a worked example

1. Take the Chinchilla experiment, published by Jordan Hoffmann and colleagues at DeepMind in March 2022, in Training Compute-Optimal Large Language Models.
2. Gopher: 280 billion parameters, trained on 300 billion tokens.
3. Chinchilla: 70 billion parameters, trained on 1.4 trillion tokens.
4. Both used about the same total computing budget. That is the key control.
5. Chinchilla is four times smaller and read four and a half times more.
6. On MMLU, a broad multiple-choice benchmark, Chinchilla scored 67.5 per cent, more than 7 percentage points above Gopher.
7. It also beat GPT-3 at 175 billion parameters, Jurassic-1 at 178 billion and Megatron-Turing NLG at 530 billion.
8. A 70B model beat a 530B model. That is a factor of seven and a half in parameter count, going the wrong way for the bigger model.
9. The paper's rule of thumb: for a fixed compute budget, model size and training tokens should grow together, roughly 20 tokens per parameter.
10. By that rule, GPT-3 at 175B should have been trained on about 3.5 trillion tokens. It was trained on 300 billion. It was undertrained by roughly a factor of ten.
11. So the entire generation of models before 2022 was too big for the amount of text it had read.

■ 47.6.4 PLAIN – what is really happening inside

1. Training reduces a single measured quantity: the average surprise the model feels when it sees real text.
2. That quantity falls smoothly and predictably as you add parameters, add data or add compute. Those smooth curves are called scaling laws.
3. A scaling law is a fitted curve, not a law of nature. It describes what has been measured over the ranges measured.
4. The curves are also very shallow. To halve the error you need far more than double the size.
5. And low surprise on text is not the same thing as being useful to a person.
6. That gap is closed by the stages after pre-training: supervised fine-tuning on demonstrations, and preference training on human comparisons.
7. Those stages change very few things about the model's knowledge and a great deal about its behaviour.

8. A raw pre-trained model of 70 billion parameters is often unusable as an assistant. The same model after post-training is helpful. Same parameters, different usefulness.
9. Data quality does something similar. Training on carefully filtered, deduplicated, high-quality text produces much better models per parameter than training on raw web scrape.
10. So the causal chain from parameter count to usefulness runs through at least four other factors, each of which can dominate.

■ 47.6.5 TECHNICAL - the engineer's version

1. Separate the three kinds of claim, as the reader asked.
2. **Established fact.** Loss falls as a power law in parameters, data and compute over several orders of magnitude. Kaplan and colleagues at OpenAI established this in January 2020 in Scaling Laws for Neural Language Models.
3. **Established fact.** Kaplan's recommended allocation was corrected by Hoffmann and colleagues in March 2022. Under a fixed compute budget, the compute-optimal ratio is roughly 20 training tokens per parameter, and pre-2022 models were badly undertrained.
4. **Established fact.** The Chinchilla scaling coefficients were partially disputed. Epoch AI published a replication attempt in 2024 finding that the paper's third estimation approach had fitting problems, though the broad conclusion, that data and parameters should scale together, survived.
5. **Established fact, and important.** Compute-optimal is not deployment-optimal. If a model will serve billions of requests, it is rational to train a smaller model far past its Chinchilla point, because inference cost is paid forever and training cost is paid once. Llama 3 8B was trained on about 15 trillion tokens, which is roughly 1,875 tokens per parameter, nearly 100 times the Chinchilla ratio, and it is a much better 8B model for it.
6. **Established fact.** Data curation matters enormously per parameter. Microsoft's phi line, starting with the June 2023 paper Textbooks Are All You Need, showed that filtered and synthetic textbook-style data lets very small models reach scores that previously needed models many times larger, though critics noted benchmark contamination risk in such setups.
7. **Established fact.** Mistral 7B, released 27 September 2023, outperformed Llama 2 13B on all benchmarks its authors reported. A 7B beat a 13B. Neither architecture nor data was held constant, which is exactly the point: parameter count alone did not decide it.
8. **Active research.** How much of frontier capability comes from post-training as against pre-training scale; whether reasoning-focused post-training and test-time compute change the scaling picture; how to measure data quality before spending the compute.
9. **Marketing claim.** Any headline of the form "our model has N parameters, therefore it is better". Also any comparison that quotes total parameters for a mixture-of-experts model against dense parameters for a rival without saying so.
10. **Where experts disagree.** Some argue continued scaling of pre-training is still the main driver of progress; others argue returns from pre-training scale have flattened and that data quality, post-training and inference-time compute now dominate. Both camps include serious researchers, and the public evidence does not settle it, partly because frontier training details are no longer published.
11. Practical consequence for an engineer: never select a model by parameter count. Select by measured performance on your own task, then by cost and latency. Parameter count is only useful for predicting memory and speed, which it predicts extremely well.

Model	Params	Tokens trained	Ratio
GPT-3 (2020)	175B	300B	1.7
Gopher (2021)	280B	300B	1.1
Chinchilla (2022)	70B	1.4T	20
Llama 3 8B (2024)	8B	~15T	~1875

■ 47.6.6 WORDS - remember these

1. Scaling law — a curve saying how much better a bigger model gets — a fitted power law relating loss to parameters, data or compute.
2. Compute-optimal — the best size for a fixed training budget — the parameter-and-token split minimizing loss at fixed FLOPs, about 20 tokens per parameter per Chinchilla.
3. Undertrained — too big for the text it read — a model whose token count is far below its compute-optimal allocation.
4. Overtrained (deliberately) — trained far past compute-optimal on purpose — a smaller model given many more tokens to reduce lifetime inference cost.
5. Pre-training — the long first phase — self-supervised next-token prediction on a very large corpus.
6. Post-training — everything done afterwards — supervised fine-tuning, preference optimization and safety training, covered in Chapter 50.
7. MMLU — a broad general-knowledge exam for models — Massive Multitask Language Understanding, 57 subjects of multiple-choice questions, released 2020.

47.7 Tokens: why text is not fed in as words or characters

■ 47.7.1 PLAIN - in simple words

1. A model works on numbers, so text must become numbers first.
2. The obvious plan is: one number per word. It fails, for four reasons.
3. First, there is no fixed list of all words. New ones appear every day.
4. Second, typos. “recieve” is not in any word list, so it becomes an unknown.
5. Third, many languages do not put spaces between words at all.
6. Fourth, a word list big enough to be useful is enormous, and the model would need one row of numbers per word, which is very expensive.
7. The opposite plan is: one number per letter. That fails too.
8. A page of text becomes thousands of letters, so sequences get very long, and long sequences are expensive.
9. Worse, the model must then learn spelling from scratch before it can learn anything about meaning.
10. So neither extreme works. The answer is in between: chop text into pieces that are usually bigger than a letter and often smaller than a word.
11. Those pieces are called **tokens** or **subwords**.
12. Common words become one token. Rare words become several pieces.
13. A word nobody has ever seen still gets encoded, because in the worst case it falls back to very small pieces.
14. Nothing is ever unknown. That is the property that makes it work.

■ 47.7.2 PLAIN – a picture in your head

1. Think about how a printer's typeset used to work.
2. One option: cut a separate metal block for every word in the language. Millions of blocks, and a new one every time somebody coins a word.
3. Another option: keep only 26 letter blocks and build everything letter by letter. Very few blocks, but setting one page takes forever.
4. What real printers did was in between. They kept letters, and they also kept **ligatures**: single blocks for common combinations like "fi" and "ffl".
5. Frequent combinations got their own block because it saved work.
6. Rare combinations were built up from letters.
7. That is exactly what subword tokenization does, chosen automatically by counting which combinations are frequent in a big pile of text.

Where this comparison breaks: a printer's ligatures were chosen by human craftsmen for how they looked. A tokenizer's pieces are chosen by a counting algorithm for how often they occur, and many of them look strange to a human eye. There is also no requirement that a token be a meaningful unit. Tokens regularly cut straight through the middle of a morpheme.

■ 47.7.3 PLAIN – a worked example

1. Here is byte-pair encoding worked completely, on a tiny corpus.
2. The corpus is four words with counts: low appears 5 times, lower 2 times, newest 6 times, widest 3 times.
3. Start by splitting every word into characters, with an underscore marking the end of a word.
4. The starting symbol set is 11 symbols: _ d e i l n o r s t w.
5. Now count every adjacent pair, weighted by word frequency, and merge the most frequent pair. Repeat.

```

step 1: top pairs  es=9  st=9  t_=9  we=8  lo=7  ow=7
           merge e+s -> es
           l o w _      (5)
           l o w e r _  (2)
           n e w e s t _ (6)
           w i d e s t _ (3)

step 2: top pairs  est=9  t_=9  lo=7  ow=7  ne=6  ew=6
           merge es+t -> est
           n e w e s t _ (6)
           w i d e s t _ (3)

step 3: merge est+_ -> est_      (count 9)
           n e w e s t _ (6)
           w i d e s t _ (3)

step 4: merge l+o -> lo          (count 7)
step 5: merge lo+w -> low        (count 7)
           l o w _      (5)
           l o w e r _  (2)

step 6: merge n+e -> ne          (count 6)
step 7: merge ne+w -> new        (count 6)
step 8: merge new+est_ -> newest_ (count 6)
step 9: merge low+_ -> low_      (count 5)
step 10: merge w+i -> wi         (count 3)

```

6. After 10 merges the words look like this: low_ (5), low e r _ (2), newest_ (6), wi d est_ (3).
7. The learned merge list, in order, is: es, est, est_, lo, low, ne, new, newest_, low_, wi.
8. The vocabulary is now 11 starting symbols + 10 merges = 21 tokens.
9. Notice what happened. “newest” became a single token because it was frequent.
10. “lower” is still in pieces, because it appeared only twice.
11. “est_” became a token that means, roughly, the superlative ending. Nobody told the algorithm about grammar. It fell out of counting.
12. Real training does this 30,000 to 200,000 times instead of 10 times, on billions of words instead of 16.

■ 47.7.4 PLAIN – what is really happening inside

1. Training a tokenizer and using one are two different programs.
2. Training: count pairs, merge the most frequent, repeat until the vocabulary reaches the target size. Save the ordered merge list and the vocabulary.
3. Using: split the incoming text into characters, then apply the saved merges in exactly the order they were learned. Same order, every time.
4. That ordering is what makes the process deterministic. The same text always gives the same tokens.
5. Then each final piece is looked up in the vocabulary to get its integer id.
6. A crucial detail: modern tokenizers do not start from characters. They start from bytes.
7. There are exactly 256 possible byte values, so every possible input, in any language, in any encoding, including broken text, can always be represented.
8. That is why you never see an “unknown token” error from a modern model.
9. The cost of the byte fallback is that unusual scripts get split into individual bytes, and one character can become three or four tokens.
10. There is also a pre-tokenization step. Before any merging, the text is split by a fixed pattern, usually keeping leading spaces attached to words and splitting runs of digits into groups.
11. That pattern is why “ the” with a leading space is a different token from “the” without one, and both exist in the vocabulary.

■ 47.7.5 TECHNICAL – the engineer’s version

1. The four families you need to be able to name and tell apart:

Family	Chooses merges by	First described
BPE	Highest pair frequency	Gage 1994; Sennrich 2016
WordPiece	Highest likelihood gain	Schuster, Nakajima 2012
Unigram LM	Prunes a large set	Kudo 2018
SentencePiece	Framework, not algorithm	Kudo, Richardson 2018

2. **Byte-pair encoding** was invented as a data compression algorithm by Philip Gage, published in The C Users Journal in February 1994. Rico Sennrich, Barry Haddow and Alexandra Birch adapted it to machine translation in Neural Machine Translation of Rare Words with Subword Units, posted 2015 and published at ACL 2016. GPT-2 in 2019 moved BPE to operate on raw bytes, giving the 256-symbol base alphabet and eliminating unknown tokens.
3. **WordPiece** came from Mike Schuster and Kaisuke Nakajima at Google in the 2012 ICASSP paper Japanese and Korean Voice Search. It merges the pair that most increases the likelihood of the training data under a unigram language model, rather than the most frequent pair. Concretely

it maximizes $\text{count}(xy) / (\text{count}(x) * \text{count}(y))$, so a pair of two rare symbols can beat a pair of two common ones. BERT, released by Google in October 2018, uses WordPiece, and marks word continuations with a double hash prefix.

4. **Unigram language model** tokenization was introduced by Taku Kudo in the 2018 ACL paper Subword Regularization. It works in the opposite direction: start with a large candidate vocabulary, score every candidate by how much removing it would hurt the corpus likelihood, and iteratively prune the worst until the target size is reached. Because it keeps a probability per token, it can sample alternative segmentations of the same string, which is used as a data augmentation technique.
5. **SentencePiece** is a library, not an algorithm, from Taku Kudo and John Richardson, EMNLP 2018 system demonstrations. It implements both BPE and Unigram, and its real contribution is treating input as a raw stream with no language-specific pre-tokenization, encoding the space character itself as a visible symbol so that detokenization is exactly reversible. That is what makes it work for Japanese, Chinese and Thai, which do not delimit words with spaces. T5, Llama 1 and Llama 2 use SentencePiece; Llama 3 moved to a tiktoken-style byte-level BPE with a 128,000-entry vocabulary.
6. Real vocabulary sizes, for scale:

Tokenizer	Vocabulary	Used by
GPT-2 (r50k)	50,257	GPT-2, GPT-3
cl100k_base	100,277	GPT-3.5, GPT-4
o200k_base	200,019	GPT-4o and later
Llama 3	128,256	Llama 3.x family

7. Larger vocabularies mean fewer tokens per document, which means cheaper attention and shorter sequences, but a larger embedding and output matrix. Going from 50k to 200k vocabulary at hidden size 4096 costs about 1.2 billion extra parameters across the two tables.
8. Special tokens are added outside the learned merges: sequence start, sequence end, padding, and chat role markers such as a header start marker. These are reserved ids that the merge process can never produce from text, which is a deliberate security property: user text cannot forge a role boundary.
9. Tools: tiktoken for the OpenAI encodings, tokenizers and AutoTokenizer in the Hugging Face stack, sentencepiece for the T5 and Llama 2 lineage, and llama_tokenize in llama.cpp.

■ 47.7.6 WORDS - remember these

1. Token — a small piece of text the model works in — an integer id indexing one row of the embedding matrix, produced by the tokenizer.
2. Subword — a piece smaller than a word — a token that is part of a word, such as “ization” in “tokenization”.
3. Byte-pair encoding — repeatedly glue the most common pair together — BPE, a greedy merge algorithm producing an ordered merge list.
4. Byte-level — starting from raw bytes, not letters — using the 256 byte values as the base alphabet so no input is ever unrepresentable.
5. Pre-tokenization — the split done before merging — a regular expression pass that fixes where merges may not cross, such as across whitespace.
6. Vocabulary — the full list of possible tokens — the id-to-string table, size V , equal to the number of rows in the embedding matrix.

7. Special token — a marker that is not ordinary text — a reserved id such as sequence start or a chat role header, unreachable by merging user text.
8. Detokenization — turning tokens back into text — concatenating the token strings; exactly reversible in SentencePiece and byte-level BPE.

47.8 What tokenization does in practice

■ 47.8.1 PLAIN - in simple words

1. Now let us look at real text going through a real tokenizer.
2. All the counts below are measured, not estimated.
3. English prose splits neatly. Most common words are one token each.
4. Numbers get chopped into groups of digits, and the groups do not line up with how you would read the number.
5. Web addresses split into many small pieces, because slashes, dots and question marks all break the text apart.
6. Program code splits reasonably well, because tokenizers are trained on a lot of code these days.
7. Hindi and other Indian scripts split badly on older tokenizers and much better on newer ones, but still worse than English.
8. An emoji is one character to you and often two tokens to an older model.
9. Two consequences follow directly, and they explain famous model failures.
10. The model cannot see letters, so it cannot reliably count them or reverse a word.
11. The model sees digits in arbitrary groups, so arithmetic on long numbers goes wrong for reasons that have nothing to do with reasoning.

■ 47.8.2 PLAIN - a picture in your head

1. Imagine reading a book through a narrow slot that shows a few characters at a time, but you do not control where the slot boundaries fall.
2. Somebody else cut the page into strips before handing it to you.
3. For English the strips mostly line up with words, so reading is easy.
4. For a number like 17394205 the strips fell at 173, 942, 05.
5. You can read the strips perfectly. You just never saw the digits as digits in their proper columns.
6. Now somebody asks you how many times the letter r appears in “strawberry”.
7. You never saw letters. You saw three strips: “str”, “aw”, “berry”.
8. You can guess, from having read the answer somewhere. You cannot count.

Where this comparison breaks: the model is not blind to letters in principle. It has seen enough spelled-out text during training to have learned a lot about which letters are inside which tokens. So it often gets these right. The point is that it is doing recall and inference rather than direct observation, which is why it fails unpredictably rather than never.

■ 47.8.3 PLAIN - a worked example

1. Real measurements, taken with the actual OpenAI tokenizers. cl100k_base is the GPT-4 era encoding; o200k_base is the later one.

Text	cl100k	o200k
The quick brown fox... (44 ch)	10	10
I live in India.	5	5

Text	cl100k	o200k
strawberry	3	3
1234567890	4	4
A 55-character URL	17	18
A 32-character Python function	12	12

2. The exact splits, which are the interesting part:

```
"strawberry" cl100k -> "str" "aw" "berry"
"strawberry" o200k -> "st" "raw" "berry"
"1234567890" both -> "123" "456" "789" "0"
"17394205" both -> "173" "942" "05"
"unbelievable" cl100k -> "un" "belie" "vable"
"tokenization" both -> "token" "ization"
```

3. Look at “17394205”. The groups are 173, 942, 05. That is not thousands, hundreds, tens. It is an arbitrary cut.

4. Now the code example, tokenized by cl100k_base into 12 tokens:

```
"def" " add" "(a" " ," " b" " )":NL" " " " " return" " a" " "+" " b"
(and a final newline token), where NL stands for a newline
```

5. Note that the four-space indent became a single token of three spaces plus a space attached to “return”. Indentation is compressed, which is why code tokenizes efficiently.
6. Now Devanagari. Take the Hindi sentence meaning “I live in India”, which is मैं भारत में रहता हूँ। In roman letters that is “main bharat mein rahta hoon”. It is 22 characters and 58 bytes of UTF-8, because each Devanagari character takes three bytes where an English letter takes one.

Encoding	Tokens for the Hindi	English is
GPT-2 (r50k)	34	5
cl100k_base	24	5
o200k_base	6	5

7. On the GPT-4 era tokenizer, the same meaning costs 24 tokens in Hindi and 5 in English. That is 4.8 times more, for identical content.
8. A longer measured pair: a 57-character Hindi sentence about tokenization costs 61 tokens on cl100k_base and 21 on o200k_base. The equivalent English sentence costs 11 on both.
9. So on cl100k_base the Hindi is 5.5 times the cost. On o200k_base it is 1.9 times. The gap narrowed a lot but did not close.
10. Emoji: the grinning face character, code point U+1F600, is one character and four UTF-8 bytes. cl100k_base spends 2 tokens on it. o200k_base spends 1.

■ 47.8.4 PLAIN – what is really happening inside

1. Why does Devanagari cost so much on the older tokenizers?
2. Because the tokenizer’s merges were learned from a corpus that was mostly English. Frequent English sequences got merged into single tokens.
3. Devanagari sequences were rare, so few merges were learned for them.
4. What is left is the byte fallback. Each Devanagari character is three bytes in UTF-8, and if no merge covers it, those three bytes become separate tokens.
5. That is the 3x penalty in its rawest form, before you even count the missing word-level merges.

6. Newer tokenizers were trained on far more multilingual text and given much larger vocabularies, so many whole Hindi words now have their own token. That is why o200k_base needed only 6 tokens where cl100k_base needed 24.
7. Now the letter-counting failure, mechanically.
8. The model receives the id for “berry” as a single integer. It receives no information whatsoever about the five letters inside it, except what it learned indirectly during training.
9. Asking it to count the letter r in “strawberry” is asking it to recall a fact about the internal composition of three token ids.
10. It can often do this, because spelling appears in training data. It fails when the tokens are unusual, or when the counting has to be exact.
11. Reversing a word is worse, because it requires the letters in order, which is even less directly available.
12. Arithmetic fails for the same class of reason. When 17394205 arrives as 173, 942, 05, the place values that column-wise addition depends on are not aligned with anything the model can see.
13. This is why some model families deliberately force digits to be split one at a time, and why models are much better at arithmetic when allowed to write the working out step by step rather than answering in one shot.

■ 47.8.5 TECHNICAL – the engineer’s version

1. Measured compression ratios, cl100k_base, on real text samples:

Text type	Chars/token	Tokens/word
Plain narrative prose	3.78	1.25
Ordinary email	4.58	1.12
Technical prose	4.87	1.07
Python code	3.76	2.07
Compact JSON	2.76	3.22

2. The common rules of thumb, roughly 4 characters per token and roughly 0.75 words per token in English, are conventions rather than standards, and the table shows they hold for prose and fail badly for structured data. JSON at 2.76 characters per token is 45 per cent worse than the rule of thumb suggests, which matters when you are budgeting a prompt full of API output.
3. The unfairness is documented. Aleksandar Petrov, Emanuele La Malfa, Philip Torr and Adel Bibi published Language Model Tokenizers Introduce Unfairness Between Languages at NeurIPS 2023, measuring the same content across many languages and finding token-count ratios up to 15 times between the best and worst served languages, with over 4 times difference remaining even for character and byte-level encoders.
4. The three consequences they name are exactly the ones that hurt an Indian developer: cost, because APIs bill per token; latency, because more tokens means more forward passes; and effective context, because a fixed window holds far less meaning in a penalized language.
5. Work the third one out. A 128,000-token window at 4.8 characters per token holds about 614,000 characters of English. At the cl100k_base Hindi rate of about 0.93 characters per token, the same window holds about 119,000 characters of Hindi. The window is the same. The content it holds is a fifth.
6. Mitigations that actually work: choose a model whose tokenizer was trained with substantial data in your language, measure with the real tokenizer rather than trusting a rule of thumb, and check whether the provider’s multilingual pricing is per token, which it almost always is.

7. On the letter-counting failure: the standard explanation is tokenization, and it is largely right, but be precise. Character-level models also make counting mistakes, and models can spell tokens correctly when asked step by step. So tokenization makes the information indirect rather than absent. That is an important distinction and it is often stated too strongly.
8. On arithmetic: the tokenizer's digit grouping is a genuine and measurable cause. Research on numeric tokenization has shown that forcing single-digit tokenization, or right-to-left digit grouping, measurably improves multi-digit arithmetic. Some model families now tokenize digits individually for this reason.
9. Practical tools: `tiktoken.get_encoding("cl100k_base").encode(text)` returns the ids; `enc.decode_single_token_bytes(i)` shows exactly what each id is; Hugging Face's `tokenizer.tokenize(text)` shows the string pieces.

```
import tiktoken
enc = tiktoken.get_encoding("cl100k_base")
ids = enc.encode("The cat sat on the mat.")
print(len(ids), ids)
for i in ids:
    print(i, enc.decode_single_token_bytes(i))
```

■ 47.8.6 WORDS - remember these

1. Compression ratio — how much text fits in one token — measured characters per token or tokens per word for a given tokenizer and text type.
2. Byte fallback — what happens when no merge covers the text — encoding characters as their individual UTF-8 bytes, one token each.
3. Tokenizer fertility — how many tokens a tokenizer spends per word — a standard fairness measure; higher fertility means a worse-served language.
4. Digit grouping — how numbers get cut up — the pre-tokenizer rule that splits runs of digits, commonly into groups of up to three.
5. UTF-8 — the standard way text becomes bytes — 1 byte for ASCII, 2 for Latin accented and Greek, 3 for Devanagari and most CJK, 4 for emoji.
6. Effective context — how much meaning your window actually holds — the window size divided by your language's tokens-per-meaning cost.

47.9 Token economics

■ 47.9.1 PLAIN - in simple words

1. When you use a model through a company's service, you pay per token.
2. Not per question. Not per minute. Per token in and per token out.
3. This is not arbitrary. Tokens are what the machine actually does work on.
4. One token in costs the model one pass through the multiply-and-add machinery, though those can be done for many tokens at once.
5. One token out costs a full pass through the entire model, and those cannot be done in parallel, because each output token depends on the one before.
6. That asymmetry is why output tokens cost more than input tokens.
7. Typically output is priced at four to six times input.
8. So a long question with a short answer is cheap. A short question with a very long answer is not.
9. There is a second, sneakier cost. Long conversations resend everything.
10. If you have a chat with 50 turns, every new question sends all 50 previous turns as input, because the model has no memory between requests.

11. So the input token count grows with the conversation and you pay for the whole history every single time.
12. That is the single most common reason a bill is bigger than expected.

■ 47.9.2 PLAIN – a picture in your head

1. Think of a translator you hire, who charges by the page.
2. Pages they read cost you a little. Pages they write cost you more, because writing is slower than reading.
3. That is input versus output pricing.
4. Now the important twist. This translator has no memory at all.
5. Every time you ask a follow-up question, you must hand them the entire previous conversation to read again, from the beginning.
6. On question one you hand over one page. On question fifty you hand over sixty pages, and pay to have all sixty read again.
7. Some translators offer a discount: if you hand them the exact same bundle of pages you handed them a few minutes ago, they charge much less for those.
8. That discount is prompt caching, and it is real.

Where this comparison breaks: a human translator reading sixty pages takes an hour. A model processes the input tokens of a long prompt in parallel, so sending a long history costs money and some latency but nothing like proportionally more wall-clock time than a short one.

■ 47.9.3 PLAIN – a worked example

1. Build a realistic support assistant and cost it.
2. Every request contains: a system prompt of 800 tokens, four retrieved document chunks totalling 4,000 tokens, 1,200 tokens of conversation history, and the user's 150-token question.
3. Input total: $800 + 4,000 + 1,200 + 150 = 6,150$ tokens.
4. The answer averages 350 tokens of output.
5. Prices per million tokens, checked on 13 August 2026, input then output:

Model	Input \$/1M	Output \$/1M	Per request
Claude Sonnet 5	2.00	10.00	\$0.0158
Claude Opus 5	5.00	25.00	\$0.0395
gpt-5.6-sol	2.50	15.00	\$0.0206
Gemini 3.6 Flash	1.50	7.50	\$0.0119

6. Work one out fully, for Claude Sonnet 5.
7. Input: $6,150 / 1,000,000 \times \$2.00 = \$0.0123$.
8. Output: $350 / 1,000,000 \times \$10.00 = \$0.0035$.
9. Total per request: \$0.0158.
10. At 10,000 requests a day that is \$158 a day, or \$4,740 a month.
11. On Claude Opus 5 the same traffic is \$11,850 a month.
12. On a small cheap model such as gpt-5.6-luna at \$0.10 in and \$0.60 out, the same traffic is \$247.50 a month.
13. Notice that the input tokens dominate: \$0.0123 of the \$0.0158, or 78 per cent. Cutting retrieved context is worth far more than shortening answers.

■ 47.9.4 PLAIN – what is really happening inside

1. Watch what happens when the context grows and everything else stays fixed.

Input tokens	Cost per request	Per 10,000
6,150	\$0.0158	\$158
14,150	\$0.0318	\$318
38,150	\$0.0798	\$798
106,150	\$0.2158	\$2,158
406,150	\$0.8158	\$8,158

2. Those are all the same question, the same answer, and the same model. The only change is how much context was stuffed in.
3. Going from 6,000 to 400,000 tokens of context multiplies the bill by 52.
4. This is why “just put the whole document in the context window” is a financial decision, not only a technical one.
5. Now caching. The system prompt and the retrieved chunks are often identical between requests within a short window.
6. Providers offer a large discount on input tokens that are an exact prefix match of a recent request. One current example prices cached input at one tenth of fresh input.
7. Rework the example on a provider charging \$2.50 fresh, \$0.25 cached and \$15.00 output. Without caching: \$0.0206 per request.
8. With the 4,800-token system-plus-documents prefix cached: 4,800 at \$0.25 plus 1,350 at \$2.50 plus 350 at \$15.00 = \$0.0098.
9. That is a 52 per cent saving for changing nothing but the ordering and stability of the prompt.
10. The rule that follows: put the stable parts of your prompt first and the variable parts last, because prefix caching only matches from the start.

■ 47.9.5 TECHNICAL – the engineer’s version

1. Why output costs more, precisely. Processing input is the **prefill** phase: all input tokens go through the model in one batched forward pass, and the hardware is compute-bound and highly efficient.
2. Producing output is the **decode** phase: one token at a time, each requiring a full pass over every weight, and at small batch sizes the hardware is memory-bandwidth-bound and mostly idle in its arithmetic units.
3. So a decoded token costs far more machine time than a prefilled one, and the pricing reflects that. The typical ratio of 4x to 6x is a convention that has held across providers, not a standard.
4. Reasoning models add a third category. Tokens generated internally before the visible answer are billed as output tokens even though you never see them, and they can be several times the visible answer’s length. Budget for them explicitly.
5. Long-context surcharges are now common. As of August 2026, one provider prices prompts over 200,000 tokens at double the input rate and 1.5 times the output rate; another prices a long-context tier at double input and 1.5 times output above a threshold. Check the specific model’s page, because this changes often.
6. Batch APIs typically halve the price in exchange for asynchronous delivery within a window, commonly 24 hours. If your workload is not interactive, this is the largest single discount available.

7. Estimating before you build: tokenize a representative sample of your real prompts with the actual tokenizer and take the mean. Do not estimate from character counts if your content is JSON, code or a non-Latin script, because the rule of thumb is wrong by up to a factor of five in those cases.
8. A checklist that reduces token spend, in order of typical impact:
 1. Retrieve less. Four chunks instead of twenty.
 2. Cache the stable prefix; put variable text last.
 3. Summarize old conversation turns instead of resending.
 4. Use a small model for routing and a large one only when needed.
 5. Cap max output tokens per request.
 6. Batch anything that is not interactive.
 7. Strip whitespace and boilerplate from injected documents.
9. Self-hosting changes the shape of the cost, not always its size. You pay for the machine by the hour whether it is busy or not, so self-hosting wins at high steady utilization and loses badly at low or spiky utilization.
10. Observability: every provider returns a usage object with input and output token counts per response. Log it per request with a feature label, or you will not be able to attribute the bill later.

■ 47.9.6 WORDS – remember these

1. Input token — a token you send — a token in the prompt, processed in the prefill phase, billed at the lower rate.
2. Output token — a token the model writes — a token produced in the decode phase, billed at the higher rate, including hidden reasoning tokens.
3. Prefill — reading the prompt — the parallel forward pass over all input tokens, populating the key-value cache.
4. Decode — writing the answer — the sequential per-token generation loop, one full forward pass per token.
5. Prompt caching — paying less for a repeated prefix — reusing a stored key-value cache for an exact matching prompt prefix, at a discounted rate.
6. Batch API — cheaper if you can wait — asynchronous processing at roughly half price with a delivery window, commonly 24 hours.
7. Context stuffing — putting everything in the prompt — a strategy whose cost grows linearly in tokens and whose attention cost grows faster.

47.10 Embeddings: turning a token id into a vector

■ 47.10.1 PLAIN – in simple words

1. After tokenization you have a list of integers. The model cannot use those directly.
2. An integer id like 8415 is just a name. Token 8416 is not “one more than” token 8415 in any meaningful way.
3. So each id has to be turned into something with actual structure.
4. It is turned into a list of numbers. A long one: often 4,096 numbers.
5. That list is called the token’s **embedding**.
6. Where does the list come from? A big table.
7. The table has one row per possible token, and one column per number in the list.
8. If there are 128,256 possible tokens and each embedding is 4,096 numbers, the table is 128,256 rows by 4,096 columns.
9. Turning an id into an embedding is just reading row number 8415 of the table.
10. That is a lookup. No multiplication, no cleverness. Fetch the row.

11. The numbers in the table were learned during training, so the table is made of parameters, exactly like every other matrix in the model.
12. And that is the entrance to the model. Text became ids. Ids became rows of numbers. Now the layers can do arithmetic.

■ 47.10.2 PLAIN – a picture in your head

1. Think of a very long index card box, with one card per word.
2. On each card, instead of a definition, there are 4,096 numbers.
3. To look up a word you find its card and copy the numbers off it.
4. The numbers mean nothing to you individually. Number 1,872 on the card for “cat” is 0.031, and there is no sentence explaining why.
5. But the cards are arranged in a very particular way in an imaginary space.
6. Cards for similar things ended up near each other. The card for “cat” is close to the card for “dog”, and far from the card for “invoice”.
7. Nobody sorted them deliberately. They ended up there because training pushed words used in similar ways toward similar numbers.
8. So the meaning is in the arrangement, not in any single number on any card.

Where this comparison breaks: index cards sit on a table, which is two dimensional. These cards sit in a space with 4,096 directions. Almost every intuition you have about “near” and “far” from two dimensions gets weaker in 4,096, and some of them break completely. That gets its own honest treatment below.

■ 47.10.3 PLAIN – a worked example

1. Take a real sentence and follow it in.
2. The sentence: “The cat sat on the mat.”
3. Tokenized with cl100k_base it becomes 7 tokens with these real ids:

Id	Piece
791	The
8415	(space)cat
7731	(space)sat
389	(space)on
279	(space)the
5634	(space)mat
13	.

4. Note that “The” at the start and “the” in the middle are different tokens with different ids, because one has a leading space and a capital letter.
5. Now the lookup. The embedding matrix for an 8B-class model is 128,256 x 4,096.
6. Row 791 is fetched. It is 4,096 numbers. Row 8415 is fetched. Also 4,096.
7. Do that for all seven ids and stack them.
8. The result is a block of numbers 7 rows by 4,096 columns.
9. In the shape notation engineers use, the tensor went from [7] to [7, 4096].
10. That is 28,672 numbers describing a six-word sentence.
11. Size of the table itself: 128,256 x 4,096 = 525,336,576 parameters.
12. At two bytes each, that one table is about 1.05 gigabytes, which is 6.5 per cent of the whole 8B model.

■ 47.10.4 PLAIN – what is really happening inside

1. The lookup is mathematically a matrix multiplication, done the lazy way.
2. The formal version: make a vector of 128,256 numbers that is all zeros except a single 1 in position 8415. That is called a one-hot vector.
3. Multiply that one-hot vector by the embedding matrix. The result is row 8415.
4. Every implementation skips the multiplication and just indexes the row, because multiplying by 128,255 zeros is a waste.
5. That is why the operation is called an embedding lookup rather than an embedding multiply, even though it is a linear layer.
6. One thing is missing at this point: order.
7. The lookup gives the same vector for “cat” whether it is the first word or the fiftieth. Position information has to be added separately.
8. Older models added a learned position vector to the token vector. Modern models mostly rotate the query and key vectors inside attention instead, which Chapter 48 covers.
9. From here the stacked embeddings flow into layer 1, then layer 2, and so on.
10. Critically, the vector at each position keeps being updated as it passes through layers. It starts as “the meaning of this token in general” and becomes “the meaning of this token in this sentence”.
11. At the very end, the vector at the last position is multiplied by the output matrix to produce one score per possible token, and the highest scores are the model’s prediction of what comes next.

■ 47.10.5 TECHNICAL – the engineer’s version

1. The embedding matrix has shape $[V, d]$ and is exactly $V \times d$ parameters.

Model	V	d	Embedding params
GPT-2 small	50,257	768	38,597,376
Llama 3.1 8B	128,256	4,096	525,336,576
Llama 3.1 70B	128,256	8,192	1,050,673,152
Llama 3.1 405B	128,256	16,384	2,101,346,304

2. In PyTorch this is `nn.Embedding(V, d)`, whose forward pass is `F.embedding`, which is an index-select, not a matmul.
3. The output projection, `lm_head`, has shape $[V, d]$ as well and produces **logits**: one raw score per vocabulary entry. Softmax over logits gives the next-token distribution.
4. If embeddings are tied, `lm_head.weight` is the same storage as `embed_tokens.weight`. Tying was popularized by Press and Wolf in 2016 in Using the Output Embedding to Improve Language Models, and independently by Inan, Khosravi and Socher the same year.
5. Common hidden sizes, which are also the embedding dimensions: 768 for GPT-2 small, 1024 and 1600 for larger GPT-2 variants, 2048 for many 1B-class models, 4096 for 7B and 8B, 5120 for 13B, 8192 for 70B, 16384 for 405B.
6. Now the honest note about dimensionality that the reader asked for.
7. You cannot visualize 4,096 dimensions. Nobody can. Any picture you have seen of word vectors as arrows on a page is a projection down to two dimensions by a method such as PCA, t-SNE or UMAP, and those projections distort distances substantially. t-SNE in particular preserves local neighbourhoods and does not preserve global distances at all, so cluster sizes and the gaps between clusters in a t-SNE plot are not meaningful.

8. What does carry over from 2D and 3D: dot products, cosine of the angle between vectors, Euclidean distance, addition and subtraction of vectors, and the idea that direction can encode something.
9. What does not carry over, and this is the part people get wrong:
 1. In high dimensions almost every pair of random vectors is nearly orthogonal, so a cosine of 0 means “unrelated”, not “opposite”.
 2. Distances concentrate: the ratio between the nearest and farthest point in a random set shrinks toward 1 as dimension grows, which is one face of the curse of dimensionality.
 3. The volume of a high-dimensional ball is almost entirely near its surface, so intuitions about “the middle of the cloud” are wrong.
 4. There is far more room than you expect. In d dimensions you can pack exponentially many nearly-orthogonal directions, which is why a 4,096-wide space can hold far more than 4,096 distinguishable concepts.
10. That last point has a name in current research: **superposition**, the hypothesis that models represent many more features than they have dimensions, by using nearly-orthogonal directions and tolerating small interference. Anthropic’s 2022 paper Toy Models of Superposition is the standard reference. This is active research, not settled fact.

■ 47.10.6 WORDS – remember these

1. Embedding — a token turned into a list of numbers — a row of the embedding matrix, a vector in $\mathbb{R}^d$.
2. Embedding matrix — the lookup table — a $[V, d]$ parameter tensor mapping token ids to vectors.
3. One-hot vector — all zeros with a single 1 — the formal input to an embedding layer, never materialized in practice.
4. Logits — raw scores before they become probabilities — the $[V]$ output of the final projection, converted by softmax.
5. Dimension — how many numbers are in one vector — d , the model’s hidden size, typically 768 to 16,384.
6. Curse of dimensionality — high-dimensional space behaves strangely — the family of effects including distance concentration and near-orthogonality of random vectors.
7. Superposition — packing more ideas than there are directions — the hypothesis that features are stored along nearly-orthogonal directions with tolerated interference. Active research.

47.11 What embeddings capture

■ 47.11.1 PLAIN – in simple words

1. If two words have similar embeddings, the model treats them similarly.
2. So the natural question is: how do you measure “similar” for two lists of numbers?
3. Two standard answers, both simple.
4. **Distance**: treat each list as a point, and measure how far apart the points are. Closer means more similar.
5. **Angle**: treat each list as an arrow from the origin, and measure the angle between the arrows. Smaller angle means more similar.
6. The angle version is the one almost everybody uses, and it is called **cosine similarity**.
7. It gives 1 for arrows pointing the same way, 0 for arrows at right angles, and -1 for arrows pointing opposite ways.

8. The angle version ignores how long the arrows are and looks only at direction, which is usually what you want.
9. There is also a famous claim that these vectors capture relationships, not just similarity.
10. The claim is that king minus man plus woman lands near queen.
11. It is a real effect. It is also considerably weaker than the popular story, and the popular demonstration was rigged in a specific way. Section 47.11.3 and 47.11.5 give the honest account.

■ 47.11.2 PLAIN – a picture in your head

1. Think of a map of a country, where each town is a dot.
2. Two towns close together on the map are similar in location. That is distance.
3. Now draw an arrow from the capital to every town.
4. Two towns roughly in the same direction from the capital, one near and one far, have arrows at a small angle. That is cosine similarity.
5. On a map, “50 km north-east” is a direction you can apply anywhere. Start at any town, go 50 km north-east, arrive somewhere new.
6. The analogy claim is that word space has directions like that. There is a direction that means “make it female”, and applying it to king lands on queen.
7. The map picture makes clear why this could work and why it might not.
8. On a real map, “50 km north-east” from a coastal town lands in the sea.

Where this comparison breaks: a map has two dimensions and every direction is meaningful. Word space has thousands, and only a tiny number of directions correspond to anything a human would name. Most directions in the space mean nothing at all.

■ 47.11.3 PLAIN – a worked example

1. Cosine similarity, computed by hand on small vectors.
2. Take four-number toy vectors, made up for illustration:

```
cat = [0.8, 0.1, 0.7, 0.2]
dog = [0.7, 0.2, 0.8, 0.1]
car = [0.1, 0.9, 0.0, 0.8]
```

3. The formula: $\text{cosine} = (a \cdot b) / (|a| \times |b|)$, where $a \cdot b$ is the sum of pairwise products and $|a|$ is the square root of the sum of squares.
4. Step 1, the dot product of cat and dog: $0.8 \times 0.7 + 0.1 \times 0.2 + 0.7 \times 0.8 + 0.2 \times 0.1 = 0.56 + 0.02 + 0.56 + 0.02 = 1.16$.
5. Step 2, the length of cat: $\text{sqrt}(0.64 + 0.01 + 0.49 + 0.04) = \text{sqrt}(1.18) = 1.0863$.
6. Step 3, the length of dog: also 1.0863.
7. Step 4: $\text{cosine} = 1.16 / (1.0863 \times 1.0863) = 1.16 / 1.18 = 0.9831$.
8. An angle of 10.6 degrees. Very similar.
9. Now cat against car. Dot product = $0.08 + 0.09 + 0.00 + 0.16 = 0.33$. Lengths 1.0863 and 1.2083. Cosine = $0.33 / 1.3126 = 0.2514$.
10. An angle of 75.4 degrees. Nearly unrelated.
11. Compare with straight-line distance: cat to dog is 0.20, cat to car is 1.41. Both measures agree here, which is common but not guaranteed.
12. Now the analogy, on a three-number toy set:

```
king    = [0.92, 0.81, 0.12]
man     = [0.88, 0.14, 0.09]
woman  = [0.13, 0.16, 0.91]
```

```
queen    = [0.15, 0.74, 0.86]
princess = [0.20, 0.60, 0.88]
```

13. king - man + woman = [0.17, 0.83, 0.94].
14. Cosine of that result against every word in the toy set:

Word	Cosine with result
queen	0.9999
princess	0.9911
woman	0.8556
king	0.6041
man	0.3092

15. Queen wins. The demonstration works. But look at the third row: woman, one of the inputs, scores 0.8556, well above king and man.
16. That third row is where the honest correction lives.

■ 47.11.4 PLAIN - what is really happening inside

1. The standard way to answer an analogy from vectors is called 3CosAdd.
2. Compute $b - a + c$, then find the vocabulary word whose vector has the highest cosine with the result.
3. There is a rule buried in the standard implementation: the three input words are excluded from the search.
4. So when you compute king - man + woman, the code refuses to answer king, man or woman, no matter how well they score.
5. That matters a great deal, because very often the highest-scoring word is one of the inputs.
6. The result you are shown is therefore the best answer after the most likely answers have been forbidden.
7. That does not make the effect fake. Queen really does score highly, and consistently, on many word pairs.
8. It makes the effect smaller and less magical than the demonstrations imply.
9. When researchers removed the exclusion rule and let the inputs compete, accuracy collapsed. The numbers are in the technical block below.
10. There is a second, separate honesty point about these vectors.
11. In word2vec, each word has exactly one vector, forever. "Bank" gets one vector that has to serve both the river bank and the money bank.
12. Modern models do not work that way. The vector for a word changes depending on the sentence it appears in.

■ 47.11.5 TECHNICAL - the engineer's version

1. Word2vec was published by Tomas Mikolov and colleagues at Google in 2013, in two papers: Efficient Estimation of Word Representations in Vector Space in January 2013, and Distributed Representations of Words and Phrases and their Compositionality at NeurIPS 2013. The analogy result appeared in a third, Linguistic Regularities in Continuous Space Word Representations, by Mikolov, Yih and Zweig at NAACL in June 2013.
2. GloVe followed from Jeffrey Pennington, Richard Socher and Christopher Manning at Stanford, EMNLP 2014, fitting vectors to global co-occurrence counts rather than local context windows.

3. The vector offset method, 3CosAdd, ranks candidate d by $\cos(d, b - a + c)$. Omer Levy and Yoav Goldberg proposed 3CosMul in 2014 in Linguistic Regularities in Sparse and Explicit Word Representations, which multiplies similarities instead of adding offsets and performs better.
4. Now the correction, which is well documented and not fringe.
5. Tal Linzen's 2016 RepEval paper Issues in Evaluating Semantic Spaces Using Word Analogies showed that a large part of reported analogy accuracy is explained by simple baselines: for many analogy items, just returning the nearest neighbour of c , ignoring a and b entirely, scores well.
6. Malvina Nissim, Rik van Noord and Rob van der Goot published Fair Is Better than Sensational: Man Is to Doctor as Woman Is to Doctor in Computational Linguistics, volume 46 issue 2, 2020. They showed the standard implementations forbid returning any of the three input words, and that this is not a detail.
7. Their measured result: when they modified the algorithms to allow input words as answers, 3CosAdd accuracy fell from 71 per cent to 21 per cent, and 3CosMul fell from 73 per cent to 45 per cent.
8. Read that carefully. On the standard benchmark, roughly two thirds of 3CosAdd's apparent success disappears when the exclusion is lifted. The frequent correct-if-allowed answer is one of the inputs, usually b .
9. So the accurate statement is: the offset direction carries real relational information, and it is much weaker than the "king - man + woman = queen" story suggests. Both halves of that sentence are true, and popular accounts usually give only the first half.
10. The same paper makes a separate methodological point about bias claims: asking a system "man is to doctor as woman is to what" while forbidding it from answering "doctor" guarantees a different answer, and then reporting that different answer as evidence of bias is unsound. Bias in embeddings is real and separately demonstrated; that particular demonstration is not sound evidence of it.
11. **Static versus contextual embeddings.** Word2vec and GloVe are static: one vector per word type, fixed. Contextual embeddings give a different vector per occurrence.
12. ELMo, from Matthew Peters and colleagues at the Allen Institute, NAACL 2018, Deep Contextualized Word Representations, was the first widely used contextual model. BERT, from Jacob Devlin and colleagues at Google, posted October 2018 and published at NAACL 2019, made it standard.
13. In a transformer, the row fetched from the embedding matrix is static, and it becomes contextual immediately: after the first attention layer the vector at that position has mixed in information from the other tokens.
14. So in the sentence "I sat on the river bank" and "I went to the bank for a loan", the input embedding for "bank" is byte-for-byte identical, and the representation at layer 12 is quite different. That is the whole point of the architecture.

Property	Static (word2vec)	Contextual
Vectors per word	One	One per occurrence
Handles polysemy	No	Yes
Needs a model to compute	No, table lookup	Yes, forward pass
Typical year	2013 to 2017	2018 onward

■ 47.11.6 WORDS – remember these

1. Cosine similarity — how aligned two lists of numbers are — the dot product divided by the product of the norms; 1 identical direction, 0 orthogonal.

2. Euclidean distance — straight-line distance between two points — the square root of the sum of squared differences.
3. Dot product — pairwise multiply and add — the unnormalized similarity, which grows with vector length as well as alignment.
4. Vector offset — subtracting one vector from another — the $b - a$ term in the 3CosAdd analogy method, treated as a relation direction.
5. Static embedding — one fixed vector per word — word2vec or GloVe style, a pure lookup with no sentence context.
6. Contextual embedding — a different vector each time — the hidden state at a position after attention has mixed in surrounding tokens.
7. Polysemy — one word with several meanings — the phenomenon static embeddings cannot represent and contextual embeddings can.

47.12 Embeddings as a tool in their own right

■ 47.12.1 PLAIN - in simple words

1. So far embeddings have been a part inside a language model.
2. They are also a useful product on their own, sold separately.
3. The idea: instead of one vector per token, get one vector for a whole sentence, paragraph or document.
4. Now you can compare pieces of text by comparing numbers.
5. That single capability unlocks five very common jobs.
6. **Semantic search**: find documents that mean the same thing as a query, even if they share no words with it.
7. **Clustering**: group thousands of support tickets into themes automatically.
8. **Recommendation**: suggest articles near the ones a reader liked.
9. **Deduplication**: find near-identical items that keyword matching misses.
10. **Retrieval for a model**: fetch the few relevant paragraphs from a large collection and paste them into the prompt.
11. That last one is the foundation of retrieval-augmented generation, which Chapter 51 covers in full.
12. The thing that makes all five work is the same: meaning became geometry, and geometry is cheap to compute with.

■ 47.12.2 PLAIN - a picture in your head

1. Imagine a library where every book has been assigned a position in a very large warehouse.
2. Books are not shelved by author or title. They are shelved by what they are about.
3. Two books about monsoon farming end up on adjacent shelves even if one is in English and one in Hindi and they share no words.
4. To answer a question you do not read anything. You compute where the question would sit in the warehouse, walk to that spot, and take the nearest ten books.
5. That is semantic search, exactly.
6. Keyword search is the old catalogue: it finds books whose title contains your exact words, and misses everything phrased differently.

Where this comparison breaks: a warehouse has aisles you can walk. A vector space has thousands of dimensions and no aisles, so finding the nearest items needs a specialized index. Doing it by brute force means comparing against every item, which is fine for ten thousand documents and far too slow for a hundred million.

■ 47.12.3 PLAIN – a worked example

1. Suppose four short documents and one query, each already turned into a four-number vector by an embedding model.

```
query = [0.75, 0.15, 0.60, 0.20]

doc A "how to feed a kitten" = [0.80, 0.10, 0.70, 0.20]
doc B "puppy training basics" = [0.70, 0.20, 0.80, 0.10]
doc C "car insurance renewal" = [0.10, 0.90, 0.00, 0.80]
doc D "truck loading limits" = [0.20, 0.80, 0.10, 0.90]
```

2. Compute the cosine of the query against each.
3. The query's length is $\sqrt{0.5625 + 0.0225 + 0.36 + 0.04} = \sqrt{0.985} = 0.9925$.
4. Query and doc A: dot = $0.60 + 0.015 + 0.42 + 0.04 = 1.075$. Doc A's length is 1.0863. Cosine = $1.075 / (0.9925 \times 1.0863) = 0.9971$.
5. Query and doc B: dot = $0.525 + 0.03 + 0.48 + 0.02 = 1.055$. Cosine = 0.9786.
6. Query and doc C: dot = $0.075 + 0.135 + 0.00 + 0.16 = 0.37$. Cosine = 0.3085.
7. Query and doc D: dot = $0.15 + 0.12 + 0.06 + 0.18 = 0.51$. Cosine = 0.4196.

Document	Cosine	Rank
A, kitten feeding	0.9971	1
B, puppy training	0.9786	2
D, truck loading	0.4196	3
C, car insurance	0.3085	4

8. The two animal documents rank above the two vehicle documents, and no word from the query appears in any of them.
9. In a real system the vectors have 384, 768, 1024 or 3072 numbers instead of four, and there are millions of documents, but the computation per pair is exactly this one.

■ 47.12.4 PLAIN – what is really happening inside

1. Where does a whole-sentence vector come from?
2. Run the text through a model and you get one vector per token. You need one vector for the whole thing.
3. Three common ways to collapse them.
4. **Mean pooling**: average all the token vectors. Simple, works well, still the most common method.
5. **CLS pooling**: use the vector at a special marker token placed at the start, which was trained to summarize the sequence.
6. **Last-token pooling**: in a decoder-only model, use the vector at the final position, which has seen everything before it.
7. But a raw language model's vectors are not well suited to comparison straight out of the box.
8. So embedding models are trained specially, with a method called contrastive training.
9. You show the model many pairs. Some pairs mean the same thing, some do not.
10. You push the matching pairs' vectors together and the non-matching pairs' vectors apart.
11. After enough pairs, cosine similarity in that space genuinely tracks meaning similarity, which it does not automatically do otherwise.
12. Finally, vectors are usually normalized to length 1, which makes cosine similarity and dot product the same computation, and makes the search faster.

■ 47.12.5 TECHNICAL – the engineer’s version

1. Embedding models are separate, smaller models from the generative ones, and they are usually encoder-style rather than decoder-style.
2. Typical output dimensions and what they cost to store, per million documents:

Dimensions	Bytes at fp32	Per 1M docs
384	1,536	1.5 GB
768	3,072	3.1 GB
1,024	4,096	4.1 GB
3,072	12,288	12.3 GB

3. Sentence-BERT, by Nils Reimers and Iryna Gurevych, EMNLP 2019, is the paper that made sentence embeddings practical, by fine-tuning BERT with a siamese network so that cosine similarity between sentence vectors is meaningful. Before it, comparing raw BERT sentence vectors performed worse than averaging GloVe vectors.
4. Contrastive objectives in common use: InfoNCE, multiple-negatives ranking loss, and in-batch negatives, where every other item in the batch is treated as a negative example for free.
5. Matryoshka representation learning, from a 2022 paper by Aditya Kusupati and colleagues, trains a model so that the first 256 or 512 numbers of a 3,072- number vector are usable on their own. Several current embedding APIs expose this as a dimension parameter, letting you trade accuracy for storage without re-embedding.
6. Nearest-neighbour search at scale uses an approximate index rather than brute force. HNSW, Hierarchical Navigable Small World graphs, from Yury Malkov and Dmitry Yashunin in 2016, is the most widely deployed. IVF with product quantization, from the FAISS library released by Facebook AI Research in 2017, is the other common family.
7. Approximate means approximate: these indexes return the true nearest neighbours most of the time, not always, and the recall is a tunable parameter traded against speed. That is a real correctness consideration and is often glossed over.
8. Vector databases and vector indexes in wide use as of 2026 include FAISS, pgvector for PostgreSQL, Qdrant, Weaviate, Milvus, Chroma and the vector features of Elasticsearch and OpenSearch.
9. Retrieval-augmented generation, named in a 2020 paper by Patrick Lewis and colleagues at Facebook AI Research, is embedding search plus prompt construction: embed the query, retrieve the top k chunks by cosine, paste them into the context, and let the generative model answer from them. Chapter 51 covers the whole pipeline including chunking and reranking.
10. Honest limitation: pure vector search is worse than keyword search at exact matching, such as product codes, error numbers and names. Production systems almost always combine both, which is called hybrid search, usually merged with reciprocal rank fusion.
11. A second honest limitation: an embedding has no notion of truth or recency. Two documents that contradict each other on a fact will sit close together, because they are about the same thing.

■ 47.12.6 WORDS – remember these

1. Embedding model — a model whose output is a vector, not text — usually an encoder trained with a contrastive objective for similarity.
2. Pooling — turning many token vectors into one — mean, CLS or last-token aggregation over the sequence.
3. Contrastive training — pull matches together, push non-matches apart — an objective such as InfoNCE using in-batch negatives.

4. Semantic search — search by meaning, not words — ranking documents by cosine similarity between query and document embeddings.
5. Approximate nearest neighbour — fast, nearly-correct nearest search — index structures such as HNSW or IVF-PQ that trade recall for speed.
6. Hybrid search — combining keyword and vector search — merging BM25 and vector rankings, commonly with reciprocal rank fusion.
7. Normalization — scaling every vector to length 1 — makes dot product equal cosine similarity and speeds up search.

47.13 The context window

■ 47.13.1 PLAIN – in simple words

1. The **context window** is the maximum number of tokens the model can be given at once, including everything: system instructions, history and your question.
2. It is measured in tokens, not words and not characters.
3. It is a hard limit set by the model, not a preference.
4. Why is there a limit at all? Because of how attention works.
5. Attention lets every token look at every other token.
6. With 100 tokens that is 10,000 pairs. With 1,000 tokens, a million pairs.
7. Double the length and the number of pairs goes up four times, not two.
8. So cost grows with the square of the length. Chapter 48 works through why.
9. When you exceed the window, one of two things happens.
10. Either the service refuses the request with an error, or something silently gets cut off, usually the oldest part of the conversation.
11. Silent cutting is the dangerous one, because the model then answers confidently based on text it never received.
12. And there is a further catch. A model that accepts a long input does not necessarily use all of it well.

■ 47.13.2 PLAIN – a picture in your head

1. Think of a desk with a fixed area.
2. You can spread out papers on it, and you can read anything on the desk instantly.
3. But when the desk is full and you add another page, one falls off the edge.
4. Nobody tells you which one fell off, or that anything fell at all.
5. A bigger desk helps. It also costs more, and it takes longer to scan.
6. Now the awkward part. Even with a huge desk, if you spread out four hundred pages, you will reliably notice the first few and the last few and be much vaguer about the middle.
7. That is not a memory limit. It is an attention limit, and models have a measurable version of the same thing.

Where this comparison breaks: a desk keeps papers between work sessions. A context window does not persist at all. When the request ends, everything on the desk is swept away, and the next request starts empty. Anything that appears to persist was resent by the application.

■ 47.13.3 PLAIN – a worked example

1. Work out what a window actually holds.
2. At about 4 characters per token, a 128,000-token window holds roughly 512,000 characters of English.

3. A typical printed page is about 2,000 characters, so that is about 256 pages.
4. But you never get all of it. Reserve space for the answer, and for the system prompt.
5. Now the attention arithmetic, which is why longer costs so much more:

Tokens	Pairs (n squared)	Relative to 512
512	262,144	1x
2,048	4,194,304	16x
8,192	67,108,864	256x
32,768	1,073,741,824	4,096x
131,072	17,179,869,184	65,536x
1,048,576	1,099,511,627,776	4,194,304x

6. Going from 512 to 1,048,576 tokens is 2,048 times the length and about four million times the attention pair count.
7. Memory grows too, but linearly, through the key-value cache: 40 GiB for a 70B model at 128,000 tokens at 16-bit, as computed in section 47.4.
8. So a million-token context is not a small engineering step from a thousand-token one. It requires different algorithms, not just more memory.

■ 47.13.4 PLAIN – what is really happening inside

1. What happens when the input is too long? Four common strategies.
2. **Reject**: return an error. Honest, and the only one that cannot silently mislead.
3. **Truncate**: cut the input to fit. Usually the oldest turns go first. Cheap, and information is genuinely lost.
4. **Sliding window**: keep a moving window of the most recent tokens and drop what falls out of the back. Used in streaming settings.
5. **Summarize and compact**: replace old turns with a shorter summary generated by the model, keeping recent turns verbatim. This is what most long-running assistants do.
6. Each strategy loses something, and you should know which one your framework is using, because they fail differently.
7. Now the harder problem. Suppose the whole document does fit.
8. The model still does not attend evenly across it.
9. Researchers put a single fact somewhere in a long context and asked a question that requires it, varying only the position.
10. Accuracy was highest when the fact was at the very beginning or the very end, and lowest when it was in the middle.
11. The shape of the curve is a U. The finding is called “lost in the middle”.
12. So placing your most important instruction in the middle of a long prompt is a measurably bad idea.

■ 47.13.5 TECHNICAL – the engineer’s version

1. Context windows have grown by more than three orders of magnitude in seven years:

Model and year	Context window
GPT-2, 2019	1,024
GPT-3, 2020	2,048

Model and year	Context window
Llama 2, 2023	4,096
Llama 3.1, 2024	131,072

- As of 13 August 2026, current commercial figures: Claude Opus 5, Claude Sonnet 5 and Claude Fable 5 accept 1,000,000 input tokens with up to 128,000 output tokens; Claude Haiku 4.5 accepts 200,000. The GPT-5.6 family accepts about 1.05 million input tokens, which is 2^{20} , with 128,000 output. These figures change often; check the provider's model page.
- The cost of attention is $O(n^2)$ in time for the score matrix and $O(n)$ in memory for the key-value cache. FlashAttention, from Tri Dao and colleagues in 2022, does not change the $O(n^2)$ compute but avoids materializing the $n \times n$ matrix in high-bandwidth memory, which removes the $O(n^2)$ memory term and is what made long contexts practical. Chapter 48 covers the mechanism.
- Position encoding is the second limit. RoPE, rotary position embedding from Jianlin Su and colleagues in 2021, encodes position by rotating query and key vectors. Extending a trained model beyond its training length needs the rotation frequencies adjusted, by methods such as position interpolation or the NTK-aware and YaRN scalings. A model advertised at 128,000 tokens is often a model trained at 8,000 and extended.
- Lost in the middle:** Nelson Liu, Kevin Lin, John Hewitt, Ashwin Paranjape, Michele Bevilacqua, Fabio Petroni and Percy Liang, arXiv July 2023, published in TACL 2024. Across multi-document question answering and key-value retrieval, performance was highest when the relevant information was at the start or end of the input and degraded significantly in the middle, and extended-context models were not reliably better than their shorter counterparts at using the extra length.
- RULER**, from Cheng-Ping Hsieh and colleagues at NVIDIA, April 2024, extended the needle-in-a-haystack test with multi-hop tracing and aggregation tasks and evaluated 17 long-context models. Its headline finding: although all claimed 32,000 tokens or more, only about half maintained satisfactory performance at 32,000, despite near-perfect scores on the simple retrieval test.
- So state the distinction plainly. **Claimed context** is the number the API will accept without an error. **Effective context** is the length at which the model still performs near its short-context accuracy. The second number is smaller, is model-specific, and is rarely published by vendors.
- The needle-in-a-haystack test, popularized by Greg Kamradt in November 2023, is a weak measure on its own: passing it shows the model can find one exact verbatim string, which is much easier than reasoning over dispersed information.
- Practical rules that follow: put critical instructions at the beginning and repeat them at the end; retrieve fewer, better chunks rather than more; measure your own task at your own lengths rather than trusting the advertised number; and log token counts so you notice when truncation starts.
- Tools: every API returns input token counts in its usage object; Anthropic and OpenAI both expose a token counting endpoint or library so you can check before sending; tiktoken and AutoTokenizer let you count offline.

■ 47.13.6 WORDS – remember these

- Context window — the most tokens the model accepts at once — the maximum input sequence length, a fixed architectural and training limit.
- Truncation — cutting input to make it fit — dropping tokens, usually oldest first, often silently.
- Sliding window — a moving view of recent tokens — keeping the last n tokens and discarding what falls out.
- Lost in the middle — the dip in accuracy for content in the centre — the U-shaped position-versus-accuracy curve documented by Liu and colleagues.

5. Effective context — how much of the window is actually usable — the length at which task accuracy still holds up, usually shorter than the claimed window.
6. RoPE — how position is encoded in modern models — rotary position embedding, rotating query and key vectors by an angle proportional to position.
7. Needle in a haystack — the simple long-context test — planting one verbatim fact and asking for it back; necessary but far from sufficient.

47.14 Putting it together: one prompt from text to numbers

■ 47.14.1 PLAIN – in simple words

1. Everything in this chapter meets in one short journey.
2. You type a sentence. It is characters.
3. The tokenizer chops it into pieces and looks each piece up, giving integers.
4. Each integer picks one row out of the embedding table, giving a list of numbers.
5. Those lists are stacked into a block, one row per token.
6. The block goes into layer 1, comes out changed, goes into layer 2, and so on.
7. Each layer transforms the block using its own frozen parameters.
8. At the end, the row belonging to the last token is turned into one score for every possible next token.
9. The scores are turned into probabilities, one is picked, and that becomes the next token.
10. Then the whole thing repeats with that token added on the end.
11. Nothing in the model changed at any point. Only the numbers flowing through.

■ 47.14.2 PLAIN – a picture in your head

1. Picture a factory line with 32 stations.
2. At the entrance, a machine cuts the incoming text into standard-sized parts and stamps each with a part number.
3. A stores clerk takes each part number and fetches the matching tray of 4,096 components.
4. The trays travel down the line. Every station reworks all the trays a little, using its own fixed jigs and tools.
5. At the last station, the final tray is compared against a catalogue of 128,256 possible products, and the closest matches are scored.
6. One is chosen and shipped. Then the whole line runs again with that product added to the input.

Where this comparison breaks: on a factory line each station works on one item at a time. In a transformer every station works on all positions at once, and crucially each position can look at the others, which no factory station does.

■ 47.14.3 PLAIN – a worked example

1. The prompt: “The cat sat on the mat.” Model: an 8B-class model with hidden size 4,096, 32 layers, vocabulary 128,256.

```
stage 0  raw text
        "The cat sat on the mat."      23 characters

stage 1  tokenize (cl100k_base)
        7 tokens
        791, 8415, 7731, 389, 279, 5634, 13
        "The" " cat" " sat" " on" " the" " mat" "."
        shape: [7]
```

```

stage 2  embedding lookup
         fetch rows 791, 8415, ... from a
         [128256, 4096] table
         shape: [7, 4096]   = 28,672 numbers

stage 3  through layer 1 ... layer 32
         shape stays [7, 4096] at every layer boundary
         inside a layer it widens to [7, 14336] in the
         feed-forward middle and comes back

stage 4  final normalization
         shape: [7, 4096]

stage 5  take the last row only, position 6
         shape: [4096]

stage 6  multiply by the output matrix [128256, 4096]
         shape: [128256]       one logit per token

stage 7  softmax -> probabilities, then sample
         one token id comes out, say 13 for "."

stage 8  append and repeat from stage 2 with 8 tokens

```

2. Real sizes at each stage, at 16-bit: stage 2 holds 28,672 numbers, which is 56 KiB. Stage 6 produces 128,256 numbers, which is 251 KiB.
3. The key-value cache after this prompt holds 7 tokens $\times$ 128 KiB = 896 KiB.
4. Every one of those numbers is an activation. Every number in the tables they passed through is a parameter.

■ 47.14.4 PLAIN – what is really happening inside

1. Notice the two places where the vocabulary size appears.
2. Once at the entrance, as a table you index into. Once at the exit, as a table you multiply against.
3. Those two are the same shape and are sometimes literally the same numbers.
4. Notice that the shape [7, 4096] is stable through the whole stack.
5. That stable shape is called the residual stream. Every layer reads from it and writes back into it by adding.
6. Notice that only the last row is used to predict the next token, during generation. The other rows were computed anyway, and their keys and values are cached so they do not need recomputing next time.
7. Notice what the second pass costs. It processes one new token, not eight. All previous work is in the cache.
8. That is why the first token of a reply is slower than the rest: the first one pays for the whole prompt, and each later one pays for a single token.

■ 47.14.5 TECHNICAL – the engineer's version

1. The shapes with a batch dimension, which is how it really runs:

Stage	Tensor shape	dtype
Token ids	[B, S]	int64
After embedding	[B, S, 4096]	bf16

Stage	Tensor shape	dtype
FFN intermediate	[B, S, 14336]	bf16
Logits	[B, S, 128256]	fp32

- Logits are usually computed in fp32 even in a bf16 model, because softmax over 128,256 entries is numerically sensitive.
- During prefill, S is the full prompt length and all positions are computed. During decode, S is 1 and only the new position is computed, with the cache supplying the rest.
- Per-token generation cost in floating point operations is approximately $2 \times N$, where N is the parameter count, ignoring attention over the cache. For an 8B model that is about 16 billion operations per token.
- Prompt processing cost is approximately $2 \times N \times S$, so a 6,150-token prompt on an 8B model is about 98 trillion operations, which is why prefill is compute-bound and decode is bandwidth-bound.
- Memory traffic per decoded token at batch 1 is roughly the entire weight file, because every weight is read once. At 4-bit that is about 4.5 GiB per token for an 8B model, so a machine with 100 GB/s of memory bandwidth caps out near 21 tokens per second regardless of how fast its arithmetic is.
- That single fact explains most local inference performance questions, and it is why quantization speeds up generation as well as shrinking it.
- Inspecting the journey in practice: `tokenizer(text, return_tensors="pt")` gives stage 1; `model.get_input_embeddings()(ids)` gives stage 2; `model(ids, output_hidden_states=True).hidden_states` gives every stage 3 boundary as a tuple of 33 tensors for a 32-layer model.

■ 47.14.6 WORDS - remember these

- Residual stream — the stable block of numbers every layer reads and writes — the [B, S, d] tensor threaded through the network by residual connections.
- Prefill — processing the prompt — one parallel forward pass over all input positions, filling the key-value cache.
- Decode — producing one token — a forward pass with sequence length 1 reusing the cache.
- Logit — a raw score for one possible next token — one entry of the [V] output vector before softmax.
- Softmax — turning scores into probabilities — exponentiate and divide by the sum, giving a distribution over the vocabulary.
- Time to first token — how long before the reply starts — the latency of prefill, growing with prompt length.
- Memory bandwidth bound — limited by moving numbers, not by computing — the regime single-stream decoding runs in, where tokens per second is set by bytes read per token.

47.98 Common wrong ideas

- Wrong: more parameters means a smarter model. Right: parameter count sets a ceiling and predicts memory and speed very well, but Chinchilla at 70B beat Megatron-Turing NLG at 530B, and Mistral 7B beat Llama 2 13B. Data quantity, data quality, training compute and post-training all matter as much or more.
- Wrong: a token is a word. Right: a token is a subword piece. English averages about 1.1 to 1.3 tokens per word, JSON averages over 3, and a Hindi sentence can cost 24 tokens where the English equivalent costs 5.

3. Wrong: the context window is the model's memory, and a model that accepts 1,000,000 tokens uses all of them equally. Right: it is the input size limit for one request, nothing persists between requests, any apparent memory is your application resending the history, and accuracy dips for content in the middle, with RULER finding only about half of models claiming 32,000 tokens performed well at that length.
4. Wrong: quantization makes a model dumber in proportion to the bits removed. Right: the curve is very flat then steep. Going 16-bit to 8-bit cost 0.01 perplexity on a measured Llama-3.1-8B test; 16-bit to Q4_K_M cost 0.24; going to Q3_K_S cost 1.64. The first two thirds of the saving is nearly free.
5. Wrong: embeddings understand meaning. Right: they encode statistical co-occurrence as position in a space. That is enough for similarity to be useful and is not understanding. Two contradictory documents about the same fact sit close together, because they are about the same thing.
6. Wrong: hyperparameters are just small parameters. Right: hyperparameters are chosen by a human before training and are never learned. Parameters are learned by gradient descent and are never chosen.
7. Wrong: a 7B model needs 14 GB to train. Right: 14 GB is inference at 16-bit. Full training with Adam needs about 18 bytes per parameter for states alone, which is 117 GiB for 7B, before activations.
8. Wrong: king minus man plus woman equals queen proves embeddings capture relationships cleanly. Right: it is a real but weak effect, and the standard evaluation forbids returning the input words. With that exclusion removed, 3CosAdd accuracy fell from 71 per cent to 21 per cent.
9. Wrong: the model cannot count letters because it is stupid. Right: it receives "strawberry" as three integer ids and never sees individual letters. It answers from indirect knowledge, which is why it succeeds sometimes and fails unpredictably.
10. Wrong: input and output tokens cost the same. Right: output is typically priced four to six times higher, because generating is sequential and bandwidth-bound while reading the prompt is parallel and compute-bound.

47.99 Chapter summary in 20 lines

1. A parameter is one learned number sitting in one position of one matrix, set during training and frozen thereafter; "weight" and "parameter" are used interchangeably, with biases being additive parameters rather than weights.
2. A model's parameter count is the sum of the sizes of all its matrices, and it is computable by hand from five published shape numbers.
3. Worked exactly, Llama 3.1 8B holds 8,030,261,248 parameters: 32 layers of 218,112,000 plus two 525,336,576 vocabulary tables plus a final norm.
4. The billions live in the feed-forward blocks: 70 per cent for 8B, 80 per cent for 70B, 81 per cent for 405B, with attention near 17 per cent throughout.
5. Hyperparameters are pre-training human choices, activations are temporary numbers created while running, context is the input text, tokens are the pieces it is chopped into. Only parameters are in the model file.
6. Memory equals parameter count times bytes per parameter: 7B is 26.1 GiB at fp32, 13.0 at fp16, 6.5 at int8 and 3.3 at int4.
7. Inference needs more than the weights: a key-value cache of 320 KiB per token for a 70B model, plus activations and framework overhead.
8. Training needs about 18 bytes per parameter for weights, master copy, gradients and Adam's two moments, so a 7B model needs about 117 GiB of state before activations are counted.

9. Quantization stores each weight in fewer bits using a shared scale and optional zero point, per tensor, per channel or per group of 32 to 256.
10. GPTQ, AWQ, NF4 and the GGUF k-quants are the common formats; Q4_K is exactly 4.5 bits per weight, and Q4_K_M averages about 4.8 because sensitive tensors are kept at Q6_K.
11. A 70B model at Q4_K_M needs about 39.7 GiB of weights and fits a 64 GiB machine at a modest context; at fp16 it needs 131.4 GiB and does not.
12. Capability does not scale linearly with parameters: Chinchilla in 2022 showed models were undertrained, recommended about 20 tokens per parameter, and a 70B model beat a 530B one at equal compute.
13. Text is tokenized into subwords because whole words give an unbounded vocabulary and characters give sequences that are far too long.
14. Byte-pair encoding repeatedly merges the most frequent adjacent pair; on a four-word corpus, ten merges produce a 21-token vocabulary in which “newest” is a single token and “est_” emerges as a suffix without anyone naming it.
15. WordPiece merges by likelihood gain, Unigram prunes down from a large candidate set, and SentencePiece is the framework that makes both work without language-specific pre-tokenization.
16. English runs about 4 characters or 1.1 to 1.3 tokens per word; JSON is far worse; and a Hindi sentence costing 5 tokens in English cost 24 on the GPT-4-era tokenizer and 6 on the later one, which is real, measurable cost and context inequality.
17. Models cannot reliably count letters, reverse words or do long arithmetic because they never see letters or aligned digits, only token ids.
18. An embedding turns a token id into a row of a $[V, d]$ table; the numbers mean nothing individually and everything collectively, and 4,096 dimensions cannot be visualized, with distance concentration and near-orthogonality breaking most 2D intuitions.
19. Similarity is measured by cosine of the angle; the king minus man plus woman result is real but much weaker than told, since removing the input-word exclusion dropped 3CosAdd accuracy from 71 to 21 per cent.
20. The context window is limited because attention cost grows with the square of length; exceeding it truncates or errors; and accepting a long context is not the same as using it well, as the lost-in-the-middle and RULER results show.

The Transformer

48.0 What this chapter gives you

1. You will be able to say what came before the transformer, why it worked, and the exact reason the field abandoned it in about eighteen months.
2. You will be able to explain attention in ordinary words to somebody who has never seen a formula, using a sentence whose meaning flips on one adjective.
3. You will be able to write the scaled dot-product attention formula from memory and say what every symbol in it does.
4. You will be able to compute a full attention pass by hand on a four-token sentence and get numbers that match a real implementation.
5. You will be able to explain the causal mask, draw it as a matrix, and say what changes when a model does not use one.
6. You will be able to explain multi-head attention, work out the tensor shapes for a real model configuration, and say honestly what heads do and do not do.
7. You will be able to explain why attention has no sense of order at all, and describe sinusoidal, learned, ALiBi and rotary position encoding.
8. You will be able to draw a whole transformer block from memory, with residual connections and normalization in the right places, and say why.
9. You will be able to trace one prompt through a real model as a series of tensor shapes, from token ids to a probability over the vocabulary.
10. You will be able to explain the quadratic cost of attention, compute a real key-value cache size, and name the fixes that are in production today.

48.1 What came before, and why it was not enough

■ 48.1.1 PLAIN – in simple words

1. Before 2017, the standard way to handle a sentence was to read it one word at a time, left to right, the way a person reads aloud.
2. The machine that did this is called a **recurrent neural network**, usually shortened to RNN. Recurrent just means it feeds its own output back into itself.
3. It kept a single running summary of everything it had read so far. That summary is called the **hidden state**. It is a list of numbers.
4. Read word one, update the summary. Read word two, update the summary again. Keep going to the end.
5. That is the whole design. One summary, updated once per word, in order.
6. It worked. It was the best thing anybody had for sequences for about twenty-five years.

7. It had two problems, and the second one killed it.
8. Problem one: information from early words faded. By word two hundred, word three had almost no influence left on the summary.
9. Problem two, and this is the one that mattered: you cannot do the work for word ten until you have finished the work for word nine.
10. That is a rule you cannot break, because word ten literally needs the summary that word nine produced.
11. A modern graphics chip has tens of thousands of small calculators that all want work at the same time.
12. A design that insists on doing one word, then the next, then the next, cannot feed those calculators. They sit idle.
13. So training was slow, and it stayed slow no matter how much hardware you bought.
14. The transformer's central idea is to throw away the left-to-right rule and let every word look at every other word at once.
15. Once you do that, all the words can be processed in parallel, and the machine finally has enough work to do.

■ 48.1.2 PLAIN – a picture in your head

1. Imagine you are told a long story down a telephone line, one word at a time, and you are not allowed to write anything down.
2. You are allowed to keep exactly one small notepad in your head with, say, twenty facts on it. That is the hidden state.
3. Every new word arrives and you must decide what to erase to make room.
4. At word ten you still remember the beginning clearly.
5. At word two hundred the beginning has been overwritten many times. It is not gone in principle, but almost nothing of it survives.
6. Now imagine the person telling the story is speaking as fast as you can process. You cannot skip ahead. You cannot ask a friend to handle the second half while you do the first.
7. The story is strictly serial. That is the cost.
8. The transformer is the opposite arrangement. The whole story is printed on a sheet of paper in front of you, all at once, and you may look at any word whenever you want.

Where this comparison breaks: a real hidden state is not a list of twenty readable facts. It is a vector of a few hundred to a few thousand numbers with no individually meaningful entries. And nothing “decides what to erase” in a deliberate way. A learned matrix multiplication and a gate value between 0 and 1 produce that effect, and the effect looks like forgetting from outside.

■ 48.1.3 PLAIN – a worked example

1. Here is why the fading happens, with real arithmetic.
2. In training, the correction signal for word 3 has to travel backwards from word 200 through 197 update steps.
3. At each step it gets multiplied by a number. Call that number the shrink factor. If it is less than 1, the signal shrinks.
4. Here is what repeated multiplication does:

Shrink factor	After 10 steps	After 100 steps
0.5	0.00098	7.9e-31

Shrink factor	After 10 steps	After 100 steps
0.8	0.107	2.0e-10
0.9	0.349	2.7e-05
0.99	0.904	0.366

- At a shrink factor of 0.9, after 100 steps the signal is 0.0000266 of its original size. It has effectively vanished.
- That is the **vanishing gradient problem**, and over a sequence it is vanishing over time steps rather than over layers.
- Now the opposite. If the factor is 1.1 instead of 0.9, after 100 steps the signal is 13,780 times bigger. Training explodes and produces nonsense.
- So you need the factor to sit very near 1.0 for hundreds of steps in a row, which is a very hard thing to arrange by accident.
- Now the parallel problem, also with real arithmetic.
- Take a sequence of 1,000 tokens.
- An RNN needs 1,000 steps that must happen one after another. Nothing about the sequence can be done out of order.
- A transformer needs 1 step for the whole sequence, because the operation is one big matrix multiplication over all 1,000 positions at once.
- That is not a small speed-up. It is the difference between a chip running at a few per cent of its capacity and a chip running near its limit.

■ 48.1.4 PLAIN - what is really happening inside

- The RNN update is one line: new summary equals a function of the old summary and the new word.
- Written plainly: $h_t = \tanh(W_h h_{t-1} + W_x x_t + b)$.
- h_t is the summary after word t . x_t is the word. W_h and W_x are learned matrices. $\tanh$ squashes everything into the range -1 to +1.
- Notice that h_{t-1} appears on the right-hand side. That is the whole dependency chain, and it is unbreakable.
- To learn, you unroll this into a chain 200 links long and push the error backwards along it, which is the repeated multiplication just shown.
- The **LSTM**, invented by Sepp Hochreiter and Jürgen Schmidhuber in 1997, was the fix for the fading.
- It added a second track, called the cell state, that flows forward with addition rather than repeated multiplication.
- Addition does not shrink a signal, so the correction can travel a long way without dying.
- It also added **gates**: small learned circuits that output a number between 0 and 1 for each position, deciding how much to keep, how much to let in and how much to output.
- The **GRU**, from Kyunghyun Cho and colleagues in 2014, is a simpler version with two gates instead of three, and usually performs about the same.
- These fixes worked well enough for real products. Google Translate switched to an eight-layer LSTM system in September 2016.
- But gates fix the fading. They do not fix the serial rule. Step t still needs step $t-1$. That part is structural.
- Meanwhile a second problem appeared in translation. The standard design was an **encoder-decoder**: one RNN reads the whole source sentence into a single vector, and a second RNN writes

the translation out of it.

14. Everything in a fifty-word sentence had to fit through one fixed-size vector. That vector is a bottleneck, and it is the same size whether the sentence has five words or fifty.
15. In September 2014, Dzmitry Bahdanau, Kyunghyun Cho and Yoshua Bengio published a fix. Instead of one vector, keep all the encoder's per-word states, and let the decoder look back and pick out the relevant ones.
16. That "look back and weight what matters" step is attention. It was invented as an accessory bolted onto an RNN.
17. The 2017 transformer paper's move was to delete the RNN and keep only the accessory.

■ 48.1.5 TECHNICAL – the engineer's version

1. The vanishing and exploding gradient problem in recurrent networks was identified by Sepp Hochreiter in his 1991 diploma thesis at the Technical University of Munich, and analysed formally by Yoshua Bengio, Patrice Simard and Paolo Frasconi in 1994.
2. The mechanism is the chain rule applied through time. The gradient of the loss at step T with respect to the state at step t contains the product of Jacobians from t to T .
3. If the largest singular value of the recurrent Jacobian is consistently below 1, that product decays geometrically. Above 1, it grows geometrically.
4. With tanh activation the derivative is at most 1.0 and typically well below it, so decay is the common case. With sigmoid gates the derivative peaks at 0.25.
5. Exploding gradients are cheaply fixed by gradient clipping, which rescales the gradient vector when its norm passes a threshold. Vanishing gradients are not fixable that way, because you cannot amplify information that is gone.
6. LSTM, from Hochreiter and Schmidhuber, Neural Computation volume 9 issue 8, 1997, introduced the constant error carousel: an additive cell state path whose local derivative is close to 1.
7. The forget gate was not in the original LSTM. Felix Gers, Jürgen Schmidhuber and Fred Cummins added it in 1999 and 2000, and the version with the forget gate is what everybody now means by "LSTM".
8. Parameter counts per unit differ: a vanilla RNN cell has one weight matrix pair, an LSTM has four, and a GRU has three.

Model	Year	Gates	Sequential steps
Elman RNN	1990	0	n
LSTM	1997	3	n
GRU	2014	2	n
Transformer	2017	none	1

9. Sequence-to-sequence learning with a fixed context vector was published by Ilya Sutskever, Oriol Vinyals and Quoc Le in September 2014, using a 4-layer LSTM with 1,000 units per layer and a 1,000-dimensional context vector.
10. Additive attention, also called Bahdanau attention, was published the same month by Bahdanau, Cho and Bengio in the paper "Neural Machine Translation by Jointly Learning to Align and Translate". It scores each encoder state with a small feed-forward network and softmaxes the scores.
11. Multiplicative attention, from Minh-Thang Luong, Hieu Pham and Christopher Manning in 2015, replaced that small network with a dot product. That is the direct ancestor of the 2017 formula.

12. Google Neural Machine Translation, deployed in September 2016, used 8 encoder and 8 decoder LSTM layers with attention, residual connections and model parallelism across 8 GPUs. It cut translation errors substantially and was still fundamentally serial.
13. The training-time argument is about arithmetic intensity. An RNN step at batch size B computes a matrix times a matrix of shape $[B, d]$ by $[d, d]$. With $B = 32$ and $d = 1024$ that is 67 MFLOP, then a synchronization, then the next step.
14. A transformer layer at sequence length 1,000 computes $[1000, d]$ by $[d, d]$, which at $d = 4096$ is 33.6 GFLOP in a single call, with no dependency inside the call.
15. Modern accelerators need large matrix-matrix operations to reach peak. This is covered in Chapter 22, which explains why a GPU is a wide parallel machine rather than a fast serial one. Long thin operations leave most of the chip idle.
16. This is established fact and was stated openly in the abstract of the 2017 paper: the models are “more parallelizable and requiring significantly less time to train”.

■ 48.1.6 WORDS - remember these

1. Recurrent neural network — a network that reads one item at a time and keeps a running summary — a network with a cyclic dependency $h_t = f(h_{t-1}, x_t)$, unrolled over time for training.
2. Hidden state — the running summary — the vector carried from one time step to the next, of size equal to the layer width.
3. Vanishing gradient — the correction signal dying out over distance — the geometric decay of a product of Jacobians whose singular values are below 1.
4. LSTM — a recurrent cell with gates that remembers longer — long short-term memory, with input, forget and output gates and an additive cell state.
5. GRU — a simpler gated cell — gated recurrent unit, with update and reset gates and no separate cell state.
6. Encoder-decoder — one network reads, another writes — a sequence-to-sequence architecture with a context representation passed between them.
7. Bottleneck vector — squeezing a whole sentence into one fixed list of numbers — the fixed-dimension context vector in pre-attention seq2seq.
8. Attention — looking back and weighting what matters — a learned weighted average over a set of value vectors, with weights from a scoring function.

48.2 Attention in plain language, before any mathematics

■ 48.2.1 PLAIN - in simple words

1. Read this sentence carefully: “the trophy did not fit in the suitcase because it was too big”.
2. What does “it” mean here? The trophy.
3. You did not need a rule book. You worked it out.
4. Now read the same sentence with one word changed: “the trophy did not fit in the suitcase because it was too small”.
5. What does “it” mean now? The suitcase.
6. The sentence is identical except for the last word, and the meaning of “it” flipped completely.
7. Stop and notice what you just did. To understand the word “it”, you looked back at other words in the sentence.
8. You did not look back at all of them equally. “the”, “did” and “in” contributed almost nothing.
9. You looked hard at “trophy”, “suitcase”, “fit” and the final adjective.
10. Then you combined what you found and produced a meaning for “it”.

11. That is attention. Look back, weight some things more than others, combine.
12. The model does exactly this, for every word, at every layer, with the weights worked out by learned matrices rather than by a person.
13. There is one important extra bit. The model does this for every word at once, not just for the confusing ones.
14. So while it is deciding what “it” points to, it is simultaneously deciding what “big” applies to and what “fit” takes as its subject.
15. And it does not know in advance which words are the confusing ones. Every position gets the same treatment.

■ 48.2.2 PLAIN – a picture in your head

1. Picture a meeting where a decision has to be made, and eight people are in the room.
2. You are the chairperson. You ask a question.
3. Everybody in the room has something to say. Some of it is highly relevant. Most of it is not.
4. You do not take a plain average of all eight opinions, because that would drown the useful answer in noise.
5. Instead you listen to each person, decide how much their answer bears on your question, and give each one a share of your final decision.
6. Person 3 gets 60 per cent of your attention because they clearly know. Person 7 gets 25 per cent. The other six split the remaining 15 per cent.
7. Your conclusion is a blend, weighted by relevance.
8. That is one attention operation. Your question is the query. Each person’s relevance is a weight. Each person’s opinion is a value.
9. Now the part that makes it a transformer: every person in the room is doing this at the same time, each with their own question, including you.

Where this comparison breaks: in a real meeting, relevance is judged by understanding. In attention, relevance is a dot product between two learned vectors, which is a geometric measure of alignment. It correlates with what we would call relevance because training pushed it that way, and it has no independent notion of what the question is about. Also, the weights always add up to exactly 1, so a position cannot decide that nothing in the sentence is relevant. It must spread its 1.0 somewhere, and it often dumps it on a token that carries no meaning, which is a real and measured effect.

■ 48.2.3 PLAIN – a worked example

1. Take the sentence with “big”, and consider the position holding “it”.
2. Here is roughly how a trained model distributes attention from “it”, based on what published attention maps for coreference look like. These are illustrative figures to show the shape, not a measurement of one named model.

Sentence: the trophy did not fit in the suitcase
because it was too big

Attention from the position holding "it":

trophy	#####	0.41
suitcase	#####	0.18
big	#####	0.15
fit	#####	0.09
it	#####	0.08
the	##	0.03
other	###	0.06

```

-----
1.00

```

3. Now swap “big” for “small”. The same position, in the same model, shifts:

```

Sentence: the trophy did not fit in the suitcase
          because it was too small

```

```

suitcase ##### 0.39
trophy   ##### 0.17
small    ##### 0.16
fit      ##### 0.10
it       ##### 0.08
the      ##    0.03
other    #### 0.07
-----
1.00

```

- One word changed at the end of the sentence, and the top weight moved from “trophy” to “suitcase”.
- This is the point. The weights are not fixed by the identity of the word “it”. They are computed fresh from the actual contents of this sentence.
- That is why the same word gets a different representation in different sentences, which is the thing older methods could not do.
- Chapter 47 covered embeddings, which are the fixed starting vectors for tokens. The embedding for “it” is one single vector, the same every time.
- Attention is what turns that one fixed vector into a different vector in every different context. That is the entire job.
- This sentence pair is not invented for this book. It is a **Winograd schema**, a test format proposed by Hector Levesque, Ernest Davis and Leora Morgenstern in 2011, named after Terry Winograd, who used an example of this shape in 1972.
- The point of the format is that no amount of word-frequency statistics solves it. You have to model the situation being described.

■ 48.2.4 PLAIN – what is really happening inside

- Every token position holds a vector of numbers. Call it the position’s current understanding of itself.
- Attention runs in three moves, and every position does all three.
- Move one: each position emits a **query**, meaning “here is what I am looking for”. It is a vector, computed from the position’s own current vector.
- Move two: each position also emits a **key**, meaning “here is what I am, if anybody is looking”. Also a vector, also computed from the same input.
- Move three: each position emits a **value**, meaning “here is what I will contribute if you pick me”.
- Now the matching. Position 10’s query is compared against every key in the sentence, including its own.
- The comparison is a dot product: multiply the two vectors element by element and add up. A big result means the two vectors point in a similar direction.
- That gives one raw score per position. For a 12-token sentence, position 10 gets 12 scores.
- Those 12 scores go through softmax, which turns any list of numbers into positive numbers that add to exactly 1.
- Now they are weights. 0.41 on “trophy”, 0.18 on “suitcase”, and so on.

11. Finally, take every position's value vector, multiply it by that position's weight, and add them all up.
12. The result is position 10's new vector. It now contains a blend of the whole sentence, weighted by what position 10 was looking for.
13. That new vector replaces the old one, and the next layer does the whole thing again with different learned matrices.
14. Repeat 32 times for a typical 8-billion-parameter model, and information from anywhere can reach anywhere, by many different routes.

■ 48.2.5 TECHNICAL - the engineer's version

1. The operation just described is **self-attention**: queries, keys and values are all derived from the same input sequence.
2. **Cross-attention** is the same operation where queries come from one sequence and keys and values from another. It is what connects the decoder to the encoder in a translation model.
3. Self-attention is a set operation, not a sequence operation. It is permutation-equivariant, which is proved numerically in section 48.7.
4. The pairwise score matrix has shape $[n, n]$ for a sequence of length n . Every position produces one row.
5. The distance between two tokens does not appear anywhere in the computation. Position 1 and position 4,000 are exactly as easy to connect as position 1 and position 2. That is the structural difference from an RNN, where the path length between positions i and j is $|i - j|$ update steps.
6. Attention weight maps are widely published and easy to produce with the `output_attentions=True` flag in Hugging Face transformers, or with the BertViz tool from Jesse Vig, 2019.
7. Two honest warnings about reading those maps.
8. **The honest version**: an attention weight is not an explanation. Sarthak Jain and Byron Wallace published "Attention is not Explanation" in 2019, showing that alternative attention distributions can produce identical predictions. Sarah Wiegrefe and Yuval Pinter replied with "Attention is not not Explanation" the same year, arguing the test was too strict. The dispute is not settled. Attention weights show where information flowed, not why.
9. Second warning: a large fraction of attention mass in trained models lands on the first token or on punctuation. This is called an **attention sink**, and was analysed by Guangxuan Xiao and colleagues in 2023 in the StreamingLLM work. The softmax must sum to 1, so a head with nothing to say has to put its weight somewhere, and it learns to park it on a fixed harmless position.
10. Established fact: attention computes content-dependent weighted averages, and this is measurable. Active research: what individual heads compute and whether their weights can be read as explanations. Marketing claim: any statement that the model "focuses on" or "pays attention to" something in the human sense.

■ 48.2.6 WORDS - remember these

1. Self-attention — every word looking at every word in the same sentence — attention where Q, K and V all derive from one input sequence.
2. Cross-attention — one sequence looking at a different sequence — attention where Q comes from the target and K, V from the source.
3. Query — what a position is looking for — a learned linear projection of the position's hidden state, of dimension d_k .
4. Key — what a position advertises about itself — a learned projection compared against queries by dot product, of dimension d_k .

5. Value — what a position contributes if selected — a learned projection that is averaged with the attention weights, of dimension d_v .
6. Softmax — turning any scores into shares that add to 1 — $\exp(x_i)$ divided by the sum of $\exp$ over all j , applied along the key axis.
7. Attention weight — how much one word listened to another — one entry of the row-stochastic $[n, n]$ matrix produced by softmax over scaled scores.
8. Attention sink — a position that soaks up leftover weight — a token, typically the first, that receives large attention mass with no semantic role, arising from the sum-to-one constraint.
9. Winograd schema — a sentence pair whose meaning flips on one word — a coreference test designed to be unsolvable by surface statistics.

48.3 Query, key and value, taught slowly

■ 48.3.1 PLAIN - in simple words

1. Three words do all the work in attention: query, key and value.
2. They sound abstract. They are not. They are three different views of the same token, made by three different learned recipes.
3. The **query** is the question this position is asking. “I am a pronoun. I need to know what noun I stand for.”
4. The **key** is the label this position wears. “I am a singular concrete noun, and I am the subject of the sentence.”
5. The **value** is the content this position offers up if selected. “Here is my actual meaning, ready to be copied into whoever picks me.”
6. Every single position produces all three, every time.
7. So a position is simultaneously asking a question, advertising an answer, and holding content to hand over.
8. The matching happens between queries and keys only. Values take no part in deciding who wins.
9. Once the weights are decided, the values are what actually get blended and passed on.
10. That separation is the useful part of the design. What makes something findable is allowed to be different from what it contains.
11. And the crucial fact people miss: all three come from the same starting vector. There is no separate store of keys and values somewhere.
12. Take one token’s vector, multiply it by matrix number 1 to get the query, matrix number 2 to get the key, matrix number 3 to get the value.
13. Those three matrices are learned during training and frozen afterwards. They are ordinary parameters, in the sense of Chapter 47.

■ 48.3.2 PLAIN - a picture in your head

1. Picture a library, but a strange one where you may only ask one question and must get one answer back immediately.
2. You walk in with a question written on a card. That is your **query**.
3. Every book in the library has a small index card clipped to its spine. The card says what the book is about, in a compressed form. That is the **key**.
4. The book’s actual pages are the **value**.
5. You do not read any books. You hold your question card next to every index card in turn and score how well they line up.
6. Book 3’s card scores highly. Book 7’s card scores moderately. Most cards score near zero.

7. Then you do something no real library allows. You do not pick one book. You take a weighted blend of every book's contents: 60 per cent of book 3, 25 per cent of book 7, and small slivers of the rest.
8. That blend is your answer.
9. The index card is deliberately not the book. A card can say "this is a cookbook about bread" while the book contains actual recipes.
10. That is the whole reason keys and values are separate. Findability and content are different jobs.

Where this comparison breaks: in a real library the index card was written by a librarian who read the book. Here both the card and the book come from the same raw vector through two different learned matrices, so they are not independent. Also, a library has a fixed catalogue. Here the keys are recomputed from scratch for every input, so the same word gets a different key in a different sentence. And a real search returns one book. Attention always returns a blend and can never return nothing, because the weights are forced to sum to 1.

■ 48.3.3 PLAIN – a worked example

1. Now the projection, with numbers small enough to check on paper.
2. We will use a four-token sentence: "the cat was hungry".
3. Each token arrives as a vector of 4 numbers. In a real model this would be 4,096 numbers, from the embedding table of Chapter 47. Here it is 4.
4. Stack the four token vectors as rows. That is the input matrix X, shape [4 tokens, 4 dimensions]:

X (4 tokens x 4 dimensions)

	d0	d1	d2	d3
the	1	0	1	0
cat	0	1	0	1
was	1	1	0	0
hungry	0	1	1	0

5. **The honest version:** real embedding values are floating-point numbers like -0.0113 or 0.0392, never neat integers. Integers are used here only so you can verify every multiplication by hand.
6. Now the three learned matrices. Each is shape [4, 3], because we are choosing to project from 4 dimensions down to 3.

W_Q (4x3)	W_K (4x3)	W_V (4x3)
1 0 0	1 0 0	2 0 1
1 1 2	1 0 2	0 2 0
0 1 0	1 1 1	1 1 2
1 1 0	0 1 2	0 1 1

7. To get the query for "hungry", take the row for "hungry", which is [0, 1, 1, 0], and multiply it by W_Q.
8. Doing it column by column:
9. Column 0: $(0 \times 1) + (1 \times 1) + (1 \times 0) + (0 \times 1) = 1$.
10. Column 1: $(0 \times 0) + (1 \times 1) + (1 \times 1) + (0 \times 1) = 2$.
11. Column 2: $(0 \times 0) + (1 \times 2) + (1 \times 0) + (0 \times 0) = 2$.
12. So the query for "hungry" is [1, 2, 2].
13. Do the same for every token and every matrix. The three results:

Q = X W_Q	K = X W_K	V = X W_V
the 1 1 0	the 2 1 1	the 3 1 3
cat 2 2 2	cat 1 1 4	cat 0 3 1

was	2	1	2	was	2	0	2	was	2	2	1
hungry	1	2	2	hungry	2	1	3	hungry	1	3	2

14. Check one more by hand. The key for “cat” is row $[0, 1, 0, 1]$ times W_K .
15. Column 0: $0 + 1 + 0 + 0 = 1$. Column 1: $0 + 0 + 0 + 1 = 1$. Column 2: $0 + 2 + 0 + 2 = 4$. So $[1, 1, 4]$. That matches the table.
16. Notice the shapes. X is $[4, 4]$. Each W is $[4, 3]$. Each of Q, K, V is $[4, 3]$.
17. The number of tokens never changes. Only the width changes.

■ 48.3.4 PLAIN - what is really happening inside

1. There is no lookup, no dictionary, no search index. There are three matrix multiplications.
2. A matrix multiplication of a $[4, 4]$ by a $[4, 3]$ is just 12 dot products, one per output cell, which is exactly what was done above by hand.
3. The words “query”, “key” and “value” are borrowed from database retrieval. They are a naming choice, not a mechanism.
4. Nothing enforces that W_Q learns “questions” and W_K learns “labels”. Those are the roles they end up playing because of where they sit in the formula.
5. W_Q and W_K only ever appear together, inside a dot product. Their product $Q K$ -transpose is what the model actually uses.
6. That means the pair behaves as a single learned bilinear form. You could fold them into one matrix and get identical scores.
7. They are kept separate because it costs far fewer parameters. Two matrices of $[d, d_k]$ cost $2 d d_k$ parameters, while one full $[d, d]$ matrix costs d squared. With $d = 4096$ and $d_k = 128$ that is 1,048,576 against 16,777,216.
8. W_V is genuinely separate, because its output does not go into any score. It goes into the answer.
9. In code, all three projections for a whole batch are usually done as one matrix multiplication with the three weight matrices concatenated, then split afterwards. That is an implementation detail for speed, not part of the idea.
10. On the hardware side, these are exactly the dense matrix multiplications Chapter 22 described as the operation a GPU is built to do. The whole sequence goes through in one call.

■ 48.3.5 TECHNICAL - the engineer’s version

1. The projections are three linear maps with no bias in most modern models: $Q = X W_Q$, $K = X W_K$, $V = X W_V$.
2. Shapes for one attention layer, with input X of shape $[B, n, d_{\text{model}}]$:

Tensor	Shape	Notes
X	$[B, n, d_{\text{model}}]$	layer input
W_Q	$[d_{\text{model}}, h \times d_k]$	learned
W_K	$[d_{\text{model}}, h_{\text{kv}} \times d_k]$	learned
W_V	$[d_{\text{model}}, h_{\text{kv}} \times d_v]$	learned

3. In the 2017 base model, $d_{\text{model}} = 512$, $h = 8$, $d_k = d_v = 64$, so each of the four projection matrices is 512 by 512 and holds 262,144 parameters.
4. In Llama 3.1 8B, $d_{\text{model}} = 4096$, 32 query heads, 8 key-value heads, head dimension 128. So q_{proj} is $[4096, 4096]$, while k_{proj} and v_{proj} are $[1024, 4096]$. That asymmetry is grouped-query attention, covered in 48.13.

5. Bias terms: GPT-2 uses biases on these projections. The Llama family, Mistral and Qwen do not. This is an implementation detail with negligible effect on quality and a small effect on parameter count.
6. Real parameter names in a checkpoint, which you can list without loading the model using the safetensors header:

```
model.layers.0.self_attn.q_proj.weight [4096, 4096]
model.layers.0.self_attn.k_proj.weight [1024, 4096]
model.layers.0.self_attn.v_proj.weight [1024, 4096]
model.layers.0.self_attn.o_proj.weight [4096, 4096]
```

7. Note the convention: PyTorch stores a linear layer's weight as [out_features, in_features] and computes x times W -transpose. So the printed shape is the transpose of the mathematical W in the formula. This trips up almost everybody once.
8. The low-rank factorization argument is exact. Scores depend only on the product $W_Q W_K$ -transpose, which has rank at most d_k . Choosing $d_k = 128$ with $d_{\text{model}} = 4096$ imposes a rank-128 constraint on the score matrix, and that constraint is the parameter saving.
9. Whether that rank limit hurts has been studied directly. Srinadh Bhojanapalli and colleagues at Google Research published "Low-Rank Bottleneck in Multi-head Attention Models" in 2020, showing that tying d_k to d_{model} divided by the number of heads does constrain what a head can express, and that decoupling the two can help.

■ 48.3.6 WORDS - remember these

1. Projection — turning a vector into a different-shaped vector — multiplication by a learned matrix, usually without a bias term.
2. Linear layer — a matrix multiply, optionally plus a bias — `nn.Linear` in PyTorch, storing weight as [out_features, in_features].
3. d_{model} — the width of the main pipe through the model — the residual stream dimension, 512 in the 2017 base model, 4096 in Llama 3.1 8B.
4. d_k — the width of one head's queries and keys — the per-head key dimension, 64 in the 2017 paper, 128 in most current models.
5. Bilinear form — one matrix sandwiched between two vectors — the effective scoring matrix $W_Q W_K$ -transpose, of rank at most d_k .
6. Low-rank factorization — writing a big matrix as two thin ones — replacing a $[d, d]$ matrix with $[d, r]$ times $[r, d]$, costing $2dr$ instead of d squared.

48.4 Scaled dot-product attention, with the actual mathematics

■ 48.4.1 PLAIN - in simple words

1. Here is the whole formula. It is one line, and it is the most quoted line in modern machine learning.

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{Q K^T}{\sqrt{d_k}}\right) V$$
2. Read it right to left in four steps.
3. Step one: $Q K^T$. Compare every query with every key by dot product. Output is a square grid of scores, one row per token, one column per token.
4. Step two: divide by the square root of d_k , the width of a key. This is a fixed number, not learned. It stops the scores from getting too large.
5. Step three: softmax each row. Each row of scores becomes a row of weights that are all positive and add up to exactly 1.

- Step four: multiply by V. Each row of the output is a weighted average of all the value vectors, using that row's weights.
- That is it. Four steps, three of which are matrix multiplications and one of which is a division.
- The result has the same number of rows as the input. One output vector per token, exactly as many as went in.
- Everything else in this chapter is either a variation on this line, a way to make it faster, or a way to fix something it cannot do on its own.

■ 48.4.2 PLAIN – a picture in your head

- Picture a school report card, but sideways.
- Down the left are the students asking questions. Across the top are the students offering answers. Same list of students on both sides.
- In each cell you write a number: how useful is that answer for that question. This grid is Q K-transpose.
- Now the trick. Nobody trusts raw scores, so each row is converted into percentages that add to 100. That is softmax.
- Row 4 might read: 3 per cent, 60 per cent, 3 per cent, 34 per cent. That is student 4's opinion of who to listen to.
- Finally each student writes down their answer on a card. Student 4 makes a mixture: 3 per cent of card 1, 60 per cent of card 2, and so on.
- What student 4 walks away with is a blend of the whole class, weighted by their own judgement of relevance.
- And every student does this at the same time, so the entire grid is filled in one operation.

Where this comparison breaks: the “percentages” from softmax are never exactly zero. Every student always gets a nonzero share, even an irrelevant one, because the exponential function never reaches zero. And “how useful is that answer” is not a judgement. It is the cosine-like alignment of two vectors, scaled by their lengths. Two vectors can align strongly for reasons that have nothing to do with meaning.

■ 48.4.3 PLAIN – a worked example

- This is the full computation, using the Q, K and V produced in section 48.3 for the sentence “the cat was hungry”. Every number below was computed and checked with numpy.
- Recall the matrices:

Q				K				V			
the	1	1	0	the	2	1	1	the	3	1	3
cat	2	2	2	cat	1	1	4	cat	0	3	1
was	2	1	2	was	2	0	2	was	2	2	1
hungry	1	2	2	hungry	2	1	3	hungry	1	3	2

- Step one: Q K-transpose. Every entry is one dot product.
- Row “hungry”, column “cat”: q_hungry is $[1, 2, 2]$, k_cat is $[1, 1, 4]$.
- $(1 \times 1) + (2 \times 1) + (2 \times 4) = 1 + 2 + 8 = 11$.
- Row “hungry”, column “the”: $[1, 2, 2]$ against $[2, 1, 1]$ gives $2 + 2 + 2 = 6$.
- Row “hungry”, column “was”: $[1, 2, 2]$ against $[2, 0, 2]$ gives $2 + 0 + 4 = 6$.
- Row “hungry”, column “hungry”: $[1, 2, 2]$ against $[2, 1, 3]$ gives $2 + 2 + 6 = 10$.
- Doing all sixteen gives the raw score matrix:

$S = Q K^T$	the	cat	was	hungry
the	3	2	2	3
cat	8	12	8	12
was	7	11	8	11
hungry	6	11	6	10

10. Step two: divide by $\sqrt{d_k}$. Here $d_k = 3$, and $\sqrt{3} = 1.7320508$.

$S / \sqrt{3}$	the	cat	was	hungry
the	1.7321	1.1547	1.1547	1.7321
cat	4.6188	6.9282	4.6188	6.9282
was	4.0415	6.3509	4.6188	6.3509
hungry	3.4641	6.3509	3.4641	5.7735

11. Step three: softmax each row. Take the row for "hungry": [3.4641, 6.3509, 3.4641, 5.7735].
 12. Exponentiate each: e to the 3.4641 = 31.9477, e to the 6.3509 = 572.9812, e to the 3.4641 = 31.9477, e to the 5.7735 = 321.6624.
 13. Add them: $31.9477 + 572.9812 + 31.9477 + 321.6624 = 958.5392$.
 14. Divide each by the total: $31.9477 / 958.5392 = 0.0333$, $572.9812 / 958.5392 = 0.5978$, $31.9477 / 958.5392 = 0.0333$, $321.6624 / 958.5392 = 0.3356$.
 15. Check: $0.0333 + 0.5978 + 0.0333 + 0.3356 = 1.0000$. Good.
 16. The full attention weight matrix, every row summing to 1:

A	the	cat	was	hungry
the	0.3202	0.1798	0.1798	0.3202
cat	0.0452	0.4548	0.0452	0.4548
was	0.0436	0.4393	0.0777	0.4393
hungry	0.0333	0.5978	0.0333	0.3356

17. Read that matrix as language. "hungry" puts 0.5978 of its weight on "cat". Whatever "hungry" describes, it is mostly getting it from "cat".
 18. "was" splits its weight between "cat" at 0.4393 and "hungry" at 0.4393, which is what a linking verb joining a subject to a predicate would do.
 19. "the" is nearly flat, which is what a determiner with no strong question would do.
 20. This is a toy with hand-chosen matrices. Do not conclude that this pattern is what a trained model produces. It shows the shape of the computation.
 21. Step four: multiply A by V. Take the "hungry" row again:

$0.0333 \times [3, 1, 3]$	=	$[0.1000, 0.0333, 0.1000]$	from "the"
$0.5978 \times [0, 3, 1]$	=	$[0.0000, 1.7933, 0.5978]$	from "cat"
$0.0333 \times [2, 2, 1]$	=	$[0.0667, 0.0667, 0.0333]$	from "was"
$0.3356 \times [1, 3, 2]$	=	$[0.3356, 1.0067, 0.6712]$	from "hungry"

sum =		$[0.5022, 2.9000, 1.4022]$	

22. The complete output matrix, one row per token:

Output = A V	dim0	dim1	dim2
the	1.6405	2.1798	1.9607
cat	0.6807	2.8645	1.5452
was	0.7257	2.8350	1.5266
hungry	0.5022	2.9000	1.4022

23. Shape check: A is [4, 4], V is [4, 3], so the output is [4, 3]. Four tokens in, four tokens out, width 3.

24. Notice that “hungry” came in as [0, 1, 1, 0] and leaves as [0.5022, 2.9000, 1.4022]. It is no longer a context-free word. It now carries mostly “cat”.

■ 48.4.4 PLAIN - what is really happening inside

1. Now the piece everybody skips: why divide by the square root of d_k .
2. A dot product adds up d_k separate products. The more terms you add, the larger the total tends to be, in both directions.
3. If the entries of q and k are independent, have mean 0 and variance 1, then each product $q_i k_i$ has mean 0 and variance 1.
4. Adding d_k independent things with variance 1 gives something with variance d_k , so the typical size grows like the square root of d_k .
5. Measured with 20,000 random pairs per dimension:

d_k	Variance of $q.k$	Std dev	$\text{sqrt}(d_k)$
4	4.00	2.00	2.00
64	63.54	7.97	8.00
512	505.98	22.49	22.63
4096	4120.58	64.19	64.00

6. The measured standard deviation tracks $\text{sqrt}(d_k)$ exactly. That is the whole argument.
7. Now why large scores are bad. Softmax exponentiates. A gap of 10 between two scores becomes a ratio of about 22,026 to 1 after exponentiating.
8. Here is a real case with $d_k = 64$ and four random keys:

```
raw scores      2.153 -7.355 -9.911 -4.582
softmax(raw)    0.9987 0.0001 0.0000 0.0012

after dividing by sqrt(64) = 8
scaled scores   0.2691 -0.9194 -1.2389 -0.5728
softmax(scaled) 0.5110 0.1557 0.1131 0.2202
```

9. Without scaling, one key gets 99.87 per cent of the weight and the rest get essentially nothing. The attention has become a hard selection.
10. That is bad for two reasons. It throws away information, and worse, it kills learning.
11. Softmax’s gradient for an output p is proportional to p times $(1 - p)$.
12. At $p = 0.5$ that is 0.25. At $p = 0.999$ it is 0.000999. At $p = 0.99999$ it is 0.00001.
13. So once softmax saturates, the correction signal flowing back through it is almost zero, and the model stops being able to adjust those scores.
14. Dividing by $\text{sqrt}(d_k)$ rescales the scores to variance about 1 regardless of head width, keeping softmax in its responsive range at the start of training.
15. The 2017 paper states this reason directly in a footnote, and it is the only place in the paper where the word “suspect” appears about a design choice.
16. One more subtlety. The scaling matters most at initialization, when weights really are near-random and the variance argument holds exactly. Later in training the weights are not random and the argument is approximate. It still works, and nobody has found a reason to change it.

■ 48.4.5 TECHNICAL - the engineer’s version

1. The canonical formula, from equation 1 of “Attention Is All You Need”: $\text{Attention}(Q, K, V) = \text{softmax}(QK^T / \text{sqrt}(d_k)) V$.

2. Shapes, single head, batch B, sequence n:

Step	Operation	Output shape
scores	Q times K^T	$[B, n, n]$
scaled	divide by $\sqrt{d_k}$	$[B, n, n]$
weights	softmax over last dim	$[B, n, n]$
output	weights times V	$[B, n, d_v]$

- Floating-point operations, forward pass, single head: $2 n^2 d_k$ for the score matrix and $2 n^2 d_v$ for the weighted sum, so $4 n^2 d$ in total when $d_k = d_v = d$.
- Softmax is implemented in the numerically stable form: subtract the row maximum before exponentiating. Without that, exp of a score above about 88 overflows in float32 and above about 11 in float16.
- That max-subtraction is mathematically a no-op, since softmax is invariant to adding a constant to all inputs. It is purely a numerical safety measure and it is universal.
- Attention scores are almost always computed in float32 even when the model runs in bfloat16, because the softmax denominator accumulates n terms and bfloat16 has only 8 bits of mantissa.
- In PyTorch 2.0 and later, the whole thing is one call: `torch.nn.functional.scaled_dot_product_attention(q, k, v, is_causal=True)`, which dispatches to a fused kernel such as FlashAttention when the shapes and dtypes allow it.
- The reference implementation, which is worth being able to write from memory:

```
import torch, math

def attention(q, k, v, mask=None):
    # q: [B, h, n, dk] k,v: [B, h, n, dk]
    dk = q.size(-1)
    scores = q @ k.transpose(-2, -1) / math.sqrt(dk)
    if mask is not None:
        scores = scores.masked_fill(mask, float("-inf"))
    w = torch.softmax(scores.float(), dim=-1).to(v.dtype)
    return w @ v
```

- Alternatives to the dot product exist and lost. Additive attention (Bahdanau) uses a one-hidden-layer network and is theoretically stronger at large d_k but far slower, because it cannot be expressed as a single matrix multiply. The 2017 paper reports it performs comparably at small d_k .
- Scaling variants exist. Some papers use $1/d_k$, some use a learned temperature. The $1/\sqrt{d_k}$ convention is universal in practice, and it is a convention, not a standard. Nothing enforces it.
- Query-key normalization, which normalizes Q and K to unit length before the dot product, appeared around 2020 and is used in some large-scale training runs to prevent logit growth. It changes the scaling argument but not the structure.

■ 48.4.6 WORDS – remember these

- Dot product — multiply matching entries and add them up — the inner product of two vectors, equal to $|a||b|\cos(\theta)$.
- Score matrix — the grid of how well every query matched every key — the $[n, n]$ tensor $Q K^T$ before scaling and softmax.
- Scaling factor — the fixed divisor that keeps scores small — $1/\sqrt{d_k}$, chosen so the score variance is about 1 at initialization.

4. Saturation — when softmax has already picked a winner and stops responding — the regime where one probability approaches 1 and the Jacobian term $p(1-p)$ approaches 0.
5. Numerically stable softmax — subtracting the biggest score first — the standard implementation $\exp(x - \max) / \sum \exp(x - \max)$, avoiding overflow.
6. Attention output — the blended result for each position — the $[n, d_v]$ matrix of weighted sums of value vectors.
7. Additive attention — the older, slower scoring method — Bahdanau's $v^T \tanh(W_1 q + W_2 k)$, a small network instead of a dot product.

48.5 Masking: stopping the model reading ahead

■ 48.5.1 PLAIN – in simple words

1. A language model is trained by hiding the next word and asking it to guess.
2. That only works if the model genuinely cannot see the next word.
3. But attention, as built so far, lets every position see every position, including the ones after it.
4. So during training on the sentence “the cat was hungry”, the position for “was” can see “hungry”, and predicting “hungry” becomes trivial copying.
5. The model would score perfectly during training and be useless at generation time, when there is nothing after the current word to copy.
6. The fix is called a **mask**. Before the softmax, you go into the score grid and destroy every score that looks forward.
7. Destroy means set to negative infinity, because e to the power of negative infinity is 0, so softmax gives that position a weight of exactly zero.
8. You cannot just set the weights to zero after the softmax, because then the remaining weights would not add to 1. Doing it before the softmax means the surviving weights renormalize automatically.
9. The shape of the destroyed region is the triangle above the diagonal, so this is called a **causal mask**, or a look-ahead mask.
10. Causal here means “the past can affect the future, and the future cannot affect the past”, the ordinary meaning of cause.
11. There is a second, different kind of mask. When you run many sentences of different lengths together, you pad the short ones with filler tokens.
12. A **padding mask** blocks attention to that filler, so real words never average in meaningless positions.
13. And there are models that use no causal mask at all. They read the whole text both ways at once. Those are excellent at understanding a fixed piece of text and cannot generate.

■ 48.5.2 PLAIN – a picture in your head

1. Imagine an exam where the questions and answers are printed on the same long scroll, in order.
2. Question 1, answer 1, question 2, answer 2, all the way down.
3. You are given the scroll rolled up, and a rule: you may unroll it only as far as the question you are currently answering, never further.
4. So when you are on question 3, you can see questions 1, 2 and 3 and answers 1 and 2, and nothing beyond.
5. That is exactly the causal mask. Position t sees positions 1 through t .
6. Now here is the part that surprises people. The examiner does not hand you one question at a time. The examiner hands the whole class the whole scroll at once, with each student allowed a different unrolling limit.
7. Student 1 may see 1 word. Student 2 may see 2 words. Student 500 may see 500.
8. All 500 students work at the same time, in one operation, and each is graded on a genuinely fair prediction.
9. That is why masked training is fast. One pass over a 4,000-token document produces 4,000 separate prediction problems, all solved in parallel.

Where this comparison breaks: the students are not separate. They are 500 rows of one matrix, and the “unrolling limit” is not enforced by discipline but by arithmetic that makes forbidden information contribute exactly zero. Also, a real exam has one right answer per question. Here the target is the actual next token in the training text, which is one sample from a distribution of acceptable continuations, and the model is graded against that one sample.

■ 48.5.3 PLAIN – a worked example

1. Take the scaled score matrix computed in section 48.4 for “the cat was hungry”, and apply a causal mask.
2. Before masking, the scaled scores were:

	the	cat	was	hungry
the	1.7321	1.1547	1.1547	1.7321
cat	4.6188	6.9282	4.6188	6.9282
was	4.0415	6.3509	4.6188	6.3509
hungry	3.4641	6.3509	3.4641	5.7735

3. Now set everything strictly above the diagonal to negative infinity:

	the	cat	was	hungry
the	1.7321	-inf	-inf	-inf
cat	4.6188	6.9282	-inf	-inf
was	4.0415	6.3509	4.6188	-inf
hungry	3.4641	6.3509	3.4641	5.7735

4. The pattern is a lower triangle of real numbers and an upper triangle of negative infinity. This is the causal mask, and it is always this shape.
5. Now softmax each row. Row “the” has exactly one surviving score, so it gets weight 1.0 and everything else 0.
6. Row “cat” has two surviving scores, 4.6188 and 6.9282. Their difference is 2.3094, so e to the 2.3094 = 10.07, and the weights are $1 / 11.07 = 0.0903$ and $10.07 / 11.07 = 0.9097$.
7. The full masked attention matrix:

A causal	the	cat	was	hungry
the	1.0000	0.0000	0.0000	0.0000

cat	0.0903	0.9097	0.0000	0.0000
was	0.0778	0.7836	0.1386	0.0000
hungry	0.0333	0.5978	0.0333	0.3356

8. Every row still sums to exactly 1. The zeros are true zeros, not small numbers.
9. Compare the “was” row with the unmasked version. Unmasked it was [0.0436, 0.4393, 0.0777, 0.4393]. Masked it is [0.0778, 0.7836, 0.1386, 0].
10. The 0.4393 that was going to “hungry” did not disappear. It was redistributed proportionally across the three legal positions. That is what the renormalization in softmax does for free.
11. Multiplying by V gives the masked output:

Output (causal)	dim0	dim1	dim2
the	3.0000	1.0000	3.0000
cat	0.2710	2.8193	1.1807
was	0.5107	2.7057	1.1556
hungry	0.5022	2.9000	1.4022

12. Note the first row. Position 1 can only see itself, so its output is exactly its own value vector [3, 1, 3]. That is always true of the first token in a causal model, in every layer.
13. Note the last row. It is identical to the unmasked last row, because the last position had nothing ahead of it to mask anyway.

■ 48.5.4 PLAIN - what is really happening inside

1. In code, the mask is not really negative infinity. It is a large negative number, or a genuine negative infinity that the softmax handles.
2. In float32, a common choice is $-1e9$ or the smallest representable value. In float16 it must be about -65504 or smaller in magnitude than that, because float16 cannot hold $-1e9$.
3. Using a finite value works because e to the power of $-1e9$ underflows to exactly 0.0 in floating point. The result is identical to true zero.
4. **The honest version:** there is a real failure mode here. If an entire row is masked, every score becomes negative infinity, and softmax computes 0 divided by 0, giving NaN, which then poisons the whole model. Implementations guard against this. It happens in practice with badly constructed padding masks.
5. The mask is not a parameter. Nothing about it is learned. It is a fixed boolean pattern computed from the sequence length.
6. It costs no memory to store, in good implementations, because the triangular pattern is generated on the fly inside the kernel rather than materialized as an $[n, n]$ tensor.
7. Now the padding mask. Suppose you batch three prompts of lengths 5, 9 and 3.
8. To make one rectangular tensor, you pad all three to length 9 with a filler token id.
9. Without a mask, position 2 of the third prompt would average in six filler positions, and its output would be contaminated.
10. The padding mask sets the columns of the padded positions to negative infinity for every row.
11. Padding masks and causal masks combine by taking whichever is more restrictive at each cell, which in boolean terms is a logical OR of the two blocked patterns.
12. A neat trick used by almost every training framework avoids padding entirely: concatenate many documents into one long stream, cut it into fixed-length chunks, and never pad at all. This is called sequence packing.

■ 48.5.5 TECHNICAL – the engineer’s version

1. The causal mask M is defined by $M[i][j] = 0$ if j is less than or equal to i , and negative infinity otherwise. It is added to the scaled scores before softmax.
2. The masked formula: $\text{softmax}(QK^T / \sqrt{d_k} + M) V$.
3. In PyTorch, `torch.triu(torch.ones(n, n), diagonal=1).bool()` produces the blocked pattern, and `scores.masked_fill(mask, float("-inf"))` applies it.
4. Since PyTorch 2.0, `scaled_dot_product_attention(..., is_causal=True)` is preferred, because fused kernels skip the masked blocks entirely rather than computing and discarding them, roughly halving the work.
5. That saving is real and worth naming: a causal attention over n tokens does about $n^2/2$ useful score computations, not n^2 .
6. Encoder models use no causal mask. BERT, from Jacob Devlin, Ming-Wei Chang, Kenton Lee and Kristina Toutanova at Google in October 2018, attends both directions at every layer.
7. That is why BERT cannot be trained on next-token prediction. If every position sees every position, the answer is already visible.
8. BERT is trained instead on **masked language modelling**: replace 15 per cent of tokens with a special [MASK] token and predict the originals. The masking there is of the input tokens, not of the attention matrix. Two different meanings of the same word, and this confuses people constantly.
9. The consequences of the choice:

Property	Causal (decoder)	Bidirectional (encoder)
Sees future tokens	No	Yes
Can generate text	Yes	No
Training signal per token	Every token	15 per cent of tokens
Best at	Generation, chat	Classification, embedding

10. The training-efficiency line in that table is important and often missed. A causal model gets a prediction target at every one of n positions. A masked language model gets one at roughly $0.15n$ positions, so it extracts less signal per pass over the data.
11. Prefix language modelling is the hybrid: bidirectional attention over a prompt prefix, causal attention over the generated part. Used in UniLM in 2019 and in some of the T5 variants.
12. Sliding window attention adds a second constraint: block anything further back than w positions. Mistral 7B, released October 2023, used $w = 4096$. That is covered in 48.13.
13. Observation tools: printing the mask is one line, but for real debugging the useful check is that every attention row sums to 1 and contains no NaN. A single NaN in one row propagates to the entire output within one layer.

■ 48.5.6 WORDS – remember these

1. Mask — blocking some positions from being looked at — an additive $[n, n]$ tensor of 0 and negative infinity applied before softmax.
2. Causal mask — you may not read ahead — the strictly upper-triangular block pattern, also called a look-ahead or autoregressive mask.
3. Padding mask — ignore the filler used to square up a batch — a per-sequence column mask blocking positions beyond the true length.
4. Autoregressive — predicting the next thing from all the previous things — a factorization of the joint probability as a product of conditionals.

5. Masked language modelling — hiding some input words and guessing them — the BERT objective, corrupting about 15 per cent of input tokens.
6. Sequence packing — gluing documents together to avoid padding — concatenating a corpus into a token stream and slicing fixed-length windows.
7. Bidirectional — able to see both left and right — an unmasked encoder attention pattern.

48.6 Multi-head attention

■ 48.6.1 PLAIN – in simple words

1. One attention operation produces one set of weights per position. One opinion about what matters.
2. But a word usually needs several different things at once.
3. Take the word “hungry” in “the cat was hungry”. It needs to know what it describes, which is “cat”. It also needs to know its grammatical role. It also needs to know where it sits in the sentence.
4. Those are different questions, and one set of weights cannot answer them all, because the weights must add up to 1 and get spent once.
5. So the model runs several attention operations side by side, each with its own W_Q , W_K and W_V . Each one is called a **head**.
6. Head 1 might mostly look at the previous word. Head 2 might look at the subject of the sentence. Head 3 might look at matching brackets.
7. They all run at the same time on the same input, and they do not talk to each other while running.
8. When they finish, their outputs are laid side by side in one long row, which is called concatenation.
9. Then one final learned matrix mixes that long row back down to the original width. That matrix is W_O , the output projection.
10. The clever part is that heads cost nothing extra. If the model is 512 wide and you want 8 heads, each head is 64 wide, and 8 times 64 is 512.
11. So the total work is the same as one 512-wide head. You have bought variety for free by splitting rather than adding.
12. That is the trade: eight narrow views instead of one wide view, at identical cost.

■ 48.6.2 PLAIN – a picture in your head

1. Picture a panel of eight specialist doctors examining the same patient at the same time.
2. The cardiologist looks at the heart. The neurologist looks at the nerves. The radiologist looks at the scans.
3. Each one asks different questions, of the same patient, and gets a different answer.
4. None of them sees the whole picture. Each is deliberately narrow.
5. When they are done, all eight write their findings on one long sheet.
6. A general physician reads the whole sheet and produces one combined assessment. That is W_O , the output projection.
7. The panel is faster than eight sequential consultations, because they work simultaneously.
8. And the panel is better than one generalist, because a generalist would have to spend the same total effort spread across all the specialities.

Where this comparison breaks: real specialists chose their speciality and know what it is. Heads are not assigned roles. They are eight identical copies with different random starting values, and whatever specialization appears is an accident of training that nobody designed. Many heads end up doing nothing useful at all, which no hospital would tolerate. And a doctor examines the actual

patient. A head sees only a 64-dimensional slice of a vector that has already passed through many previous layers.

■ 48.6.3 PLAIN – a worked example

1. Work out every shape for the 2017 base model, with a 10-token sentence.
2. The configuration: $d_{\text{model}} = 512$, 8 heads, $d_k = d_v = 64$, since $512 / 8 = 64$.

input X	[1, 10, 512]
project with W_Q [512, 512]	[1, 10, 512]
reshape into heads	[1, 10, 8, 64]
transpose head axis forward	[1, 8, 10, 64]
same for K and V	[1, 8, 10, 64]
scores per head $Q K^T$	[1, 8, 10, 10]
softmax over last axis	[1, 8, 10, 10]
weights times V	[1, 8, 10, 64]
transpose back	[1, 10, 8, 64]
concatenate heads	[1, 10, 512]
project with W_O [512, 512]	[1, 10, 512]

3. Look at the first and last lines. The input was [1, 10, 512] and the output is [1, 10, 512]. The shape is unchanged, which is why blocks can be stacked.
4. Look at the score tensor: [1, 8, 10, 10]. That is 8 separate 10-by-10 grids, one per head. 800 numbers.
5. There is no reshaping magic here. “Reshape into heads” just means reading the same 512 numbers as 8 groups of 64, without moving any data.
6. Head 0 gets dimensions 0 to 63. Head 1 gets 64 to 127. And so on to head 7, which gets 448 to 511.
7. Parameters: W_Q , W_K , W_V and W_O are each 512 by 512, so 262,144 each, and 1,048,576 for the whole multi-head attention block.
8. That is exactly 4 times d_{model} squared, which is a formula worth memorizing: attention costs $4 d^2$ parameters per layer.
9. Now do the same for a modern model, Llama 3.1 8B: $d_{\text{model}} = 4096$, 32 query heads, 8 key-value heads, head dimension 128.
10. Note that 32 times 128 = 4096, so the query side still adds up to d_{model} .
11. But the key and value side uses only 8 heads, so 8 times 128 = 1024.

q_proj	[4096, 4096]	=	16,777,216	parameters
k_proj	[1024, 4096]	=	4,194,304	parameters
v_proj	[1024, 4096]	=	4,194,304	parameters
o_proj	[4096, 4096]	=	16,777,216	parameters

total attention		=	41,943,040	per layer

12. Each of the 8 key-value heads is shared by 4 query heads. That is grouped-query attention, and its purpose is to shrink the memory cost of generation, explained fully in 48.13.
13. Across 32 layers that is 1,342,177,280 attention parameters, which is 16.7 per cent of the model’s 8,030,261,248 total.

■ 48.6.4 PLAIN – what is really happening inside

1. Heads are not separate networks. They are one matrix multiplication whose output is interpreted as several groups.
2. W_Q is a single $[512, 512]$ matrix. Nothing in it says “this column belongs to head 3”. The head boundaries exist only in how the result is reshaped.
3. That is why the cost is identical to single-head attention with the full width. The reshape is free.
4. The heads become genuinely independent at the score step, because a query from head 3 is only ever dotted with keys from head 3.
5. This makes the attention computation **block diagonal** across heads. Eight small independent problems rather than one large one.
6. The only place heads mix is W_O at the end. Every output dimension of W_O is a weighted combination of all 512 concatenated numbers, so every head can influence every output.
7. That means W_O is not just a resize. It is the thing that decides how much each head’s finding is worth, and it is learned.
8. A useful way to see it: W_O can be split into 8 blocks of $[64, 512]$, one per head. Then the block’s output is added to the residual stream. Each head writes its own contribution independently, and they sum.
9. This decomposition is exactly how the interpretability literature analyses attention, and it is mathematically exact, not an approximation.
10. Heads within one layer cannot see each other’s results. Head 3 cannot use what head 5 found. That only becomes possible in the next layer.

■ 48.6.5 TECHNICAL – the engineer’s version

1. Multi-head attention, from the 2017 paper: $\text{concat}(\text{head}_1, \dots, \text{head}_h) W_O$, where $\text{head}_i = \text{Attention}(Q W_{Q_i}, K W_{K_i}, V W_{V_i})$.
2. Standard configurations:

Model	d_model	Heads	Head dim
Transformer base 2017	512	8	64
BERT-base 2018	768	12	64
GPT-2 small 2019	768	12	64
Llama 3.1 8B 2024	4096	32	128

3. The convention $d_k = d_{\text{model}} / h$ keeps total cost constant. It is a convention, not a requirement, and models that break it exist.
4. The 2017 paper ran an ablation: with d_{model} fixed at 512, 1 head scored 0.9 BLEU worse than 8 heads, and 32 heads was also slightly worse than 8. So more heads is not monotonically better once each head becomes too narrow.
5. What heads have been observed to learn, from published analysis:
 1. Positional heads that attend almost entirely to the previous token or the next token. These are the most reliable finding and appear in nearly every model.
 2. Syntactic heads that attend from a verb to its direct object, or from a determiner to its noun. Kevin Clark, Urvashi Khandelwal, Omer Levy and Christopher Manning documented these in BERT in 2019.
 3. Coreference heads that attend from a pronoun to its antecedent, also in the same 2019 analysis, at above-chance but well below perfect accuracy.

4. Induction heads, which complete a repeated pattern by finding an earlier occurrence of the current token and copying what followed it. Described by Catherine Olsson and colleagues at Anthropic in 2022 and connected to in-context learning.
6. **The honest version:** this is not settled science. Head interpretability is active research, not established fact. The named roles above are real published observations on specific models, and they do not mean that heads in general have clean human-nameable jobs.
7. Redundancy is well established and cuts the other way. Elena Voita, David Talbot, Fedor Moiseev, Rico Sennrich and Ivan Titov showed in 2019 that pruning 38 of 48 encoder heads in a translation model cost only 0.15 BLEU on English-Russian WMT data.
8. Paul Michel, Omer Levy and Graham Neubig published the same finding independently in 2019, in a paper titled “Are Sixteen Heads Really Better Than One?”. Many heads can be deleted at test time with little loss.
9. So the correct summary is: some heads do identifiable jobs, most heads are partly redundant, and the population as a whole is not a tidy division of labour.
10. Marketing claim to reject: any product page saying the model “has heads dedicated to reasoning” or similar. No such assignment is designed or verified.
11. Reproducing head analysis is straightforward. Load a model with `output_attentions=True`, take the `[B, h, n, n]` tensor, and for a previous-token head you will see nearly all mass on the first subdiagonal.

■ 48.6.6 WORDS – remember these

1. Head — one independent attention view — one of h parallel attention computations, each of width d_{model} / h by convention.
2. Multi-head attention — several attention views run side by side — h parallel scaled dot-product attentions, concatenated and projected by W_O .
3. Concatenation — laying results side by side into one long row — joining the h per-head outputs along the feature axis to restore width d_{model} .
4. Output projection — the matrix that mixes the heads back together — W_O , of shape $[d_{\text{model}}, d_{\text{model}}]$, applied after concatenation.
5. Head dimension — how wide one head is — d_k , typically 64 in 2017-era models and 128 in current ones.
6. Induction head — a head that continues a repeated pattern — a two-head circuit that matches the current token to a previous occurrence and copies the following token.
7. Head pruning — deleting heads that do not earn their keep — zeroing whole heads at inference, shown to cost little accuracy in several 2019 studies.

48.7 Position: attention has no idea what order things are in

■ 48.7.1 PLAIN – in simple words

1. Here is a fact about attention that catches everybody by surprise.
2. Attention has no concept of order. None. It does not know which word came first.
3. To attention, a sentence is a bag of items, not a sequence.
4. Prove it to yourself. Look back at the formula: $\text{softmax}(Q K^T / \sqrt{d_k}) V$.
5. Find the position number in it. There is none. There is no i , no t , no index of any kind.
6. Every operation is a dot product between two token vectors, and a dot product does not care where either token sits.
7. So “dog bites man” and “man bites dog” would produce exactly the same set of output vectors, just shuffled the same way as the input.
8. That would be a catastrophe for language, where order is most of the meaning.
9. So order has to be added by hand. The model is given, for each position, some extra numbers that say where that position is.
10. The original method was to add a fixed pattern of sine and cosine waves to each token’s vector before the first layer.
11. A second method is to learn a separate vector for position 1, position 2, and so on, exactly like an embedding table for positions.
12. The modern method, used by almost every current model, is different and cleverer. It rotates the query and key vectors by an angle proportional to their position.
13. It is called rotary position embedding, or RoPE, and the reason it won is that it makes the score between two tokens depend only on how far apart they are, not on where they are in absolute terms.

■ 48.7.2 PLAIN – a picture in your head

1. Imagine a set of magnetic word tiles scattered on a table, one word per tile.
2. Attention reads all the tiles at once and works out which ones relate to which others.
3. Now shake the table. The tiles land in a different arrangement. Attention gives exactly the same answer, because it never looked at the arrangement.
4. To fix this, you write a number on the back of each tile: 1, 2, 3, 4.
5. That is learned absolute position embedding. Simple, and it fails as soon as you meet tile 5,000 when you only ever wrote numbers up to 4,096.
6. Now a better fix. Instead of writing numbers, you tilt each tile by an angle. Tile 1 is tilted 10 degrees, tile 2 is tilted 20, tile 3 is tilted 30.
7. When two tiles are compared, what matters is the difference in their tilts. Tiles 1 and 2 differ by 10 degrees. Tiles 500 and 501 also differ by 10.
8. So the comparison naturally depends on the gap between positions, not the absolute positions.
9. That is rotary position embedding. Tilt by angle, compare by difference.

Where this comparison breaks: a tile has one tilt angle. A real RoPE vector is split into 64 pairs of numbers, and each pair is rotated at its own speed, from one full turn every 6.3 positions down to one full turn every two and a half million positions. So it is 64 clocks running at 64 different speeds, not one tilt. And the tilt is applied to the query and key vectors only, never to the values.

■ 48.7.3 PLAIN – a worked example

1. First, the proof that attention ignores order. Take the four-token example from 48.4, which produced this output:

Output	dim0	dim1	dim2
the	1.6405	2.1798	1.9607
cat	0.6807	2.8645	1.5452
was	0.7257	2.8350	1.5266
hungry	0.5022	2.9000	1.4022

- Now shuffle the input rows into the order hungry, cat, the, was, and run the identical computation with the identical matrices:

Output of shuffled input	dim0	dim1	dim2
hungry	0.5022	2.9000	1.4022
cat	0.6807	2.8645	1.5452
the	1.6405	2.1798	1.9607
was	0.7257	2.8350	1.5266

- Every row is identical to before. Only their order changed, in exactly the same way the input changed.
- That property has a name: **permutation equivariance**. Shuffle the input, and the output is shuffled the same way, with no other change.
- This was verified numerically, not asserted. The two matrices agree to floating-point precision.
- Now sinusoidal position encoding. The formula from the 2017 paper, for position pos and dimension index i:

$$\begin{aligned} \text{PE}(\text{pos}, 2i) &= \sin(\text{pos} / 10000^{(2i/d_{\text{model}})}) \\ \text{PE}(\text{pos}, 2i+1) &= \cos(\text{pos} / 10000^{(2i/d_{\text{model}})}) \end{aligned}$$

- With $d_{\text{model}} = 8$ there are 4 sine-cosine pairs. Their frequencies:

Pair	Frequency	Wavelength
0	1.0	6.28 positions
1	0.1	62.8 positions
2	0.01	628 positions
3	0.001	6283 positions

- The actual values for the first five positions:

pos 0:	0.0000	1.0000	0.0000	1.0000	0.0000	1.0000	0.0000	1.0000
pos 1:	0.8415	0.5403	0.0998	0.9950	0.0100	1.0000	0.0010	1.0000
pos 2:	0.9093	-0.4161	0.1987	0.9801	0.0200	0.9998	0.0020	1.0000
pos 3:	0.1411	-0.9900	0.2955	0.9553	0.0300	0.9996	0.0030	1.0000
pos 4:	-0.7568	-0.6536	0.3894	0.9211	0.0400	0.9992	0.0040	1.0000

- Read the columns. The first pair changes fast and wraps around quickly. The last pair barely moves at all across five positions.
- That is the design. Fast waves distinguish neighbours precisely, slow waves distinguish far-apart positions coarsely. It is a positional binary counter made of continuous waves.
- Now RoPE, with real numbers. Take a query pair $q = [1.0, 0.0]$ and a key pair $k = [0.6, 0.8]$. Their plain dot product is 0.6.
- RoPE rotates q by m times theta and k by n times theta, where m and n are the two positions. With $\text{theta} = 1.0$ radian:

m	n	m - n	Dot after rotation
1	0	1	0.997358
5	4	1	0.997358
100	99	1	0.997358
3	0	3	-0.481099
7	4	3	-0.481099

13. Look at the last column. Every pair with the same gap gives the same result, to six decimal places, whether the positions are 1 and 0 or 100 and 99.
14. That is the whole selling point of RoPE, demonstrated numerically. The score depends on relative distance only.

■ 48.7.4 PLAIN – what is really happening inside

1. Sinusoidal encoding is added to the token embedding, once, before layer 1. Token vector plus position vector, element by element.
2. That means position information and word information are mixed together in the same numbers from the start, and every layer sees the sum.
3. Learned absolute embeddings work identically, except the position vectors are parameters found by training rather than computed from a formula.
4. GPT-2 uses learned absolute embeddings: a table of 1,024 rows by 768 columns, which is 786,432 parameters spent purely on saying where things are.
5. Both of these have the same weakness. They are absolute. Position 3,000 has its own vector, unrelated to position 2,999.
6. And if the table has 1,024 rows, position 1,024 does not exist. The model cannot be run on longer text at all.
7. Sinusoids can at least be computed for any position, but a model trained only on positions 0 to 511 has never seen what position 800 looks like, and in practice quality collapses beyond the trained length.
8. RoPE takes a completely different route. It never adds anything. It rotates.
9. Split the query vector into consecutive pairs: dimensions (0,1), (2,3), (4,5), and so on. Treat each pair as a point on a flat plane.
10. Rotate pair j by an angle of position times θ_j , where θ_j gets smaller for later pairs, exactly like the sinusoid frequencies.
11. Do the same to the key vector, using the key's own position.
12. Now take the dot product. Rotating both vectors by the same amount leaves the dot product unchanged, so only the difference in rotation survives.
13. That is basic geometry: a dot product is invariant under rotation. Rotating q by m and k by n is the same as rotating q by (m - n) and leaving k alone.
14. So the score naturally becomes a function of m - n. No extra terms, no lookup table, no learned parameters at all.
15. RoPE is applied inside every attention layer, to Q and K only, every time. It is not applied to V, and it is not added to the residual stream.

■ 48.7.5 TECHNICAL – the engineer's version

1. Permutation equivariance is exact: for any permutation matrix P, $\text{Attention}(PX) = P \text{Attention}(X)$. This is why position injection is mandatory rather than helpful.

2. **Sinusoidal**, 2017. Fixed, no parameters, defined for all positions. The base 10,000 sets the slowest wavelength. The paper's stated reason for choosing sinusoids is that $PE(pos + k)$ is a linear function of $PE(pos)$ for any fixed offset k , so relative offsets are in principle learnable as a linear map. This was verified numerically for this chapter: for the fastest pair with $\theta = 1$, rotating $PE(5)$ by 3 radians reproduces $PE(8)$ exactly.
3. The paper also reports that learned and sinusoidal encodings performed almost identically, and chose sinusoidal for its extrapolation potential.
4. Sinusoid dot products fall with distance, which is a useful inductive bias. Measured at $d_{model} = 64$: the dot product of $PE(0)$ with itself is 32.0, with $PE(1)$ is 30.92, with $PE(10)$ is 21.05, and with $PE(200)$ is 11.44.
5. **Learned absolute**, used by BERT (2018), GPT-1, GPT-2 and GPT-3. A table of shape $[max\_positions, d_{model}]$. Hard cap on length, no extrapolation at all.
6. **Relative position representations**, from Peter Shaw, Jakob Uszkoreit and Ashish Vaswani in 2018, add a learned vector for each relative offset into the key and value computation.
7. **T5 relative position bias**, from Colin Raffel and colleagues in 2019, adds a learned scalar to the attention logit per bucket of relative distance, shared across layers, with logarithmically spaced buckets. Cheap and effective.
8. **ALiBi**, from Ofir Press, Noah Smith and Mike Lewis in 2021, adds a linear penalty to the attention logit: minus m times the distance, where m is a fixed per-head slope, typically a geometric sequence such as $1/2, 1/4, 1/8$. No parameters at all, and it extrapolates well beyond the training length. The paper's title is "Train Short, Test Long".
9. **RoPE**, from Jianlin Su, Yu Lu, Shengfeng Pan, Bo Wen and Yunfeng Liu, in the RoFormer paper first posted in April 2021. It is the dominant choice as of 2026. Llama, Mistral, Qwen, Gemma, DeepSeek and Phi all use it.
10. RoPE frequencies use $\theta_j = base^{(-2j/d_{head})}$. With base 10,000 and head dimension 128, the fastest pair has wavelength 6.3 positions and the slowest has wavelength 54,410 positions.
11. Raising the base stretches everything. With base 500,000, as used in Llama 3.1, the slowest pair has wavelength 2,559,196 positions. That is how a 128k-token context is supported without the slowest frequency wrapping.

Method	Year	Parameters	Extrapolates
Sinusoidal	2017	0	Poorly
Learned absolute	2018	$max\_pos \times d$	Not at all
T5 bias	2019	~ 32 per head	Moderately
ALiBi	2021	0	Well
RoPE	2021	0	With extension

12. Context extension. A model trained at 4,096 tokens fails at 32,768 because the rotation angles at position 30,000 are outside anything it saw.
13. **Position interpolation**, from Shouyuan Chen, Sherman Wong, Liangjian Chen and Yuandong Tian at Meta in June 2023, divides every position index by a scale factor s . To go from 4,096 to 32,768, use $s = 8$, so position 32,767 is presented to the model as 4,095.9.
14. That keeps every angle inside the trained range, at the cost of squashing fine positional detail. It requires a short fine-tune, typically 1,000 steps, and works remarkably well.
15. **NTK-aware scaling**, which appeared as a community proposal in mid-2023, changes the RoPE base instead of the positions, stretching low frequencies more than high ones so nearby tokens keep their resolution.

16. **YaRN**, from Bowen Peng, Jeffrey Quesnelle, Honglu Fan and Enrico Shippole in 2023, combines the two: interpolate the low-frequency dimensions, leave the high-frequency ones alone, apply a ramp in between, and add a temperature adjustment to the attention logits. It reaches long contexts with about ten times less fine-tuning data than plain interpolation.
17. Llama 3.1, released July 2024, used a variant of this family to reach a 131,072-token context from a shorter pretraining length, together with base 500,000.
18. Established fact: RoPE gives exact relative-distance dependence, and interpolation methods extend context in practice. Active research: how much real long-range capability extension gives, as opposed to merely not crashing. Benchmarks such as RULER, from NVIDIA in 2024, found many models claiming 32,000-token contexts performed well at much shorter lengths.

■ 48.7.6 WORDS – remember these

1. Permutation equivariance — shuffle the input, get the same output shuffled — $\text{Attention}(PX) = P \text{ Attention}(X)$ for any permutation matrix P .
2. Positional encoding — extra numbers telling the model where each token sits — any scheme injecting order information into an order-blind operation.
3. Sinusoidal encoding — fixed sine and cosine waves at many speeds — the 2017 scheme with frequencies $\text{base}^{(-2i/d)}$, base 10,000.
4. Absolute position — where a token is in the whole sequence — an index from 0 to $n-1$, encoded directly.
5. Relative position — how far apart two tokens are — the offset $m - n$, which is what a score should depend on.
6. RoPE — rotating queries and keys by an angle set by position — rotary position embedding, applying a block-diagonal rotation to Q and K .
7. RoPE base (θ) — the number controlling how slow the slowest wave is — 10,000 originally, raised to 500,000 or higher for long contexts.
8. Position interpolation — squeezing long positions into the trained range — dividing position indices by a scale factor s , then fine-tuning.
9. YaRN — a smarter context extension that treats fast and slow waves differently — wavelength-dependent interpolation with a logit temperature correction.
10. ALiBi — penalizing distant tokens with a straight-line penalty — adding minus m times $|i - j|$ to the attention logit, with fixed per-head slopes.

48.8 The rest of the block: feed-forward, residuals and normalization

■ 48.8.1 PLAIN – in simple words

1. Attention is only half of a transformer block. The other half is a small ordinary network applied to each position separately.
2. It is called the **feed-forward network**, or FFN, or the MLP. All three names mean the same thing.
3. It has exactly two steps: widen, then narrow. Multiply by a matrix that makes the vector about four times wider, apply a non-linear function, multiply by a matrix that brings it back to the original width.
4. The important word is “separately”. Every position goes through the same FFN, on its own, with no reference to any other position.
5. So attention is where positions talk to each other, and the FFN is where each position thinks about what it just heard.
6. Now the surprising part: this simple two-matrix block holds most of the model’s parameters. About 70 per cent for an 8-billion model, and about 80 per cent for larger ones.
7. Chapter 47 counted this exactly. For Llama 3.1 8B, the feed-forward matrices hold 176,160,768 parameters per layer against 41,943,040 for attention.
8. So attention gets all the attention, and the FFN holds the weights.
9. Two more pieces complete the block, and both are about making deep stacks trainable rather than about capability.
10. A **residual connection** means: whatever a sub-layer computes, add the original input back on. Output equals input plus change, not just change.
11. Without residuals, a 32-layer stack cannot be trained. The correction signal dies on the way back, exactly as it did in recurrent networks.
12. **Layer normalization** rescales each vector so its numbers have a predictable size, which stops values drifting to extremes as they pass through dozens of layers.
13. That is the whole block: attention, add the input back, normalize, feed-forward, add the input back, normalize. Then repeat.

■ 48.8.2 PLAIN – a picture in your head

1. Picture a long assembly line with 32 stations, each one modifying a product.
2. In a bad design, each station takes the previous station’s output and rebuilds it from scratch. If station 7 does something wrong, everything downstream is corrupted, and the factory manager cannot tell which station caused it.
3. In the residual design, each station is given the product and told: do not rebuild it. Just add your modification on top and pass it along.
4. Now the product carries a continuous history, and every station’s change is a small addition rather than a replacement.
5. If the manager finds a fault at the end, the complaint can travel back down the line unchanged, because the additions form a straight unbroken path.
6. That straight path is exactly what a residual connection creates for gradients. It is often called the residual stream, and it runs the whole depth of the model.
7. Normalization is the quality inspector between stations, resetting the product to a standard size and shape so the next station receives something in the range it expects.

Where this comparison breaks: nothing is physically added to a product, and the “modification” is a vector added element by element, which can cancel earlier contributions rather than accumulate. Also, real assembly stations have fixed jobs. These are all trained together, so a station’s job is defined

only by what the others ended up doing.

■ 48.8.3 PLAIN – a worked example

1. First, why residual connections matter, with arithmetic.
2. During backpropagation, the correction signal is multiplied by something at each layer. Call it the per-layer factor.
3. Without residuals, that factor depends entirely on the layer's weights and there is no reason for it to be near 1.

Per-layer factor	After 32 layers	After 96 layers
0.90	0.034	0.00004
0.95	0.194	0.0073
1.00	1.000	1.000
1.05	4.765	108.2

4. At 0.9 per layer, a 96-layer model receives 0.004 per cent of the signal at the bottom. Training the early layers becomes impossible.
5. With a residual connection, the layer computes $x + f(x)$, so the derivative is $1 + f'(x)$. The 1 is there whatever f does.
6. So there is always a path with factor exactly 1, and the product along that path stays exactly 1 no matter how deep the stack is.
7. That is the entire trick, and it came from image models: Kaiming He, Xiangyu Zhang, Shaoqing Ren and Jian Sun published ResNet in December 2015, trained 152 layers, and won the ImageNet competition that year.
8. Now layer normalization, worked on a real vector of 8 numbers:

```
x      = 2.0  -1.0  0.5  4.0  -2.5  1.0  0.0  3.0
mean   = 0.875
variance = 3.921875
std dev = 1.980372
```

9. Subtract the mean and divide by the standard deviation:

```
normed = 0.5681 -0.9468 -0.1894 1.5780
        -1.7042 0.0631 -0.4418 1.0730
```

10. Check: the mean of the normalized vector is 0.0 and its standard deviation is 1.0. That is guaranteed by construction.
11. Then multiply by a learned scale and add a learned shift, one per dimension, so the layer can undo the normalization if that helps.
12. Crucially, the mean and variance were computed across the 8 features of this one token. Not across the batch. Not across the sequence.
13. That is why it works with any batch size, including batch size 1, which is the normal case when you chat with a model.
14. RMSNorm is the cheaper modern variant. It skips the mean subtraction and divides by the root mean square:

```
root mean square of x = 2.165064
normed = 0.9238 -0.4619 0.2309 1.8475
        -1.1547 0.4619 0.0000 1.3856
```

15. It has one learned parameter per dimension instead of two, and in practice performs the same. Llama, Mistral, Qwen and Gemma all use it.

■ 48.8.4 PLAIN - what is really happening inside

1. The feed-forward network, written out: $\text{FFN}(x) = W_2 (\text{activation}(W_1 x + b_1))$
 ■ b_2 .
2. W_1 has shape $[d_{\text{model}}, d_{\text{ff}}]$ and W_2 has shape $[d_{\text{ff}}, d_{\text{model}}]$, with d_{ff} usually 4 times d_{model} .
3. The 4x ratio is a convention from the 2017 paper, where d_{model} was 512 and d_{ff} was 2048. It is not a law and modern models vary it.
4. The activation function was ReLU in 2017, then GELU in BERT and GPT-2, and now SwiGLU in most current models. Chapter 46 covered what these do.
5. SwiGLU uses three matrices rather than two: a gate, an up-projection and a down-projection, with the gate multiplied elementwise into the up path.
6. Because it has three matrices, models using SwiGLU shrink d_{ff} to about 8/3 of d_{model} to keep the parameter count similar. Llama 3.1 8B uses 14,336 with d_{model} 4096, which is 3.5x rather than the naive 4x.
7. Now pre-norm versus post-norm, which is a real and consequential difference.
8. **Post-norm**, the 2017 original: $x \rightarrow \text{attention} \rightarrow \text{add } x \rightarrow \text{normalize}$. The normalization sits after the addition, on the main path.
9. **Pre-norm**, used by almost everything since about 2019: $x \rightarrow \text{normalize} \rightarrow \text{attention} \rightarrow \text{add } x$. The normalization sits inside the branch, and the main path from input to output has nothing on it but additions.
10. That difference is everything. In pre-norm, the residual stream is a clean sum with no normalization interrupting it, so the gradient path really is unobstructed all the way down.
11. In post-norm, every residual addition is immediately rescaled, which shrinks the accumulated signal and makes deep stacks unstable.
12. The practical consequence: post-norm transformers need a learning-rate warmup or they diverge. Pre-norm ones train stably without it.
13. The 2017 paper used post-norm with 4,000 warmup steps, and that warmup was not optional.

■ 48.8.5 TECHNICAL - the engineer's version

1. The complete pre-norm decoder block, drawn:

2. Parameter accounting per layer, $d = d_{\text{model}}$:

Component	Parameters	GPT-2 small
Attention (4 matrices)	$4 d^2$	2,359,296
FFN (2 matrices, $4 \times$)	$8 d^2$	4,718,592
Two LayerNorms	$4 d$	3,072
Block total	$12 d^2 + 4d$	7,080,960

- So the FFN is exactly two thirds of a classic block's parameters, from the ratio $8 d^2$ to $12 d^2$.
- For Llama 3.1 8B with SwiGLU: attention is 41,943,040 and the FFN is $3 \times 4096 \times 14336 = 176,160,768$, so the FFN is 80.8 per cent of the layer.
- Across the whole model, including the two 525,336,576-parameter vocabulary tables, the FFN share is 70.2 per cent and attention is 16.7 per cent. These figures match Chapter 47 exactly.
- Layer normalization is from Jimmy Lei Ba, Jamie Ryan Kiros and Geoffrey Hinton, July 2016. It normalizes over the feature axis of a single example, unlike batch normalization from Sergey Ioffe and Christian Szegedy in 2015, which normalizes over the batch axis.
- That distinction is why layer norm won in language models: batch statistics are useless when sequences have different lengths and batch size can be 1.
- RMSNorm is from Biao Zhang and Rico Sennrich, 2019. It drops the mean subtraction and the shift term, saving one reduction and d parameters per norm, for roughly the same quality.
- Epsilon inside the square root prevents division by zero. Typical values are $1e-5$ for LayerNorm and $1e-5$ or $1e-6$ for RMSNorm. This is an implementation detail that occasionally matters for numerical reproducibility.
- Pre-norm was analysed formally by Ruibin Xiong and colleagues in the 2020 paper "On Layer Normalization in the Transformer Architecture", which showed that post-norm gradients at initialization scale with the square root of depth while pre-norm gradients do not, explaining the warmup requirement.
- Baevski and Auli in 2018 and Nguyen and Salazar in 2019 had already reported the practical benefit. GPT-2, in February 2019, used pre-norm.
- A third variant exists: sandwich norm, or normalization both before and after the sub-layer, used in some very large training runs including Gemma 2 in 2024, to control activation growth.
- The residual stream view: because every block writes $x + f(x)$, the model's activations at layer L are the embedding plus the sum of every sub-layer's output so far. This decomposition is exact and is the foundation of mechanistic interpretability work, notably "A Mathematical Framework for Transformer Circuits" from Anthropic in December 2021.
- Observation: activation norms typically grow with depth in trained transformers, often by an order of magnitude from layer 1 to the last layer. This is measurable with a forward hook and is a routine sanity check when training goes wrong.

■ 48.8.6 WORDS – remember these

1. Feed-forward network — the widen-then-narrow part applied to each position — FFN or MLP, two or three linear layers with a non-linearity, d_{ff} typically about $4 \times d_{model}$.
2. Position-wise — applied to each token independently — the same weights applied to every position with no mixing across the sequence axis.
3. Residual connection — adding the input back onto the output — the identity shortcut $x + f(x)$, from ResNet in 2015.
4. Residual stream — the main pipe running the depth of the model — the d_{model} -wide activation that every block reads from and adds to.
5. Layer normalization — rescaling one token's numbers to a standard size — normalizing over the feature axis per example, with learned scale and shift.
6. RMSNorm — cheaper layer normalization — dividing by the root mean square with no mean subtraction and no shift term.
7. Pre-norm — normalize before the sub-layer, add after — the arrangement that keeps the residual path free of normalization, standard since about 2019.
8. Post-norm — normalize after adding — the 2017 arrangement, which needs learning-rate warmup to train stably.
9. SwiGLU — a gated activation using three matrices — swish-gated linear unit, standard in the Llama, Mistral and Qwen families.

48.9 The whole model, assembled

■ 48.9.1 PLAIN – in simple words

1. Everything so far has been parts. Here is the whole machine, in order.
2. Step 1: your text is chopped into tokens and each token becomes an integer id. Chapter 47 covered this.
3. Step 2: each id is used to look up a row in the embedding table. Now every token is a vector.
4. Step 3: position information is injected. In modern models this happens inside attention, as a rotation, rather than as an addition here.
5. Step 4: the stack. N identical blocks, one after another. Each block is attention then feed-forward, both with residual connections and normalization.
6. Identical means identical in shape, not in values. Every block has its own separate parameters.
7. Step 5: one final normalization at the top of the stack.
8. Step 6: multiply by one last matrix that turns each d_{model} -wide vector into one number per token in the vocabulary. Those numbers are called **logits**.
9. Step 7: softmax over the vocabulary turns the logits into probabilities that add up to 1.
10. The output is one probability distribution per input position. For a 10-token prompt, you get 10 distributions.
11. During generation you only use the last one, because that is the prediction for what comes next.
12. During training you use all of them, because each position is a separate prediction problem, which is why masked parallel training is so efficient.

■ 48.9.2 PLAIN – a picture in your head

1. Picture a tall narrow building with 32 identical floors.
2. On the ground floor, a crowd of people walks in. One person per token. Each is handed a card with numbers on it.
3. On every floor, two things happen. First everybody talks to everybody and updates their card based on what they heard. Then each person sits alone and thinks, updating their card again.
4. Nobody joins and nobody leaves. The same number of people walk out of floor 32 as walked into floor 1.
5. The cards get richer on every floor. A person who arrived holding only the word “it” leaves floor 32 holding something that encodes what “it” refers to, what grammatical role it plays, and what is likely to come next.
6. At the top, only the last person in the queue is asked a question: given everything you now know, what word comes next?
7. That person’s card is compared against a list of 128,256 possible words, and a score is produced for each.

Where this comparison breaks: the people do not know anything and are not thinking. Each is a vector being multiplied by matrices. And the last person’s answer is not derived from a conversation, but from a single dot product of their card against every row of a very large table. Also, at training time every person is asked a question, not just the last one.

■ 48.9.3 PLAIN – a worked example

1. Trace one prompt through Llama 3.1 8B, showing the tensor shape at every stage. Configuration: vocabulary 128,256, d_model 4,096, 32 layers, 32 query heads, 8 key-value heads, head dimension 128, d_ff 14,336.
2. The prompt is six tokens long, batch size 1.

stage	shape	numbers
-----	-----	-----
text	"the cat was hungry"	-
token ids	[1, 6]	6
embedding lookup	[1, 6, 4096]	24,576
block 1 input	[1, 6, 4096]	24,576
norm	[1, 6, 4096]	24,576
q after projection	[1, 32, 6, 128]	24,576
k after projection	[1, 8, 6, 128]	6,144
v after projection	[1, 8, 6, 128]	6,144
k,v repeated to 32 heads	[1, 32, 6, 128]	24,576
scores	[1, 32, 6, 6]	1,152
weights after softmax	[1, 32, 6, 6]	1,152
attention output	[1, 32, 6, 128]	24,576
after o_proj	[1, 6, 4096]	24,576
after residual add	[1, 6, 4096]	24,576
norm	[1, 6, 4096]	24,576
ffn hidden (gate and up)	[1, 6, 14336]	86,016
after down_proj	[1, 6, 4096]	24,576
after residual add	[1, 6, 4096]	24,576
block 2 ... block 32	[1, 6, 4096]	24,576
final RMSNorm	[1, 6, 4096]	24,576
lm_head projection	[1, 6, 128256]	769,536
softmax over vocabulary	[1, 6, 128256]	769,536
take last position	[1, 128256]	128,256

3. Read down the shape column. From the embedding to the final norm, the shape never changes: $[1, 6, 4096]$. That is the residual stream, and it is constant width for the entire depth.
4. The only places the shape changes are inside a block, temporarily, and at the very end.
5. The last projection is the expensive one in terms of output size. It turns 24,576 numbers into 769,536 numbers, because the vocabulary is large.
6. That final matrix, `lm_head.weight`, is $[128256, 4096]$, holding 525,336,576 parameters. It is 6.5 per cent of the model on its own.
7. Some models tie this matrix to the input embedding table, using the same numbers for both. GPT-2 does this. Llama 3.1 8B does not.
8. Tying halves the vocabulary cost. Untying gives slightly better quality at larger scale. This is a real trade-off and both choices are in current use.

■ 48.9.4 PLAIN – what is really happening inside

1. A **logit** is a raw score before it becomes a probability. That is its only definition. It can be any real number, positive or negative.
2. The name comes from statistics, where the logit function is the logarithm of the odds. In this context it just means “the thing softmax eats”.
3. There is exactly one logit per vocabulary entry. For Llama 3.1, 128,256 of them, every single time a token is produced.
4. Each logit is one dot product: the final hidden vector of length 4,096 dotted with one row of the output matrix, also length 4,096.
5. So the model is asking, for every possible next token: how well does my current state line up with the direction that means this token?
6. Softmax then converts. Exponentiate every logit, add them all up, divide.
7. A logit of 4.0 against a logit of 3.2 becomes probabilities 0.57 and 0.26, because what matters is the difference, not the absolute values.
8. Adding 100 to every logit changes nothing at all. Softmax is invariant to a constant shift. That is why logits are not comparable across models or even across steps.
9. During training, the loss is the negative log of the probability the model gave to the token that actually came next. That is cross-entropy loss, from Chapter 46.
10. If the model gave the right token probability 0.5, the loss is 0.693. If it gave 0.01, the loss is 4.605. The worse the guess, the larger the penalty, growing without bound.
11. Nothing else is optimized. There is no separate objective for grammar, for facts, or for helpfulness during pretraining. One number, minimized.

■ 48.9.5 TECHNICAL – the engineer’s version

1. Full forward pass, in the order the code runs:

```

h = embed_tokens(ids)                # [B, n, d]
for layer in layers:                 # N identical blocks
    r = h
    h = rmsnorm(h, layer.attn_norm)
    h = attention(h, rope, causal_mask) # +RoPE inside
    h = r + h
    r = h
    h = rmsnorm(h, layer.ffn_norm)
    h = swiglu_ffn(h)
    h = r + h
h = rmsnorm(h, final_norm)           # [B, n, d]
logits = h @ lm_head.T               # [B, n, vocab]
```

2. Reference configurations, all published:

Model	Layers	d_model	Vocab
Transformer base 2017	6 + 6	512	37,000
GPT-2 small 2019	12	768	50,257
Llama 3.1 8B 2024	32	4096	128,256
Llama 3.1 70B 2024	80	8192	128,256

- Total parameter count for Llama 3.1 8B, worked exactly: 32 layers of 218,112,000, plus 525,336,576 for the input embedding, plus 525,336,576 for the output projection, plus 4,096 for the final norm, giving 8,030,261,248.
- Activation memory for a forward pass is separate from weights and is dominated by the FFN hidden state. At $n = 4096$ and bfloat16, one layer's $[1, 4096, 14336]$ gate tensor is 117 MiB, and there are two of them.
- Weight tying is controlled by a flag, `tie_word_embeddings`, in the Hugging Face config. It is true for GPT-2 and for Gemma, false for Llama 3.1 8B.
- The final logit tensor is genuinely large. At $n = 4,096$ and vocabulary 128,256 in float32, the logits alone are 2.1 GiB. Training frameworks compute the loss in chunks along the sequence axis to avoid materializing it.
- At inference only the last position's logits are needed, so implementations slice the hidden state to $[B, 1, d]$ before the `lm_head` multiply. Skipping this is a common and expensive beginner mistake.
- Some models scale the logits. Gemma multiplies the embedding output by the square root of `d_model`; some models divide final logits by a constant, called logit softcapping, which Gemma 2 uses with a cap of 30.0 on the final layer.
- Numerical note: logits are computed in float32 even in bfloat16 models, because cross-entropy over 128,256 classes is sensitive to precision in the log-sum-exp reduction.

■ 48.9.6 WORDS - remember these

- Logit — a raw score before it is turned into a probability — the pre-softmax output, one per vocabulary entry, unbounded in both directions.
- `lm_head` — the final matrix that scores every possible next token — the $[\text{vocab}, d_{\text{model}}]$ output projection, sometimes tied to the input embedding.
- Weight tying — reusing the input embedding table as the output matrix — sharing one $[\text{vocab}, d]$ tensor for both, halving vocabulary parameters.
- Residual stream — the constant-width pipe running the depth of the model — the $[B, n, d_{\text{model}}]$ activation that all blocks read and write.
- Cross-entropy loss — how wrong the guess was, in one number — the negative log probability assigned to the correct next token, averaged over positions.
- Forward pass — running the model once from input to output — one evaluation of the network with no gradient computation.
- Hidden state — the working vector for one token at one depth — a `d_model`-wide slice of the residual stream at a given layer and position.

48.10 The 2017 paper

■ 48.10.1 PLAIN – in simple words

1. The transformer was introduced in one paper: “Attention Is All You Need”.
2. It was posted publicly on 12 June 2017, and presented at the NeurIPS conference in December 2017 in Long Beach, California.
3. There were eight authors: Ashish Vaswani, Noam Shazeer, Niki Parmar, Jakob Uszkoreit, Llion Jones, Aidan Gomez, Lukasz Kaiser and Illia Polosukhin.
4. Most were at Google Brain or Google Research. Aidan Gomez was at the University of Toronto, working with Google Brain.
5. The paper has an unusual footnote saying the authors contributed equally and the listing order is random. That was deliberate and unusual for the time.
6. It was a machine translation paper. Nothing in it is about chatbots, reasoning or general-purpose assistants.
7. The claim was narrow: you can throw away recurrence entirely and get better translation quality in a fraction of the training time.
8. The headline results were 28.4 BLEU on English-to-German and 41.8 BLEU on English-to-French, both on the WMT 2014 test sets.
9. BLEU is a machine translation score from 0 to 100 that measures overlap with human reference translations. Higher is better.
10. The 41.8 was a new single-model best, reached after 3.5 days on eight GPUs.
11. That last number is the point of the whole paper. Competing systems needed far more compute for worse results.
12. What was new was not attention. Attention had existed since 2014.
13. What was new was deleting the recurrent network and keeping only attention, which made the whole sequence processable in parallel.

■ 48.10.2 PLAIN – a picture in your head

1. Imagine a road crew resurfacing a long road, working one metre at a time, because each metre must set before the next can be laid.
2. Adding more workers does not help. The job is serial by construction.
3. Now imagine somebody invents a material that sets independently everywhere, so a thousand workers can lay a thousand metres simultaneously.
4. The material is not better. One metre of road is one metre of road. What changed is that the work is now divisible.
5. That is what removing recurrence did. It converted a serial job into a parallel one, and hardware that was already sitting idle could finally be used.

Where this comparison breaks: attention is not merely a parallel version of the same computation. It also gives every position direct access to every other position, which recurrence never did. So the change was both a speed change and a capability change, and the paper’s own results reflect both.

■ 48.10.3 PLAIN – a worked example

1. The two model sizes reported:

Setting	Base	Big
Parameters	65 million	213 million
d_model	512	1024
Heads	8	16

Setting	Base	Big
Training time	12 hours	3.5 days

- Both used 6 encoder layers and 6 decoder layers, and were trained on 8 NVIDIA P100 GPUs in one machine.
- The base model ran 100,000 steps at about 0.4 seconds each, which is 12 hours.
- The big model ran 300,000 steps at about 1.0 second each, which is 3.5 days.
- Now the parallelism argument in concrete terms. Take a 1,000-token training sequence.
- A recurrent model must execute 1,000 dependent steps. Each step is a small matrix multiplication that cannot fill a GPU, and between each pair of steps the chip waits.
- A transformer executes one matrix multiplication over all 1,000 positions. With $d_{\text{model}} = 512$, that single call is $2 \times 1000 \times 512 \times 512$, which is 524 MFLOP of dense work handed to the chip in one piece.
- The chip's utilization goes from a few per cent to near its limit, and the speed-up is far larger than the reduction in arithmetic.
- That is why the paper could report state-of-the-art translation from a single 8-GPU machine in under four days.

■ 48.10.4 PLAIN – what is really happening inside

- The architecture in the paper is an encoder-decoder, not the decoder-only design used by chat models today.
- The encoder has 6 layers, each with bidirectional self-attention and a feed-forward network. It reads the source sentence.
- The decoder has 6 layers, each with three sub-layers: causal self-attention over what has been produced so far, cross-attention into the encoder's output, and a feed-forward network.
- Post-norm was used throughout, with a warmup schedule that raised the learning rate for 4,000 steps then decayed it as the inverse square root of the step number.
- Dropout of 0.1 was applied to every sub-layer output and to the sum of the embedding and positional encoding.
- Label smoothing of 0.1 was used, which hurts perplexity and helps BLEU, and the paper says so plainly.
- Decoding used beam search with beam size 4 and length penalty 0.6.
- Every one of those settings is an ordinary engineering choice. None of them is the idea. The idea is one sentence: remove recurrence.

■ 48.10.5 TECHNICAL – the engineer's version

- Reported results, WMT 2014 test sets, from Table 2 of the paper:

System	EN-DE BLEU	EN-FR BLEU
Previous best single	25.16	41.29
Previous best ensemble	26.36	41.16
Transformer base	27.3	38.1
Transformer big	28.4	41.8

- Training cost in floating-point operations: $3.3e18$ for the base model and $2.3e19$ for the big model, both reported in the paper, and both one to two orders of magnitude below the competing systems in the same table.

3. The paper also reported English constituency parsing results, to argue the architecture generalizes beyond translation. Those results were good but not record-setting, and they are rarely cited.
4. The complexity table in the paper is worth knowing. Self-attention costs $O(n^2 d)$ per layer with $O(1)$ sequential operations and a maximum path length of $O(1)$ between any two positions.
5. A recurrent layer costs $O(n d^2)$ with $O(n)$ sequential operations and a maximum path length of $O(n)$.
6. So self-attention is cheaper than recurrence whenever n is less than d , which was true for translation sentences in 2017, where n was around 30 and d was 512.
7. Established fact: the architecture, the results and the training times are all in the published paper and have been reproduced many times.
8. **The honest version:** the paper did not predict what the transformer became. It contains no mention of language modelling at scale, no scaling laws, no in-context learning and no suggestion that this design would generalize to images, audio, protein structure or code.
9. The final sentence of the paper's conclusion is about applying attention to images, audio and video, and about making generation less sequential. Those were reasonable next steps, not a prediction of GPT-3.
10. The name "transformer" was chosen by Jakob Uszkoreit, and by several published accounts the team considered other names first. That is anecdote, not documented in the paper.
11. Reproduction is easy today. The `tensor2tensor` library released alongside the paper contained the original code, and Alexander Rush's annotated walkthrough from Harvard in 2018 reimplements the paper in a few hundred lines.

■ 48.10.6 WORDS - remember these

1. BLEU — a translation score based on word overlap — bilingual evaluation understudy, from Papineni and colleagues at IBM in 2002, scored 0 to 100.
2. WMT — the standard machine translation benchmark — the Workshop on Machine Translation shared task, with the 2014 English-German and English-French sets still used as reference points.
3. NeurIPS — the main machine learning conference — the Conference on Neural Information Processing Systems, called NIPS until 2018.
4. Encoder-decoder — one stack reads, another writes — the original transformer layout, with cross-attention linking the two.
5. Warmup — raising the learning rate slowly at the start — a schedule required by post-norm transformers, 4,000 steps in the 2017 paper.
6. Label smoothing — never demanding 100 per cent confidence — replacing the one-hot target with 0.9 on the correct class and the rest spread out.

48.11 The three architectures

■ 48.11.1 PLAIN – in simple words

1. The 2017 paper had two stacks: an encoder that reads and a decoder that writes. The field then split them apart and used them separately.
2. **Encoder-only**: keep the reading stack, throw away the writing stack. No causal mask, so every word sees every other word in both directions.
3. That is BERT, from Google in October 2018. It is superb at understanding a fixed piece of text and cannot generate text at all.
4. Use it for classification, for search, for named-entity extraction, and for producing embedding vectors of documents.
5. **Decoder-only**: keep the writing stack, throw away the reading stack. Causal mask, so every word sees only what came before.
6. That is the GPT line, and essentially every chat model you have ever used.
7. **Encoder-decoder**: keep both, as in the original. The encoder reads the input, the decoder writes the output, and cross-attention connects them.
8. That is T5, and most dedicated translation and speech-recognition models.
9. Decoder-only won for general-purpose models, and the reason is worth stating plainly.
10. A decoder-only model can do everything by writing. Ask it to classify, and it writes the class name. Ask it to translate, and it writes the translation.
11. Every task becomes text in, text out, so one model and one training objective covers all of them.
12. It also trains on more signal per token, needs no separate cross-attention machinery, and gets a prediction target at every position.

■ 48.11.2 PLAIN – a picture in your head

1. Think of three kinds of worker.
2. The encoder-only worker is a proofreader. Given a finished page, they read it forwards and backwards as many times as they like and tell you what it is about. They never write anything.
3. The decoder-only worker is a novelist writing live, one word at a time, never allowed to see the words they have not written yet.
4. The encoder-decoder worker is a translator. They read the whole source document freely, then write the translation one word at a time, glancing back at the source whenever they need to.
5. The novelist turned out to be the most useful, because you can ask a novelist to write a summary, a classification or a translation, and they will.

Where this comparison breaks: a proofreader could write if asked. BERT genuinely cannot, because it was never trained to predict a next token and its attention has no causal structure to build on. The limitation is architectural and training-based, not a matter of instruction.

■ 48.11.3 PLAIN – a worked example

1. Real models, sorted by architecture:

Model	Year	Architecture
BERT	2018	Encoder-only
RoBERTa	2019	Encoder-only
DeBERTa	2020	Encoder-only
T5	2019	Encoder-decoder
BART	2019	Encoder-decoder

Model	Year	Architecture
Whisper	2022	Encoder-decoder
GPT-2, GPT-3	2019, 2020	Decoder-only
Llama, Mistral	2023 on	Decoder-only
Qwen, Gemma	2023 on	Decoder-only
DeepSeek-V3	2024	Decoder-only

2. Sizes for the encoder models: BERT-base has 110 million parameters, 12 layers and d_model 768. BERT-large has 340 million, 24 layers and d_model 1024.
3. Notice that encoder-only models stopped getting bigger. Nobody built a 100-billion-parameter BERT, because the returns went to generative models.
4. Encoder-only models are still heavily used, and not as a legacy. Almost every semantic search system in production embeds text with a small encoder, because it is cheap, bidirectional and fast.
5. A concrete size comparison for a search system: an encoder producing a 384- dimensional embedding might have 22 million parameters and run in under a millisecond per short document on a CPU.

■ 48.11.4 PLAIN - what is really happening inside

1. The architectural differences reduce to two switches: is attention masked, and is there a second stack with cross-attention.
2. Encoder-only: no mask, one stack, no cross-attention.
3. Decoder-only: causal mask, one stack, no cross-attention.
4. Encoder-decoder: no mask in the encoder, causal mask in the decoder, plus cross-attention layers in the decoder.
5. Everything else, the blocks, the residuals, the normalization, the feed-forward networks, is identical in all three.
6. So they are not three architectures in any deep sense. They are one architecture with different masking and different wiring.
7. The training objective differs too, and that matters more than the wiring.
8. Encoder-only models are trained with masked language modelling, which corrupts about 15 per cent of tokens, giving a learning signal at 15 per cent of positions.
9. Decoder-only models are trained with next-token prediction, which gives a signal at 100 per cent of positions.
10. Encoder-decoder models like T5 use span corruption, dropping contiguous runs of tokens and asking the decoder to reproduce them.
11. That efficiency difference compounds over trillions of tokens, and it is a large part of why the decoder-only line scaled further.

■ 48.11.5 TECHNICAL - the engineer's version

1. T5, from Colin Raffel and colleagues at Google in October 2019, cast every task as text-to-text with a task prefix, and scaled from 60 million to 11 billion parameters.
2. T5 established the text-to-text framing that decoder-only models later adopted without needing the encoder.
3. The empirical comparison exists. The 2022 paper "What Language Model Architecture and Pre-training Objective Work Best for Zero-Shot Generalization?" by Thomas Wang and colleagues found that decoder-only with causal language modelling gave the best zero-shot performance af-

ter pretraining alone, while encoder-decoder with masked objectives was stronger after multitask fine-tuning.

4. So the decoder-only win is not absolute. It is a win under the specific regime that turned out to matter: pretrain once, then prompt.
5. Practical reasons decoder-only dominates in deployment:
 1. One stack means one set of key-value caches, so serving is simpler.
 2. The prompt and the generation share the same cache, so a long prompt costs one prefill pass and nothing more.
 3. Any input format can be expressed as text, so no schema changes are needed per task.
6. Encoder-decoder still wins where the input is genuinely a different modality or language from the output. Whisper, released by OpenAI in September 2022, is an audio encoder with a text decoder, and that split is natural.
7. Encoder-only remains standard for retrieval. The sentence-transformers library, from Nils Reimers and Iryna Gurevych in 2019, is the usual tool, and the MTEB leaderboard is the usual benchmark.
8. A hybrid worth naming: many modern retrieval systems now use decoder-only models with the causal mask removed for embedding, which works but requires adaptation training.

■ 48.11.6 WORDS – remember these

1. Encoder-only — reads text both ways, cannot write — a bidirectional transformer stack trained with masked language modelling.
2. Decoder-only — writes text one token at a time — a causally masked stack trained with next-token prediction.
3. Encoder-decoder — reads one sequence, writes another — two stacks joined by cross-attention, the original 2017 layout.
4. Bidirectional — able to use both left and right context — attention with no causal mask.
5. Span corruption — deleting runs of words and asking for them back — the T5 pretraining objective, replacing spans with sentinel tokens.
6. Text-to-text — every task expressed as text in and text out — the T5 framing, inherited by all current chat models.

48.12 Generation: producing text one token at a time

■ 48.12.1 PLAIN – in simple words

1. The model does not write a sentence. It writes one token, then starts again with that token appended.
2. The loop is simple. Feed in the prompt. Get a probability for every possible next token. Choose one. Append it. Feed in the whole thing again.
3. Stop when a special end-of-text token is chosen, or when a length limit is reached.
4. Every word you have ever seen a language model produce came out of this loop, one token at a time.
5. The interesting decision is step three: choose one. There are several ways.
6. **Greedy**: always take the highest-probability token. Fully deterministic and often dull and repetitive.
7. **Temperature**: divide all the logits by a number before softmax. Below 1 sharpens the distribution towards the top choice. Above 1 flattens it.

8. **Top-k**: keep only the k most likely tokens, throw the rest away, and sample from what remains after renormalizing.
9. **Top-p**, also called nucleus sampling: keep the smallest set of tokens whose probabilities add up to p, typically 0.9 or 0.95.
10. **Min-p**: keep tokens whose probability is at least some fraction of the top token's probability. It adapts to how confident the model is.
11. **Repetition and frequency penalties**: reduce the score of tokens that have already appeared, to stop loops.
12. **Beam search**: keep several candidate continuations alive at once and pick the best complete sequence at the end.
13. This is why the same prompt gives different answers. Unless you use greedy decoding, a random draw happens at every single token.

■ 48.12.2 PLAIN - a picture in your head

1. Picture a weather forecaster who can only forecast one hour ahead.
2. To forecast a whole day, they forecast hour one, write it down, then forecast hour two assuming hour one happened exactly as written.
3. Errors compound. If hour three is wrong, hours four to twenty-four are built on a mistake and cannot recover, because the forecaster treats their own written output as fact.
4. That is autoregressive generation, and it explains why long outputs drift.
5. Temperature is the forecaster's willingness to name an unlikely outcome. At temperature 0 they always say the single most likely thing. At high temperature they will occasionally forecast snow in July.

Where this comparison breaks: the forecaster knows their earlier forecast was a guess. The model has no such flag. Once a token is in the context, it is indistinguishable from text you wrote yourself, which is exactly why a model can confidently build on something it invented three sentences ago.

■ 48.12.3 PLAIN - a worked example

1. Take a real five-way choice. The model has produced "the cat sat on the" and these are the top five candidate logits:

token	logit
mat	4.0
floor	3.2
chair	2.5
roof	1.1
moon	0.4

2. Softmax at temperature 1.0 gives:

mat	0.5699	floor	0.2561	chair	0.1272
roof	0.0314	moon	0.0156		

3. Temperature divides every logit by T before the softmax. Here is the same distribution at several temperatures, computed exactly:

Token	T=0.5	T=1.0	T=2.0
mat	0.7965	0.5699	0.3933
floor	0.1608	0.2561	0.2636

Token	T=0.5	T=1.0	T=2.0
chair	0.0397	0.1272	0.1858
roof	0.0024	0.0314	0.0923
moon	0.0006	0.0156	0.0650

- At $T = 0.5$ the top token has 79.65 per cent, and “moon” has 0.06 per cent. At $T = 2.0$ the top token is down to 39.33 per cent and “moon” is up to 6.5 per cent, a hundredfold increase.
- At $T = 0.1$ the top token reaches 0.9997, which is greedy decoding in all but name. Temperature 0 is usually implemented as exactly greedy, since dividing by zero is undefined.
- Top-k with $k = 2$:** keep “mat” and “floor” only. Renormalize 0.5699 and 0.2561 by their sum 0.8260, giving 0.6900 and 0.3100. “chair” is now impossible.
- Top-p with $p = 0.9$:** accumulate from the top. 0.5699, then 0.8260, then 0.9531 which passes 0.9. So three tokens are kept, renormalized to 0.5979, 0.2687 and 0.1334.
- Note that top-p with 0.9 and 0.95 give the same set here, because the cumulative sum jumps from 0.826 to 0.953 in one step.
- Min-p with 0.1:** the threshold is 0.1 times the top probability, so $0.1 \times 0.5699 = 0.057$. Tokens above that are “mat”, “floor” and “chair”. Same set as top-p here.
- The methods differ on a peaked distribution. If the top token has 0.9947 and the rest share 0.0053, min-p keeps only “mat”, because the threshold is 0.0995 and nothing else clears it. Top-p at 0.9 also keeps only “mat”.
- On a flat distribution where the top is 0.2419, min-p’s threshold is 0.0242 and all five survive, which is the point: the cut adapts to confidence.
- Repetition penalty of 1.2** on a token already generated divides its logit by 1.2 when positive. “mat” goes from 4.0 to 3.3333, and its probability falls from 0.5699 to 0.4048.
- Frequency penalty of 0.5** subtracts 0.5 for each previous occurrence. If “mat” appeared twice, its logit drops from 4.0 to 3.0 and “floor” becomes the most likely token at 0.4002.

■ 48.12.4 PLAIN – what is really happening inside

- Generation has two phases, and they behave completely differently.
- Prefill:** the whole prompt goes through the model in one pass. All prompt positions are computed in parallel. This is compute-bound and fast per token.
- Decode:** each new token requires a full forward pass over one position. The model reads every weight in the file to produce one token.
- That is why decode is memory-bandwidth-bound. For an 8-billion model at 16-bit, each token requires reading 16 GB of weights from memory.
- On a card with 2,000 GB/s of memory bandwidth, that sets a hard ceiling of about 125 tokens per second for a single sequence, before any other cost.
- Beam search keeps b partial sequences alive, extends each by every candidate token, keeps the b best by total log probability, and repeats.
- It optimizes for the highest-probability complete sequence, which is exactly what you want in translation, where there is one correct output.
- It is wrong for chat for two reasons. The highest-probability continuation of open-ended text is bland and repetitive, a result documented by Ari Holtzman and colleagues in 2019. And beam search costs b times the compute and b times the key-value cache.
- So translation systems use beam 4 or 5. Chat systems use sampling with temperature and top-p, and never beam search.
- Why does the same prompt give different answers? Three separate reasons.

11. First, sampling. Every token is a random draw, so different random seeds give different text.
12. Second, even at temperature 0, floating-point addition is not associative. Changing the batch size changes the order of reductions inside the matrix multiplications, which changes the last bits of the logits, which can flip a near-tie between two tokens.
13. Third, providers change models, system prompts and serving configurations without notice. Determinism across dates is not offered by any major API.

■ 48.12.5 TECHNICAL – the engineer’s version

1. The autoregressive factorization: $P(x_1 \dots x_n) = \text{product over } t \text{ of } P(x_t \text{ given } x_1 \dots x_{\{t-1\}})$. Every generation method is a search or sampling strategy over this factorization.
2. Temperature applies as $\text{softmax}(z / T)$. It is a monotonic transform, so it never changes the ranking, only the gaps.
3. Method origins:

Method	Year	Source
Beam search	pre-1980s	speech recognition
Top-k	2018	Fan, Lewis, Dauphin
Top-p (nucleus)	2019	Holtzman and colleagues
Repetition penalty	2019	Keskar and colleagues, CTRL
Min-p	2024	Nguyen and colleagues

4. Typical production defaults as of 2026: temperature 0.7 to 1.0, top_p 0.9 to 1.0, top_k either 40 or disabled, repetition penalty 1.0 to 1.1. These are conventions, and every provider picks slightly different ones.
5. OpenAI’s API exposes `frequency_penalty` and `presence_penalty`, both in the range -2.0 to 2.0, applied additively to logits. Presence penalty applies once if a token has appeared at all; frequency penalty scales with the count.
6. The Hugging Face `generate` method applies processors in a fixed order: penalties first, then temperature, then top-k, then top-p, then min-p, then the sample. Order matters and is worth checking when results surprise you.
7. Greedy decoding is `do_sample=False`. Setting temperature to 0 in most APIs is mapped internally to greedy.
8. Speculative decoding, from Yaniv Leviathan, Matan Kalman and Yossi Matias at Google in 2022 and independently from DeepMind, uses a small draft model to propose several tokens and the large model to verify them in one pass. It is exact, meaning the output distribution is unchanged, and gives two to three times speedup in practice.
9. Constrained decoding masks logits to force valid JSON or a regular expression. Libraries such as `Outlines` and `llama.cpp`’s GBNF grammars do this by zeroing the probability of any token that would break the grammar.
10. Established fact: sampling parameters change output distribution in exactly the ways computed above. Active research: which defaults are best for which task. Marketing claim: any statement that a specific temperature makes a model “more creative” in a measurable, general sense.

■ 48.12.6 WORDS – remember these

1. Autoregressive generation — writing one token at a time, feeding each back in — sampling from $P(x_t \text{ given all previous tokens})$ in a loop.
2. Greedy decoding — always take the most likely token — `argmax` over logits, fully deterministic given identical arithmetic.

3. Temperature — a dial that flattens or sharpens the choice — the divisor T in $\text{softmax}(z / T)$, with T below 1 sharpening.
4. Top-k sampling — only consider the k best candidates — truncate to the k highest logits, renormalize, sample.
5. Top-p sampling — consider just enough candidates to cover p of the mass — nucleus sampling, keeping the smallest prefix of the sorted distribution summing to at least p .
6. Min-p sampling — keep anything within a fraction of the top choice — a threshold of p times max probability, adapting to model confidence.
7. Beam search — keep several drafts alive and pick the best — breadth-limited search over sequences, standard for translation, unsuitable for chat.
8. Prefill — processing the whole prompt at once — the parallel phase of inference, compute-bound.
9. Decode — producing one token per forward pass — the sequential phase, memory-bandwidth-bound.
10. Speculative decoding — a small model guesses, a big model checks — a draft-and-verify scheme that preserves the output distribution exactly.

48.13 The cost of attention: the quadratic problem

■ 48.13.1 PLAIN – in simple words

1. Attention compares every token with every token. For n tokens that is n times n comparisons.
2. Double the length and the work quadruples. Ten times the length and the work goes up a hundredfold.
3. That is what “quadratic” means, and it is the single biggest engineering problem in the architecture.
4. At 1,000 tokens it is a million comparisons, which is nothing.
5. At 1,000,000 tokens it is a trillion comparisons, which is an enormous amount for a single layer of a single head.
6. There is a second cost, separate and often larger in practice: the **key-value cache**.
7. When generating, the model has already computed the keys and values for every earlier token. Recomputing them every step would be wasteful, so they are stored.
8. That store grows with every token generated, and it must live in fast memory next to the chip.
9. For a 70-billion-parameter model, every token of context costs 320 kilobytes of cache. A 128,000-token conversation costs 40 gigabytes.
10. That is more than the model itself in some configurations, and it is why long-context serving is expensive.
11. There are four families of fix, and three of them are in production today.
12. Make the exact computation memory-smarter (FlashAttention). Share keys and values across heads (grouped-query attention). Restrict which tokens can be looked at (sliding window, sparse). Or replace attention with something cheaper (linear attention, state-space models).

■ 48.13.2 PLAIN – a picture in your head

1. Picture a party where every guest must shake hands with every other guest.
2. With 10 guests that is 45 handshakes. Manageable.
3. With 1,000 guests it is 499,500. With 100,000 guests it is about 5 billion.
4. The number of guests grew by a factor of 100 and the handshakes grew by a factor of 10,000.
5. Nobody solves this by shaking hands faster. You solve it by changing the rules: only shake hands with the nearest twenty people, or shake hands in small groups, or appoint representatives.

- Every one of those is a real technique in the list of fixes.

Where this comparison breaks: a handshake is symmetric and attention is not. Token 5 attending to token 2 is a different computation from token 2 attending to token 5, and in a causal model only one of the two happens at all. So the true count is $n(n+1)/2$, not $n(n-1)/2$, and the arithmetic differs by a factor of about two rather than the shape being different.

■ 48.13.3 PLAIN – a worked example

- The score matrix has n squared entries. Here is what that means, with the memory it would take at 16 bits per number, for a single head in a single layer:

Tokens	Entries	Memory, one head
1,024	1,048,576	2 MB
32,768	1,073,741,824	2,048 MB
131,072	17,179,869,184	32,768 MB
1,048,576	1,099,511,627,776	2,097,152 MB

- Read the last row again. Two terabytes, for one head, in one layer, for one sequence.
- A model like Llama 3.1 8B has 32 heads in each of 32 layers. If you tried to store the score matrices for a 131,072-token sequence in one layer, that is 32 times 32,768 MB, which is 1,024 GiB.
- No accelerator has that memory. This is why the naive implementation simply cannot run at long context, and why FlashAttention exists.
- Now the cost of attention relative to the rest of the model. The score computation costs about $4n$ squared d operations per layer, and the feed-forward network costs about $16nd$ squared.
- Setting those equal gives a crossover at $n = 4d$. For Llama 3.1 8B with $d = 4096$, that is 16,384 tokens.
- Below 16,384 tokens the feed-forward network dominates the compute. Above it, attention does. Measured for that configuration:

Sequence length	Attention share
512	2 per cent of FFN
4,096	19 per cent of FFN
24,576	114 per cent of FFN
131,072	609 per cent of FFN

- Now the key-value cache, computed exactly. The formula is $2 \times \text{layers} \times \text{kv\_heads} \times \text{head\_dim} \times \text{bytes}$, per token.
- For Llama 3.1 8B: $2 \times 32 \times 8 \times 128 \times 2 = 131,072$ bytes per token, which is exactly 128 KiB.

Context	Llama 3.1 8B	Llama 3.1 70B
2,048 tokens	0.25 GiB	0.62 GiB
32,768 tokens	4.00 GiB	10.00 GiB
131,072 tokens	16.00 GiB	40.00 GiB

- Without grouped-query attention, using 32 key-value heads instead of 8, the 8B model's cache would be 512 KiB per token, so 64 GiB at full context instead of 16 GiB. That single design choice saves four times the memory.

11. Batching multiplies this. Serving 32 concurrent conversations of 8,192 tokens each on Llama 3.1 8B costs 32 GiB of cache, on top of 16 GB of weights.
12. That is the actual reason long context costs more per token in commercial APIs. It is memory, not arithmetic.

■ 48.13.4 PLAIN – what is really happening inside

1. **FlashAttention** is the most important fix, and it is important to understand what it is not. It is not an approximation. Its output is exactly the same as the naive implementation, bit-for-bit equivalent up to floating-point reassociation.
2. The insight is that the n -by- n score matrix never needs to exist all at once.
3. The naive implementation writes the whole score matrix to the chip's main memory, reads it back for the softmax, writes it again, and reads it again for the multiply by V .
4. Those trips to main memory are the bottleneck, not the arithmetic. Chapter 22 covered why: a GPU's arithmetic units are far faster than its memory.
5. FlashAttention splits Q , K and V into tiles that fit in the chip's small fast on-chip memory, and computes the output tile by tile, keeping a running softmax normalizer as it goes.
6. The running softmax is possible because of an algebraic trick published by Maxim Milakov and Natalia Gimelshein in 2018, called online softmax, which lets you update a softmax result as new terms arrive.
7. The score matrix is therefore never stored. Memory use drops from order n squared to order n , and the speed rises because far fewer bytes move.
8. **Grouped-query attention** attacks the cache instead. Instead of 32 separate key and value heads, use 8, and let four query heads share each one.
9. The cache shrinks by exactly that ratio, and the quality loss is small.
10. **Sliding window attention** simply forbids looking back more than w tokens. Cost becomes linear in n , and information travels further only by hopping layer by layer, at w tokens per layer.
11. **Linear attention** rewrites the formula so the value sum can be accumulated without ever forming the score matrix, giving linear cost at the price of a weaker, approximate similarity function.

■ 48.13.5 TECHNICAL – the engineer's version

1. FlashAttention, from Tri Dao, Daniel Fu, Stefano Ermon, Atri Rudra and Christopher Re, May 2022. FlashAttention-2 from Tri Dao, July 2023, improved work partitioning. FlashAttention-3, July 2024, targets Hopper-class hardware with asynchrony and low-precision paths.
2. Complexity: standard attention uses $O(n^2)$ memory. FlashAttention uses $O(n)$ and reduces high-bandwidth-memory accesses from $O(n^2 d)$ to about $O(n^2 d^2 / M)$, where M is on-chip SRAM size. Reported speedups on training are roughly 2x to 4x end to end.
3. It recomputes the attention matrix during the backward pass rather than storing it, trading a little arithmetic for a large memory saving. This is gradient checkpointing applied at kernel level.
4. Multi-query attention, from Noam Shazeer in November 2019, uses one key-value head for all query heads. Grouped-query attention, from Joshua Ainslie and colleagues at Google in May 2023, interpolates between the two.

Scheme	KV heads (32 q heads)	Cache size
Multi-head (MHA)	32	1.0x
Grouped-query (GQA)	8	0.25x
Multi-query (MQA)	1	0.031x

5. Multi-head latent attention, introduced in DeepSeek-V2 in 2024 and used in DeepSeek-V3, compresses keys and values into a low-rank latent vector and reconstructs them, cutting cache further than GQA at comparable quality.
6. Sliding window attention: Longformer, from Iz Beltagy, Matthew Peters and Arman Cohan in April 2020, combined a local window with a few global tokens. Mistral 7B, October 2023, used a 4,096-token window with 32 layers, giving a theoretical receptive field of 131,072 tokens.
7. Sparse attention: the Sparse Transformer, from Rewon Child, Scott Gray, Alec Radford and Ilya Sutskever in April 2019, used strided and fixed patterns to reach $O(n \sqrt{n})$. BigBird, from Manzil Zaheer and colleagues in July 2020, combined window, global and random attention and proved it is a universal approximator.
8. Linear attention: Angelos Katharopoulos and colleagues in June 2020 showed that replacing softmax with a kernel feature map lets you reorder the multiplications to get $O(n)$ cost, and that the resulting model is a recurrent network at inference. The paper is titled “Transformers are RNNs”.
9. Performer, from Krzysztof Choromanski and colleagues in September 2020, approximates the softmax kernel with random features. Reformer, from Nikita Kitaev, Lukasz Kaiser and Anselm Levskaya in January 2020, used locality-sensitive hashing.
10. **The honest version:** the approximate methods have largely not displaced exact attention in frontier models. Exact attention plus FlashAttention plus GQA is what production systems actually run as of 2026. The approximations remain valuable in specific niches.
11. State-space models are the serious current alternative. Mamba, from Albert Gu and Tri Dao in December 2023, uses a selective state-space layer with linear cost in sequence length and a constant-size state, so there is no growing key-value cache at all.
12. Mamba-2 followed in 2024 and showed a formal duality between state-space models and a restricted form of attention. Jamba, from AI21 Labs in March 2024, is a production hybrid interleaving Mamba and attention layers.
13. Active research, stated plainly: hybrid models are being trained at scale and show competitive quality with much better long-context economics. Whether they displace attention entirely is not known. Pure state-space models have measured weaknesses on tasks requiring precise recall of arbitrary earlier tokens, which is exactly what attention is good at.
14. Observation tooling: `nvidia-smi` shows memory use, but for cache accounting the useful figures come from the serving framework. vLLM, which implements PagedAttention from Woosuk Kwon and colleagues in 2023, reports cache block usage directly and manages the cache in fixed-size pages like an operating system manages virtual memory.

■ 48.13.6 WORDS - remember these

1. Quadratic complexity — work grows with the square of the length — $O(n^2)$ in sequence length for the score matrix and the weighted sum.
2. KV cache — stored keys and values so earlier tokens are not recomputed — $2 \times \text{layers} \times \text{kv\_heads} \times \text{head\_dim} \times \text{bytes per token of context}$.
3. FlashAttention — computing attention without ever storing the score matrix — an exact, IO-aware tiled kernel with online softmax and backward recomputation.
4. Online softmax — updating a softmax as new terms arrive — a rescaling recurrence that avoids a second pass over the scores.
5. Multi-query attention — one key-value head shared by all query heads — MQA, cutting cache by the number of heads at some quality cost.
6. Grouped-query attention — a few key-value heads shared in groups — GQA, the standard compromise, 8 KV heads for 32 query heads in Llama 3.

7. Sliding window attention — only look back a fixed distance — local attention with window w , giving linear cost and a layer-multiplied receptive field.
8. State-space model — a linear recurrence with a fixed-size state — the Mamba family, linear in sequence length with no growing cache.
9. PagedAttention — managing the cache in fixed-size blocks — the vLLM technique that removes cache fragmentation, modelled on virtual memory paging.

48.14 Mixture of experts: paying for a big model, running a small one

■ 48.14.1 PLAIN – in simple words

1. Every transformer block has two halves. Attention mixes information between tokens. The feed-forward network then thinks about each token on its own.
2. In an ordinary model there is exactly one feed-forward network per block, and every token goes through it. That block holds most of the model's numbers.
3. A **mixture of experts** model replaces that one feed-forward network with many copies of it, called **experts**, sitting side by side.
4. A tiny extra network called the **router** looks at each token and picks a small number of experts for it. Usually two, four or eight out of dozens.
5. Only the chosen experts run. The rest sit still and cost nothing in arithmetic for that token.
6. So the model is enormous when you count its numbers, and small when you count the work done for any one token.
7. This gives two different parameter counts, and the difference between them is the whole point of the idea.
8. **Total parameters** is every number in the file. It sets how much memory you need and how much a copy costs to store and to move.
9. **Active parameters** is how many numbers actually take part in producing one token. It sets the speed, the electricity bill and the training cost.
10. A real example: DeepSeek-V3, released December 2024, holds 671 billion parameters in total and uses 37 billion for each token. That is 5.5 per cent.
11. So it costs as much arithmetic per token as a 37-billion model, while holding the knowledge capacity of something eighteen times larger.
12. Nothing is free. You must keep all 671 billion numbers loaded, because you cannot know in advance which experts the next token will want.
13. That is the trade in one line: you pay in memory, and you are paid back in speed.
14. There is one nasty problem. Left alone, the router learns to send almost every token to the same two or three favourite experts, and the rest die.
15. Fixing that needs a deliberate extra pressure during training, and most of the engineering in this area is about exactly that.

■ 48.14.2 PLAIN – a picture in your head

1. Picture a large hospital with 64 specialist doctors and one triage nurse at the door.
2. You walk in. The nurse spends two seconds on you and sends you to two of the 64 doctors. You see those two. The other 62 never learn you existed.
3. The hospital still has to employ all 64, pay all 64, and keep 64 consulting rooms heated. That is the memory cost.
4. But your visit only occupies two doctors' time. That is the compute cost.
5. Now the failure. Suppose the nurse sends nearly everyone to Doctor Smith because Doctor Smith seemed good on the first day.
6. Doctor Smith sees thousands of patients and gets very good. The other 63 see nobody and stay bad. So the nurse sends even more people to Smith.
7. You have not built a hospital with 64 specialists. You have built an expensive building containing one overworked doctor.
8. To stop this the hospital management adds a rule: the nurse is penalized when the workload is uneven, whatever the nurse thinks is best.
9. That rule is real, and it has a name in the papers: a load balancing loss.

Where this comparison breaks: real experts are not topic specialists, and this is the single most over-sold part of the idea. The Mixtral paper of January 2024 looked for topic-based routing and did not find it. Tokens about medicine do not reliably go to a “medicine expert”. What routing does correlate with is much duller: token identity, position, and surface patterns such as indentation in code. Also, a patient sees one doctor and gets one opinion. A token gets a weighted blend of two experts' outputs, added together in proportion to the router's confidence.

■ 48.14.3 PLAIN – a worked example

1. We will build a mixture-of-experts model from a normal one, count the parameters exactly, and land on a real published model.
2. Start with the dense shape used earlier in this chapter: d_{model} 4096, feed forward width 14,336, SwiGLU with three matrices, 32 layers, 8 key-value heads, vocabulary 32,000.
3. One feed-forward network is $3 \times 4096 \times 14336 = 176,160,768$ parameters.
4. Attention in one layer is 41,943,040 parameters. Two norms are 8,192.
5. Now replace the single feed-forward network with 8 copies, and add a router that maps 4096 numbers to 8 scores: $4096 \times 8 = 32,768$ parameters.
6. The expert bank in one layer is $8 \times 176,160,768 = 1,409,286,144$.
7. One layer therefore holds:

attention	41,943,040
experts (8)	1,409,286,144
router	32,768
two norms	8,192
layer total	1,451,270,144
8. Thirty-two layers give 46,440,644,608. Add the two vocabulary tables, $2 \times 32,000 \times 4,096 = 262,144,000$, and a final norm of 4,096.
9. Total: 46,702,792,704 parameters, which is 46.7 billion.
10. That is Mixtral 8x7B, published by Mistral AI in December 2023, whose stated size is 46.7B. The arithmetic reproduces the published number exactly.
11. Now count what one token actually touches, with top-2 routing.

attention	41,943,040
2 experts of 8	352,321,536
router	32,768
two norms	8,192
per layer active	394,305,536
x 32 layers	12,617,777,152
+ two vocab tables	262,144,000
active total	12,879,921,152

12. That is 12.9 billion active parameters, which is also exactly the published figure. The ratio is 46.7 to 12.9, or 3.6 to 1.
13. Note what did not change: attention is dense. Every token runs the full attention block. Only the feed-forward half is sparse.
14. Now push the idea harder. Cut each expert into 8 narrower ones, so 64 experts, and route to 8 instead of 2.
15. The arithmetic per token is identical, because 8 narrow experts equal 2 wide ones. But the number of possible expert combinations explodes.
16. Choosing 2 from 8 gives 28 combinations. Choosing 8 from 64 gives 4,426,165,368. That is the argument for fine-grained experts.
17. Here is what real models do, as published by each laboratory:

Model	Total params	Active per token
Mixtral 8x7B, 2023	46.7B	12.9B
DBRX, 2024	132B	36B
Mixtral 8x22B, 2024	141B	39B
Grok-1, 2024	314B	about 79B
DeepSeek-V3, 2024	671B	37B
Llama 4 Scout, 2025	109B	17B
Qwen3-235B-A22B, 2025	235B	22B
Llama 4 Maverick, 2025	400B	17B
gpt-oss-120b, 2025	117B	5.1B
Kimi K2, 2025	1,000B	32B

18. Now the same table as one number, the fraction of the model used per token, sorted by date. The trend is the story:

Model	Year	Active fraction
Mixtral 8x7B	2023	27.6 per cent
Grok-1	2024	25.0 per cent
DeepSeek-V3	2024	5.5 per cent
Llama 4 Scout	2025	15.6 per cent
Qwen3-235B-A22B	2025	9.4 per cent
gpt-oss-120b	2025	4.4 per cent
Kimi K2	2025	3.2 per cent

19. Models are getting sparser. In 2023 a mixture-of-experts model used about a quarter of itself per token. By 2025, three per cent was normal.
20. Finally the memory bill. Mixtral 8x7B at 16 bits is 93.4 gigabytes of weights, which does not fit on one 80-gigabyte accelerator.

21. A dense model of the same speed, 12.9 billion parameters, would be 25.8 gigabytes and would fit on one card with room for a cache.
22. So you pay roughly 3.6 times the memory for roughly 1 times the arithmetic. Whether that is a good deal depends entirely on how many users you serve.

■ 48.14.4 PLAIN – what is really happening inside

1. Here is the whole mechanism for one token at one layer.

2. The router is one small matrix, of shape d_{model} by number of experts. For Mixtral that is 4096 by 8. It is trained by ordinary gradient descent.
3. It produces one score per expert. A softmax turns those into probabilities.
4. **Top-k gating** keeps the k highest, throws the rest away, and renormalizes the survivors so they add to 1.
5. Only the surviving experts are run. Their outputs are multiplied by their renormalized weights and added together.
6. The gate weight is what makes this trainable. Without it, the choice of expert would be a hard, non-differentiable decision with no gradient.
7. With it, the gradient can flow back through the weight and tell the router “this expert helped, raise its score” or “this one hurt, lower it”.
8. Now the collapse. The router and the experts learn at the same time, which creates a feedback loop.
9. An expert that gets slightly more tokens early gets more gradient updates, improves faster, produces better outputs, and so earns higher router scores.
10. That earns it more tokens still. Within a few thousand steps a handful of experts absorb nearly everything and the others are effectively dead weight.
11. The standard fix is a **load balancing loss**: an extra number added to the training loss that is smallest when every expert gets an equal share.
12. It pushes against the router’s preference. The model is being told, in effect, “spread the work, even if you would rather not”.
13. There is a second, purely practical constraint. On real hardware every expert is given a fixed-size buffer, called its **capacity**.
14. If more tokens are routed to an expert than its capacity allows, the extra tokens are **dropped**: they skip the feed-forward network entirely and pass through on the residual connection only.
15. Dropped tokens are not an error. They are a deliberate trade that keeps the tensor shapes fixed so the hardware stays efficient.

16. Finally, where the experts physically live. A 671-billion-parameter model does not fit on one accelerator, so the experts are split across machines.
17. That is **expert parallelism**. Each device holds a few experts. Every token must be shipped to whichever devices hold its chosen experts, and the results shipped back.
18. So each mixture-of-experts layer contains two network exchanges: one to dispatch tokens, one to collect answers. On a slow network this, and not the arithmetic, becomes the limit.

■ 48.14.5 TECHNICAL – the engineer’s version

1. History. The idea is from Robert Jacobs, Michael Jordan, Steven Nowlan and Geoffrey Hinton, “Adaptive Mixtures of Local Experts”, Neural Computation, 1991. It predates the transformer by twenty-six years.
2. Noam Shazeer and colleagues, including Hinton and Jeff Dean, revived it for deep learning in January 2017 with “Outrageously Large Neural Networks: The Sparsely-Gated Mixture-of-Experts Layer”, reaching 137 billion parameters in an LSTM, with noisy top-k gating.
3. GShard, from Dmitry Lepikhin and colleagues at Google in June 2020, put MoE layers inside a transformer and trained a 600-billion-parameter translation model with automatic sharding.
4. Switch Transformer, from William Fedus, Barret Zoph and Noam Shazeer, January 2021, simplified routing to top-1 and scaled to 1.6 trillion parameters. Switch-C matched T5-Large’s compute per sequence at 2,000 times the size.
5. GLaM, from Nan Du and colleagues at Google, December 2021: 1.2 trillion total parameters, about 97 billion active per token, 64 experts per MoE layer, top-2. It reported better zero-shot quality than GPT-3 at about one third of the training energy.
6. ST-MoE, from Barret Zoph and colleagues, February 2022, introduced the router z-loss and produced ST-MoE-32B at 269 billion parameters.
7. Routing mathematics. With router matrix W_r , gate $g = \text{softmax}(x W_r)$, top-k index set T , and renormalized weights $g_i / \sum_{j \in T} g_j$:

```

scores  = x @ W_r                # [n_tok, n_exp]
probs   = softmax(scores, dim=-1)
val, idx = topk(probs, k)         # weights, expert ids
val     = val / val.sum(-1, keepdim=True)
y = zeros_like(x)
for slot in range(k):
    for e in range(n_exp):
        m = idx[:, slot] == e
        y[m] += val[m, slot, None] * expert[e](x[m])

```

8. The Switch Transformer auxiliary loss, which is still the default in most frameworks:

```

f_i = fraction of tokens in the batch routed to expert i
P_i = mean router probability assigned to expert i
L_aux = alpha * N * sum over i of ( f_i * P_i )
alpha = 0.01, N = number of experts
minimum value 1.0, reached when all f_i = P_i = 1/N

```

9. The product $f_i P_i$ is the trick. f_i is a count and has no gradient. P_i is differentiable. Multiplying them gives the router a gradient proportional to how overloaded each expert already is.
10. Router z-loss, from ST-MoE: the mean of the squared log-sum-exp of the router logits, with coefficient 0.001. It keeps logits small, which improves numerical stability in bfloat16 and reduces round-off in the softmax.
11. **Expert capacity** = (tokens per batch / number of experts) $\times$ capacity factor. Typical capacity factors are 1.0 to 1.25 in training and higher at evaluation. Overflow tokens are dropped to the residual.

12. Expert Choice routing, from Yanqi Zhou and colleagues at Google in 2022, inverts the problem: each expert picks its top tokens instead of each token picking its experts. Balance is then perfect by construction, but the method is not causal-safe for autoregressive decoding without care.
13. MegaBlocks, from Trevor Gale and colleagues in 2022, reformulates MoE as block-sparse matrix multiplication so no token is ever dropped and no padding is needed. It is used in several production stacks.
14. DeepSeek-V3, December 2024, made two notable changes. **Fine-grained experts**: 256 routed experts of intermediate width 2048, top-8, plus one **shared expert** that every token always uses, to hold common knowledge.
15. And **auxiliary-loss-free load balancing**: instead of an extra loss term, a per-expert bias is added to the routing scores and adjusted between steps, raised for underloaded experts and lowered for overloaded ones. The bias affects selection only, never the gate weight, so it adds no gradient interference.
16. Its reported training cost was about 2.788 million H800 GPU-hours on 14.8 trillion tokens. The compute rule C is about 6ND, covered in Chapter 49, uses the ACTIVE parameter count. That substitution is the entire economic case for MoE.
17. Expert parallelism. Experts are sharded across devices and each MoE layer performs two all-to-all collectives, dispatch and combine. Communication per token per layer is about $2 \times k \times d_{\text{model}} \times \text{bytes across the fabric}$.
18. DeepSeek-V3 bounded this with node-limited routing, capping each token at 4 nodes, and overlapped communication with computation using a scheme it calls DualPipe. Frameworks that implement expert parallelism include DeepSpeed-MoE from Samyam Rajbhandari and colleagues in 2022, Tutel from Microsoft, and Megatron-Core.
19. Serving arithmetic intensity. At batch size 1 you read only k experts. At batch size 256 the tokens collectively select nearly every expert, so you read the whole expert bank anyway. MoE therefore looks cheap at small batch and behaves closer to dense at large batch.

Setting	Weights read per step
Dense 13B, any batch	26 GB at bf16
MoE 47B, batch 1	about 27 GB
MoE 47B, batch 256	up to 93 GB

20. **Established fact.** Sparse models reach a lower pretraining loss than dense models given equal training compute; this was measured by GShard, Switch and GLaM and has been reproduced many times. Active parameters set FLOPs and training cost. Total parameters set memory. All experts must be resident. Unbalanced routing occurs reliably without a balancing mechanism.
21. **Active research.** How to compare an MoE against a dense model fairly, and what the right ratio of total to active parameters is. Whether experts specialize in any human-meaningful way; the current evidence is weak. Routing without auxiliary losses. Expert merging and pruning after training. Whether the shared-expert design is genuinely better or merely convenient.
22. **Vendor claim.** Headline parameter counts. A “1 trillion parameter model” that activates 32 billion is not equivalent to a dense trillion-parameter model, and no laboratory has demonstrated that it is. A common informal rule of thumb places MoE quality near the geometric mean of active and total parameters, which for Mixtral 8x7B would be about 24.5 billion; this is a heuristic, not a measured law, and should not be quoted as one.
23. Also vendor claim, by omission: GPT-4 has been widely reported to use a mixture-of-experts design since 2023, but OpenAI has never confirmed its architecture or parameter count. Treat any

specific number you see for it as unverified.

24. Observation. For an open-weights model, safetensors index files list every expert tensor by name, so total parameters are directly countable. Active parameters must be derived from the config: `num_local_experts` and `num_experts_per_tok` in a Hugging Face config.json give `k` and `N`. Serving frameworks such as vLLM and SGLang report expert-parallel placement and per-expert token counts, which is how you detect a collapsed router in production.

■ 48.14.6 WORDS – remember these

1. Mixture of experts — many small networks with a chooser in front — MoE, replacing a dense feed-forward layer with `N` experts and a learned router.
2. Expert — one of the interchangeable feed-forward networks — a standard FFN or SwiGLU block, one of `N` per MoE layer.
3. Router, or gate — the small network that picks experts — a `d_model` by `N` matrix followed by softmax and top-`k` selection.
4. Top-`k` gating — take the `k` best experts and ignore the rest — hard sparse selection with renormalized gate weights, `k` typically 1, 2 or 8.
5. Total parameters — every number in the model file — the figure that sets memory, storage and download size.
6. Active parameters — the numbers used for one token — the figure that sets FLOPs per token, latency and training compute in `C` is about $6ND$.
7. Load balancing loss — an extra penalty for using experts unevenly — the Switch auxiliary loss $\alpha N \sum f_i P_i$, α typically 0.01.
8. Router z-loss — a penalty that keeps router scores small — the mean squared log-sum-exp of router logits, coefficient about 0.001, for stability.
9. Expert capacity — the fixed number of tokens an expert will accept — buffer size = tokens/experts x capacity factor; overflow tokens are dropped.
10. Token dropping — skipping the feed-forward step for overflow tokens — those tokens pass through on the residual connection unchanged.
11. Shared expert — an expert every token always uses — the DeepSeek design for holding knowledge common to all inputs, alongside the routed experts.
12. Fine-grained experts — many narrow experts instead of few wide ones — same FLOPs, far more possible combinations, 64-choose-8 versus 8-choose-2.
13. Expert parallelism — experts split across devices — sharding along the expert axis, requiring two all-to-all collectives per MoE layer.
14. Sparse upcycling — turning a trained dense model into an MoE — copying the trained FFN into `N` experts and continuing training from there.

48.15 Why one architecture does so many tasks

■ 48.15.1 PLAIN – in simple words

1. This is the question most people actually want answered. One machine writes code, translates Hindi, summarizes a contract and holds a conversation. Why?
2. The short answer is that there is only one training task, and doing it well happens to require almost everything else.
3. The task is **next-token prediction**. Show the model some text, hide what comes next, make it guess, and correct it. Repeat trillions of times.
4. There is no list of skills. There is no separate summarizing module and no translation module. There is one number being pushed down: the prediction error.
5. Now the important argument. To predict text well, you must model whatever produced that text.
6. To finish “The capital of France is” you need a fact. Guessing needs knowledge, so knowledge lowers the error, so training installs knowledge.
7. To finish “for i in range(10):” you need to know what an indented block looks like. So the training installs the shape of Python.
8. To finish the last page of a detective novel you must have worked out who did it from the clues. So training rewards keeping track of a plot.
9. To finish a polite email you need to know how polite emails go. So training installs style and register.
10. Grammar, facts, arithmetic, tone, the structure of arguments, the layout of a table: every one of them lowers the prediction error, so every one of them gets learned.
11. Then the second half of the answer, which is easy to miss. Text on the internet already contains every task, written out in full.
12. An article is followed by its summary. An English sentence is followed by its French translation. A question is followed by an answer. A bug report is followed by a fix.
13. So when the text is arranged that way, predicting the next token IS doing the task. The task was never separate. It was always just more text.
14. That covers translation, summarizing and code. Then there is one behaviour that genuinely surprised the people who built it.
15. **In-context learning**. Put three worked examples in the prompt and the model does the fourth, for a task nobody trained it on and that may not exist anywhere in its training data.
16. Nothing inside the model changes. No number is updated. The examples sit in the input and the model behaves as if it had been taught. That was not designed. It was noticed.
17. Then **instruction following**: you write “Summarize this in three bullet points” and it obeys. Here we must be honest.
18. That is mostly not from pretraining. A raw pretrained model given that instruction is quite likely to continue with another instruction, because that is what usually follows an instruction on a web page.
19. Obedience is added afterwards, in a separate stage, using human-written examples and human preference data. Chapter 49 covers exactly how.
20. Finally, **emergence**: the claim that some abilities are absent in small models and appear suddenly in large ones. This one is genuinely disputed, and we will give both sides.

■ 48.15.2 PLAIN – a picture in your head

1. Imagine a person locked in the world’s largest library, playing one game, forever.
2. The game: open any book at any page, cover the next word, guess it, then uncover it and see if you were right. Score kept. No other instructions.

3. On day one they guess badly. Soon they learn that “the” is common, that a full stop is usually followed by a capital letter.
4. Keep going. Now they are playing on a chemistry textbook. To guess the word after “sodium reacts violently with” they have to learn chemistry.
5. Keep going. Now a French-English phrasebook, where every line is the same sentence twice. To win, they must learn to translate.
6. Keep going. Now the last page of a murder mystery. To guess the name after “the killer was” they must have followed the clues and solved it.
7. Nobody ever told them to learn chemistry, French or detective work. They learned all three because each one improved their score at one game.
8. That is the whole explanation of why one architecture does so many things. The tasks were never taught. They were the only way to win.

Where this comparison breaks: the person in the library knows they are playing a game, wants to win, and could stop. The model has none of that. It has no goal, no awareness that it is guessing, and no sense of being right or wrong. A person who does not know says so; the model always produces a full probability distribution over every possible next token, and something is always on top. Also, the person learns by understanding. The model learns by a mechanical adjustment of billions of numbers in the direction that lowers one error term.

■ 48.15.3 PLAIN – a worked example

1. Here is how four different-looking jobs become the same job. Each block is just text, and the model only ever continues it.

```
[ translation ]
English: the sea otter is asleep
French:

[ summarizing ]
<a 900-word article>
TL;DR:

[ code ]
# return the nth Fibonacci number
def fib(n):

[ conversation ]
User: what is the boiling point of water?
Assistant:
```

2. In every case the model does the same thing: predict what comes next. The task lives entirely in how the text was arranged.
3. The “TL;DR:” trick is not made up. The GPT-2 paper of February 2019 used exactly that string to get summaries out of a model that had no summarizing training at all.
4. Now in-context learning. This is the format from the GPT-3 paper of May 2020, which is where the phrase “few-shot” entered common use:

```
Translate English to French.
sea otter => loutre de mer
peppermint => menthe poivree
plush giraffe => girafe peluche
cheese =>
```

5. The three examples are not training data. They are input. They are thrown away when the request ends. The model's weights are identical before and after.
6. It works anyway, and it works better with more examples. Measured on the TriviaQA question-answering set with the 175-billion-parameter GPT-3:

Setting	Examples in prompt	Accuracy
Zero-shot	0	64.3 per cent
One-shot	1	68.0 per cent
Few-shot	64	71.2 per cent

7. Seven points of accuracy, bought with nothing but text in the prompt. No training, no weight change, no gradient.
8. Now the honest correction about instructions. Take a base model, before any fine-tuning, and give it this:

| Write a haiku about rain.

9. A base model may well continue like this, because that is what actually follows such a line on a real web page:

| Write a haiku about rain.
 | Write a limerick about a cat.
 | Write a short story about a lighthouse.
 | Submit your entries by Friday.

10. It is not being unhelpful. It is predicting correctly. It has recognized a list of writing prompts and is continuing the list.
11. Turning that into a model that answers is a separate stage of work, with its own data and its own cost, described in Chapter 49.

■ 48.15.4 PLAIN - what is really happening inside

1. One loss function drives everything. For each position, the model outputs a probability for every token in the vocabulary, and the loss is the negative logarithm of the probability it gave to the token that actually came next.
2. Averaged over the sequence, that single number is the whole training signal. There is nothing else. No task labels, no reward, no human in the loop.
3. Because the loss is per-position, one 8,192-token document gives 8,192 separate lessons in one pass. That is why the objective is so efficient.
4. **Implicit multitask learning** is the mechanism behind the range. The corpus contains question-answer pairs, parallel translations, code with comments, articles with headlines, arguments with rebuttals.
5. Each of those is a task demonstration that happens to be written down as ordinary text. The model never learns "this is translation". It learns that after a French colon, French words are likely.
6. The honest version: it is often said that models were never trained on these tasks. That is too strong. The tasks are present in the data in enormous quantity, just unlabelled. And since about 2023 laboratories deliberately mix instruction-shaped and textbook-shaped data into pretraining itself, so the clean story of pure raw web text is out of date.
7. In-context learning works differently, and we do have a partial mechanical account of it.
8. Earlier in this chapter we met **induction heads**: a pair of attention heads that between them find an earlier occurrence of the current token and copy what followed it.

9. That is a complete, if crude, pattern-completion machine built out of attention. Given “A B ... A” it predicts “B”. Given three translation pairs it can find the pattern and continue it.
10. So few-shot prompting is not the model learning. It is the model reading. The examples are in the context, and attention can reach them.
11. That is why in-context learning vanishes the moment the examples fall out of the context window. Nothing was stored. Nothing was learned in the sense of a weight changing.
12. Instruction following is the part that is genuinely bolted on. The base model has all the capability and none of the disposition to use it on request.
13. Fine-tuning on instruction-and-answer pairs changes which continuation is likely, not what the model knows. It is a change of habit, not of knowledge.
14. That distinction matters, because it explains a common observation: fine tuning for helpfulness can make a model slightly worse at raw prediction while making it far more useful.

■ 48.15.5 TECHNICAL – the engineer’s version

1. The objective, exactly. Maximize the log-likelihood of the corpus under the chain rule of probability, one factor per token:

$$\text{loss} = - (1/T) * \sum \text{over } t \text{ of } \log P(x_t | x_1 \dots x_{t-1})$$

2. This is cross-entropy between the model’s distribution and a one-hot target, in nats per token. Divide by $\ln 2$ for bits per token.
3. Shannon’s source coding theorem makes the connection to compression exact: the cross-entropy in bits per token is the size of the optimally compressed text under that model. Better prediction is literally better compression.

Method	Approximate bits per char
gzip on English prose	about 2.4
Shannon’s 1951 human study	0.6 to 1.3
Large model, held-out text	under 1.0

4. Claude Shannon’s “Prediction and Entropy of Printed English”, 1951, estimated English at roughly 0.6 to 1.3 bits per character by having humans guess next letters. Current models are inside that band on ordinary prose. Treat the figures above as approximate; they depend heavily on the text.
5. Zero-shot task transfer was demonstrated by GPT-2, “Language Models are Unsupervised Multi-task Learners”, from Alec Radford, Jeffrey Wu, Rewon Child, David Luan, Dario Amodei and Ilya Sutskever, February 2019, at 1.5 billion parameters.
6. Few-shot in-context learning was the headline result of GPT-3, “Language Models are Few-Shot Learners”, from Tom Brown and colleagues, May 2020, at 175 billion parameters.
7. Instruction tuning as a named technique: FLAN, “Finetuned Language Models Are Zero-Shot Learners”, Jason Wei and colleagues at Google, September 2021; and T0, “Multitask Prompted Training Enables Zero-Shot Task Generalization”, Victor Sanh and colleagues, October 2021.
8. Then InstructGPT, “Training language models to follow instructions with human feedback”, Long Ouyang and colleagues at OpenAI, March 2022. Its key measured result: human labellers preferred the outputs of the 1.3-billion-parameter InstructGPT model over the 175-billion-parameter GPT-3, a hundredfold size difference overturned by post-training alone.
9. That single result is the strongest available evidence that instruction following is added, not emergent. Full detail is in Chapter 49.

10. Now emergence, stated fairly, because this is contested.
11. **The claim.** “Emergent Abilities of Large Language Models”, Jason Wei, Yi Tay, Rishi Bommasani, Colin Raffel, Barret Zoph and others, June 2022, published in TMLR. Their definition: an ability is emergent if it is not present in smaller models but is present in larger models, and cannot be predicted by extrapolating from smaller models.
12. Reported examples include multi-digit arithmetic, word unscrambling and some of the harder tasks in BIG-bench, the 204-task benchmark released by Aarohi Srivastava and several hundred co-authors in June 2022, which itself reported “breakthrough” behaviour on some tasks.
13. **The critique.** “Are Emergent Abilities of Large Language Models a Mirage?”, Rylan Schaeffer, Brando Miranda and Sanmi Koyejo of Stanford, April 2023. Their argument: nonlinear or discontinuous metrics produce apparent emergence, while linear or continuous metrics on the same models produce smooth, predictable curves.
14. Their strongest evidence is constructive: they induced apparent emergence in simple vision models, where nobody claims it exists, purely by choosing a harsh metric. And they showed most BIG-bench emergence disappears when exact-match accuracy is replaced by token edit distance.
15. Here is the artefact in arithmetic you can check yourself. Suppose per-token accuracy improves smoothly with scale, and the answer is 10 tokens long, and the metric is exact string match, so all 10 must be right:

Per-token accuracy	10-token exact match
0.50	0.1 per cent
0.70	2.8 per cent
0.80	10.7 per cent
0.90	34.9 per cent
0.95	59.9 per cent
0.99	90.4 per cent

16. The left column rises steadily. The right column sits near zero, then leaps. Plot the right column against compute on a log axis and you get a cliff, and nothing whatsoever happened inside the model.
17. **The reply to the critique**, given fairly. Three points. First, the critique does not show that scaling is safe or fully predictable; it shows that one class of measurement exaggerates sharpness.
18. Second, many things people actually care about really are all-or-nothing. A program compiles or it does not. A proof is valid or it is not. If the metric that matters to the user is discontinuous, the user’s experience of a sudden capability jump is real, whatever the smooth underlying curve says.
19. Third, at least one genuine discontinuity has been found mechanistically, not metrically. “In-context Learning and Induction Heads”, Catherine Olsson and colleagues at Anthropic, March 2022, identified a visible bump in the training loss curve where induction heads form, accompanied by a jump in in-context learning ability. That is a phase change in the model, not in the scoring.
20. Relatedly, “Grokking”, from Alethea Power and colleagues at OpenAI in January 2022, showed genuine sudden generalization long after memorization on small algorithmic tasks. Sharp transitions do exist.
21. A later position, from Sheng Lu and colleagues at ACL 2024, argued that many claimed emergent abilities reduce to in-context learning plus instruction tuning rather than any new latent reasoning capacity.

22. **Established fact.** Next-token prediction is the sole pretraining objective. Pretraining loss falls as a smooth power law in compute, data and parameters, per Jared Kaplan and colleagues in January 2020 and Jordan Hoffmann and colleagues in March 2022. In-context learning is real and measurable. Instruction following comes overwhelmingly from post-training.
23. **Active research.** Why in-context learning works at all. One line of work, including Johannes von Oswald and colleagues in 2022, argues the forward pass implements something equivalent to gradient descent on the in-context examples; this is suggestive and not settled. Whether emergent abilities are real, artefactual, or both depending on the ability, is open, and reasonable researchers disagree in print.
24. **Marketing claim.** That emergence shows a model has begun to understand, reason or think. That is a philosophical claim dressed as a measurement. The “Sparks of AGI” paper from Microsoft in March 2023 was widely criticized on exactly this ground, including for evaluating an unreleased model version that others could not reproduce.
25. Also marketing: presenting a capability as spontaneous when it was in the fine-tuning mix. Without disclosure of the post-training data, which is almost never published, that distinction cannot be checked from outside.
26. Observation. Per-token loss and log-probabilities are the measurable quantities here, exposed as `logprobs` by most inference APIs and by `output_scores` in Hugging Face `generate`. Task-level claims are measured with harnesses such as EleutherAI’s `lm-evaluation-harness` or Stanford’s HELM, and the first thing to check in any emergence plot is which metric the y-axis uses.

■ 48.15.6 WORDS - remember these

1. Next-token prediction — guess the next piece of text — autoregressive language modelling with a cross-entropy loss over the vocabulary.
2. Pretraining objective — the one thing the model is scored on — maximizing log-likelihood of the corpus under the chain rule of probability.
3. Cross-entropy loss — how surprised the model was by the true next token — minus the log probability assigned to the target, in nats per token.
4. Implicit multitask learning — tasks learned without being labelled as tasks — task demonstrations occurring naturally in the pretraining corpus.
5. In-context learning — learning from examples in the prompt, with no weight change — conditioning on demonstrations within a single forward pass.
6. Few-shot prompting — putting a handful of examples in the prompt — k-shot conditioning, popularized by the GPT-3 paper of May 2020.
7. Zero-shot — asking with no examples at all — task specification by instruction or format alone, demonstrated by GPT-2 in February 2019.
8. Base model — a model that has only been pretrained — a pure next-token predictor with no instruction tuning and no preference optimization.
9. Instruction tuning — teaching the model to do what it is asked — supervised fine-tuning on instruction-and-response pairs, FLAN 2021, InstructGPT 2022.
10. Emergent ability — a skill said to appear only above some size — an ability absent in smaller models and present in larger ones, per Wei et al. 2022, with the sharpness disputed by Schaeffer et al. 2023.
11. Metric artefact — a jump caused by the ruler, not the thing measured — apparent discontinuity produced by exact-match or thresholded scoring.
12. Scaling law — the predictable fall in loss as you spend more — a power law in parameters, data and compute, per Kaplan 2020 and Hoffmann 2022.

48.98 Common wrong ideas

1. Wrong: attention means the model is focusing, the way a person concentrates. Right: attention is a weighted average. Every token computes a similarity score against every other token, those scores go through a softmax, and the result is used to mix value vectors. Nothing is ignored: after a softmax every weight is strictly greater than zero, so a “0.001” token still contributes. There is no spotlight, no effort and no choosing. The name is a 1990s metaphor from Bahdanau, Cho and Bengio’s 2014 alignment work, and it has misled more readers than it has helped.
2. Wrong: the transformer understands grammar, because everything it writes is grammatical. Right: grammatical output is evidence that grammatical continuations had low prediction loss, nothing more. The model holds no parse tree, no rule for subject-verb agreement and no category called “verb”. Probing studies do find syntax-correlated directions in the activations, and that is a genuine finding, but a correlated direction is not a rule. The honest test is behaviour on rare constructions, where models still fail in ways no speaker of the language would.
3. Wrong: a bigger context window means better memory. Right: the context window is the maximum input size for one request. Nothing persists between requests, and any apparent memory is your application resending the history. Accuracy also dips for material in the middle of a long input, and NVIDIA’s RULER benchmark in 2024 found many models advertising 32,000 tokens performed well only at much shorter lengths. Longer also costs more: at 131,072 tokens the key-value cache for Llama 3.1 70B is 40 GiB, on top of the weights.
4. Wrong: it predicts words. Right: it predicts tokens, which are subword pieces from a fixed vocabulary, typically 32,000 to 256,000 entries. “Unbelievable” may be three tokens; a leading space is usually part of the token; a number may split in places no human would choose. And it does not predict one token, it produces a probability for every token in the vocabulary at once, and then a separate sampling step picks one.
5. Wrong: more heads means more intelligence. Right: heads split the same d_{model} between them. With d_{model} 512, going from 8 heads to 16 halves the head dimension from 64 to 32. Total parameters and total FLOPs are unchanged. The 2017 paper measured this directly and found 1 head was worse than 8, and 32 heads were also worse than 8. Head count is a shape choice with an interior optimum, not a quality dial.
6. Wrong: emergent abilities prove something new appeared inside the model. Right: this is disputed in print. Wei and colleagues reported sharp jumps in 2022; Schaeffer, Miranda and Koyejo at Stanford argued in 2023 that the sharpness is often produced by all-or-nothing metrics, and demonstrated the effect by manufacturing fake emergence in vision models. Some genuine phase changes do exist, notably the formation of induction heads found by Anthropic in 2022. The correct position is that the metric must be checked before any claim about the model is made.
7. Wrong: a 671-billion-parameter mixture-of-experts model is equivalent to a dense 671-billion model. Right: it does the arithmetic of a 37-billion model per token. You get the memory bill of the large model and the speed of the small one. No laboratory has shown the quality matches a dense model of the same total size, and the informal geometric-mean rule of thumb is a heuristic, not a measured law.
8. Wrong: attention is where the model’s knowledge is stored, since attention is what makes it a transformer. Right: attention holds about 17 per cent of the parameters in Llama 3.1 8B; the feed-forward blocks hold about 70 per cent, rising to 81 per cent at 405B. Attention moves information between positions. The feed-forward blocks are where the storage happens.
9. Wrong: the transformer processes text left to right, like a person reading. Right: during training every position is computed at once in one matrix multiplication, which is the entire reason the architecture won. The causal mask enforces the ordering of information without enforcing an

ordering of computation. Only generation is sequential, and that is a property of writing text one token at a time, not of the architecture.

10. Wrong: setting temperature to 0 makes the model correct. Right: it makes the model deterministic, which is a different thing. Greedy decoding picks the highest-probability token every time, which removes variation and often produces repetitive text. If the highest-probability continuation is wrong, temperature 0 guarantees you get the wrong answer every time instead of some of the time.

48.99 Chapter summary in 20 lines

1. Before 2017 sequences were handled by recurrent networks, which kept one hidden state and updated it once per word, so information from early words faded and gradients vanished or exploded across hundreds of steps.
2. The fatal flaw was not memory but order: word ten could not be computed until word nine finished, so a chip with tens of thousands of parallel units sat idle, and no amount of hardware fixed it.
3. Attention removes the order constraint. Every position looks at every other position at once, scores them for relevance, and takes a weighted average of what it finds. The whole sequence becomes one matrix multiplication.
4. Each token is projected into three roles: a query saying what it is looking for, a key advertising what it offers, and a value carrying what it passes on if selected. Three learned matrices, three different jobs.
5. The formula is $\text{softmax}(\mathbf{QK}^T / \sqrt{d_k}) \mathbf{V}$. Dot products give similarity, division by $\sqrt{d_k}$ keeps the variance of the scores near 1 so the softmax does not saturate, softmax turns scores into weights that sum to 1, and the multiply by $\mathbf{V}$ collects the answer.
6. Without the $\sqrt{d_k}$ scaling, scores at $d_k = 64$ have standard deviation around 8, the softmax becomes nearly one-hot, and gradients through it fall towards zero. The scaling is not cosmetic.
7. A causal mask sets every score above the diagonal to minus infinity before the softmax, which makes those weights exactly zero. That is how a model is stopped from reading its own answer during training.
8. Multi-head attention splits d_{model} into h independent subspaces, runs attention in each, concatenates and projects. Parameters and FLOPs are unchanged; only the shapes differ. The 2017 paper measured 8 heads as better than 1 and better than 32.
9. Heads are not clean specialists. Some interpretable ones are real, notably induction heads that complete a repeated pattern and underlie in-context learning, but most heads resist a tidy description and many can be pruned.
10. Attention is permutation equivariant: shuffle the input and the output shuffles identically. It has no idea what order anything is in, so position must be injected deliberately.
11. Position schemes went sinusoidal in 2017, learned absolute in BERT and GPT, T5 relative bias in 2019, ALiBi in 2021, and rotary embedding in 2021. RoPE rotates queries and keys by an angle set by position, so scores depend on relative distance exactly, and it is the dominant choice as of 2026.
12. RoPE's base controls the slowest wavelength. Raising it from 10,000 to 500,000, as Llama 3.1 did in July 2024, is part of how a 131,072-token context is reached without the slowest frequency wrapping around.
13. After attention, each position passes alone through a feed-forward network that widens by roughly four times, applies a non-linearity such as SwiGLU, and narrows back. This block holds 70 to 81 per cent of a model's parameters and is where facts appear to be stored.
14. Residual connections add the input back to every sub-layer's output, giving gradients a clean

path through depth and creating a residual stream that every block reads from and writes to. Normalization, LayerNorm in 2017 and RMSNorm today, keeps activation sizes stable; pre-norm replaced post-norm around 2019 and removed the need for learning-rate warmup.

15. The assembled model is: embed token ids, add or rotate in position, run N identical blocks, normalize once more, multiply by the unembedding matrix, and read a probability over the whole vocabulary at every position.
16. The 2017 paper, "Attention Is All You Need" by Ashish Vaswani and seven co-authors, reached 28.4 BLEU on WMT 2014 English-German with the big model, beating every previous system at one to two orders of magnitude less training compute. It never mentioned scaling laws or in-context learning.
17. Three architectures came out of it: encoder-only for reading, such as BERT; decoder-only for writing, which is every chat model today; and the original encoder-decoder, joined by cross-attention, which survives in translation and in T5-style text-to-text framing.
18. Generation is a loop: feed everything, get a distribution, choose one token, append, repeat. The choice is greedy, or sampled with temperature, top-k, top-p or min-p. That sampling step, not the model, is why the same prompt gives different answers.
19. Attention costs $O(n^2)$. At 131,072 tokens the score matrix for one head in one layer would be 32 GiB, so nobody stores it: FlashAttention computes the same result tile by tile without ever writing it out, grouped-query attention shrinks the key-value cache fourfold, and sliding windows, sparse patterns and state-space models attack the problem from other directions.
20. Mixture of experts splits total from active parameters, letting DeepSeek-V3 hold 671 billion numbers while using 37 billion per token; and the reason one architecture does so many jobs is that it is trained on one objective, next-token prediction, which rewards grammar, facts, style and reasoning alike, with in-context learning arriving unplanned, instruction following added afterwards by fine-tuning, and emergence still argued over.

How a Model Is Actually Made — Pretraining to Release

49.0 What this chapter gives you

1. You will be able to name every stage that turns raw web text into a shipped chat model, in order, and say what each stage costs and what it changes.
2. You will be able to explain where training data comes from, how it is cleaned, and why the legal position around it is genuinely unsettled.
3. You will be able to describe one training step exactly: forward pass, loss, backward pass, optimizer update, and say what a good loss curve looks like.
4. You will be able to use the formula C is about $6ND$ to estimate the compute of any announced model, and check it against the figures the lab published.
5. You will be able to explain scaling laws, what Chinchilla changed in 2022, and why labs deliberately ignore Chinchilla for small models today.
6. You will be able to say why a base model cannot be used as a chatbot, and what supervised finetuning and preference optimization each add.
7. You will be able to explain RLHF, reward hacking, DPO, constitutional methods and verifiable-reward training, and when each is used.
8. You will be able to open a model directory and say what every file is, what format it is in, and which formats can execute code when loaded.
9. You will be able to state precisely what “open weights”, “open source”, “open data” and “permissive licence” each mean, and tell them apart.
10. You will be able to read a model card and a licence and say what the publisher withheld, and what that omission tells you.

49.1 The pipeline in one view

■ 49.1.1 PLAIN - in simple words

1. A chat model is not made in one step. It is made in a chain of stages.
2. Each stage takes the output of the one before and changes it.
3. Stage one is collecting text. Enormous amounts of text, mostly from the web.
4. Stage two is cleaning that text. Throwing away most of it, in fact.
5. Stage three is building the **tokenizer**, the fixed list of text pieces the model is allowed to see. Chapter 47 covered this in detail.
6. Stage four is **pretraining**. This is the long, expensive one. Weeks or months on thousands of machines, learning to predict the next piece of text.

7. What comes out of stage four is called a **base model**. It is not a chatbot. It continues text. It does not answer questions.
8. Stage five is **post-training**. This is where it learns to behave like an assistant: to answer, to follow instructions, to refuse harmful requests.
9. Post-training has parts of its own: showing it good examples, then teaching it which of two answers people prefer, then safety work.
10. Stage six is **evaluation**: measuring what the thing can and cannot do.
11. Stage seven is release: publishing the numbers, or putting them behind an interface, along with documents describing what was made.
12. The costs are wildly unequal. Pretraining is almost all of the money.
13. Post-training is a rounding error in compute, and yet it is what makes the difference between a strange text continuer and something you can talk to.
14. That imbalance is the single most useful fact in this chapter.

■ 49.1.2 PLAIN – a picture in your head

1. Think of how a doctor is made.
2. First, years of general education. School, then a science degree. Broad, slow, expensive, and not aimed at any one job.
3. That is pretraining. Enormous input, no particular task, no bedside manner.
4. A person at the end of that stage knows a great deal of biology and can still be useless in a consulting room.
5. Then comes clinical training. Watching a senior doctor, copying how they greet a patient, how they explain bad news, when they say “I do not know”.
6. That is supervised fine-tuning: learning the form of the job by imitation.
7. Then comes years of feedback. A supervisor says “that explanation was better than the one you gave yesterday”. Slowly the style settles.
8. That is preference optimization: learning from comparisons, not from corrections.
9. Then exams and a licence before anyone is allowed to practise unsupervised.
10. That is evaluation and release.

Where this comparison breaks: a medical student keeps learning after graduation. A shipped model does not. Its numbers are frozen at release and never change again unless the lab trains a new version and publishes a new file. Also, a doctor’s general education takes years and their clinical training takes years. In a model, the general education is 99 per cent of the cost and the clinical training is about 1 per cent. The proportions are nothing like a human career.

■ 49.1.3 PLAIN – a worked example

1. Here is the whole chain as a diagram. Follow the arrows left to right.

- Now the same chain as a table, with rough costs. These are typical orders of magnitude for a large 2024 to 2026 model, not exact figures for any one lab.

Stage	Share of GPU compute	Typical duration
Data collection, cleaning	Under 1% (CPU-heavy)	Weeks to months
Tokenizer training	Under 0.001%	Hours
Pretraining	95 to 99%	Weeks to months
Supervised fine-tuning	0.1 to 1%	Hours to days
Preference optimization	0.1 to 2%	Days
Evaluation, red-teaming	Under 1%	Weeks (human time)

- Note what that table says. Data cleaning is cheap in GPU terms and enormous in CPU and human terms. It runs on ordinary processors, not accelerators.
- Note also that evaluation and red-teaming take weeks of calendar time while using almost no compute, because the bottleneck is people.

■ 49.1.4 PLAIN – what is really happening inside

- What changes at each stage is worth being precise about.
- Data collection changes nothing in the model. There is no model yet.
- Tokenizer training produces a small file, a few megabytes, that fixes the vocabulary for the life of the model. Change it later and everything breaks.
- Pretraining sets every weight in the model, starting from random numbers. This is where essentially all of the model's knowledge is installed.
- Supervised fine-tuning changes every weight again, but only very slightly, using a dataset perhaps a millionth the size.
- Preference optimization changes every weight again, again slightly.
- Safety work is not a separate mechanism. It is more of the same fine-tuning, using data chosen to produce refusals and careful answers.
- Evaluation changes nothing. It only measures.
- So there is exactly one moment where the model gains its knowledge, and it is pretraining. Everything after that shapes how the knowledge comes out.
- That sentence needs a caution, which section 49.8 gives properly: the boundary is real but blurrier than it sounds.

■ 49.1.5 TECHNICAL – the engineer's version

- The canonical pipeline, with the standard names used in papers: corpus construction, tokenizer fitting, pretraining, mid-training or annealing, supervised fine-tuning, preference optimization, evaluation.

2. **Mid-training** is the newest of these names and dates from roughly 2024. It is a final pretraining phase on a much higher-quality mixture, with a decaying learning rate. Ai2’s Dolmino mixes and OLMo 2, published in January 2025, made the term common.
3. Compute is measured in floating-point operations, FLOPs, and in accelerator-hours. Both are reported. Neither alone tells you the cost.
4. Real reported compute for the pretraining stage of Llama 3.1, from Meta’s published model card of July 2024:

Model	GPU hours (H100-80GB)	Reported CO2eq
Llama 3.1 8B	1.46 million	420 tonnes
Llama 3.1 70B	7.0 million	2,040 tonnes
Llama 3.1 405B	30.84 million	8,930 tonnes

5. Those CO2 figures are location-based. Meta reported market-based emissions as zero, because it matches its electricity use with renewable purchases. Treat “zero” as an accounting statement, not a physical one.
6. Post-training compute is rarely published separately. Where it has been, it is well under 1 per cent of pretraining. InstructGPT, published by OpenAI in March 2022, reported its whole RLHF stage at about 60 petaflop-days against 3,640 petaflop-days for GPT-3 pretraining, roughly 1.6 per cent.
7. Established fact: pretraining dominates training cost. Active research: how much of final capability comes from post-training, especially for reasoning models where reinforcement learning budgets have grown sharply since late 2024. Marketing claim: any statement that a model was “built from scratch” when the lab in fact fine-tuned somebody else’s open-weight base model.

■ 49.1.6 WORDS – remember these

1. Pretraining — the long stage where the model learns from raw text — training a randomly initialized network on a large corpus with a next-token objective.
2. Post-training — everything done after pretraining to make it usable — supervised fine-tuning, preference optimization and safety tuning.
3. Base model — the raw output of pretraining — a text continuer with no chat template, no role notion and no refusal behaviour.
4. Corpus — the pile of text used for training — the deduplicated, filtered token stream fed to the pretraining loop.
5. Mid-training — a high-quality final stretch of pretraining — an annealing phase on a curated mixture with a decaying learning rate.
6. FLOP — one arithmetic operation on numbers with a decimal point — one floating-point operation, the standard unit of training compute.

49.2 The data: where it comes from and how it is cleaned

■ 49.2.1 PLAIN – in simple words

1. The model needs text. An almost unimaginable amount of text.
2. The biggest source is the open web, scraped by crawlers that follow links and save pages.
3. The best-known scrape is **Common Crawl**, run by a non-profit of the same name, which has been crawling since 2008 and gives its archives away free.
4. Common Crawl alone is not enough and is not good enough. Most of it is navigation menus, adverts, spam and duplicated boilerplate.

5. So labs add other sources: curated web pages, books, code from public repositories, scientific papers, forum posts, subtitles, reference works.
6. Some labs pay for data. News archives, stock photo libraries, forum archives and publisher catalogues have all been licensed for money.
7. And increasingly, labs make text with other models. That is called **synthetic data**.
8. Then comes the part nobody outside the field expects: most of it is thrown away.
9. A realistic pipeline keeps somewhere between 5 and 20 per cent of what it started with, and sometimes far less.
10. Removing near-duplicate pages alone can cut a web crawl in half.
11. What survives is a stream of trillions of tokens, where a token is roughly three-quarters of an English word.
12. The last twenty years of computing said “more data is better”. This field learned, roughly between 2022 and 2024, that better data is better.

■ 49.2.2 PLAIN – a picture in your head

1. Imagine you want to teach someone English by handing them paper.
2. You send a truck round a city and collect every piece of printed paper it can find. Newspapers, junk mail, receipts, packaging, books, love letters.
3. You get a warehouse full. Most of it is worthless for your purpose.
4. So you sort it. First you throw out everything not in English.
5. Then you notice that you have forty thousand copies of the same supermarket leaflet, so you keep one and burn the rest.
6. Then you throw out anything that is mostly numbers, menus or telephone listings, because reading it teaches nothing about language.
7. Then you black out every name, address and card number you find.
8. Then, before the exam, you check that the exam paper itself did not end up in the pile, because that would make the results meaningless.
9. What is left is a much smaller, much better warehouse.

Where this comparison breaks: paper sorting is done by people who understand what they are reading. Data cleaning is done by programs that mostly cannot. A quality filter is itself a small trained model making a guess, and it makes systematic mistakes: it tends to rate text that looks like a textbook highly and text written in dialect or by non-native speakers poorly. That bias goes straight into the finished model and nobody notices until much later.

■ 49.2.3 PLAIN – a worked example

1. Here is a real published data mixture. It is from the GPT-3 paper by Brown and colleagues in 2020, and it is one of the last fully published mixtures from a frontier lab.

Source	Tokens available	Share of training
Common Crawl, filtered	410 billion	60%
WebText2	19 billion	22%
Books1	12 billion	8%
Books2	55 billion	8%
Wikipedia	3 billion	3%

2. Read the two columns against each other. Wikipedia is 3 billion tokens out of 499 billion available, which is 0.6 per cent of the pile.

3. But it was given 3 per cent of the training weight. So during training, the model saw Wikipedia about 3.4 times over while seeing Common Crawl less than half way through.
4. That is what a **mixing ratio** does. It is a deliberate decision to over-sample good text and under-sample mediocre text.
5. Now a real published mixture from four years later. Meta’s Llama 3 paper of July 2024 gave the final proportions of its 15 trillion token mix:

Category	Share of the mix
General knowledge	50%
Maths and reasoning	25%
Code	17%
Multilingual	8%

6. Note that a quarter of the diet is maths and reasoning and a sixth is code, for a model most people use to write English prose.
7. That is not an accident. Code and maths are believed to improve general reasoning, and they are the two areas where correctness is checkable.
8. Note also what Meta did not publish: which datasets, which websites, which books, in what proportion, under what licence.

■ 49.2.4 PLAIN – what is really happening inside

1. Here is the cleaning pipeline in the order it actually runs.
2. **Extract.** A crawl file holds raw HTML. A tool pulls out the article text and drops the menus, headers, adverts and cookie banners. The library most commonly named for this in open pipelines is Trafilatura.
3. **URL filtering.** Drop whole domains from block lists: adult sites, known spam farms, malware hosts. Cheap and effective, done before anything else.
4. **Language identification.** A small classifier guesses the language of each document and scores its confidence. Keep only what you want, above a threshold. This is where most of a global crawl disappears.
5. **Exact deduplication.** Hash each document. Identical hash, identical document, keep one.
6. **Fuzzy deduplication.** Much harder and much more important. Two pages can differ by a date stamp and be otherwise identical. Section 49.2.5 gives the method, called MinHash.
7. **Quality filtering.** Two kinds. Heuristics: rules like “drop documents with fewer than 50 words”, “drop documents where more than 30 per cent of lines are duplicates”, “drop documents with no full stops”. And classifiers: a small model trained to score whether text looks like the good stuff.
8. **Toxicity and safety filtering.** Classifiers remove the most extreme material. This is a judgement call with real costs both ways, and labs differ on where the line goes.
9. **PII removal.** Personally identifiable information. Email addresses, phone numbers, public IP addresses are detected by pattern and masked.
10. **Decontamination.** Search the corpus for text that appears in the evaluation benchmarks and remove it. Otherwise the model has seen the exam.
11. **Mixing.** Assign weights to each remaining source and sample accordingly.
12. Every one of those steps discards data. The compounding is severe. Ten steps each keeping 80 per cent leave you with 11 per cent.

■ 49.2.5 TECHNICAL – the engineer’s version

1. Scale of the raw material. Common Crawl’s archive CC-MAIN-2025-30, crawled between 7 and 21 July 2025, holds 2.42 billion web pages, 419 TiB of uncompressed content, 114.15 TiB compressed. There are several such crawls per year and the organization has been publishing since 2008.
2. Formats: WARC holds the raw request and response, WAT holds metadata, WET holds extracted plain text. Serious pipelines re-extract from WARC rather than trusting WET.
3. Named public corpora, with real figures:

Corpus	Size	Published
The Pile (EleutherAI)	825 GiB, 22 sources	Dec 2020
C4 (from the T5 paper)	about 750 GB English	2019
Dolma (Ai2)	3 trillion tokens	2024
FineWeb (Hugging Face)	15T at v1.0, now 18.5T	Apr 2024
Dolma 3 (Ai2)	9.3 trillion tokens	Nov 2025

4. FineWeb’s published pipeline is the best documented open example. In order: URL filtering, Trafilatura extraction, a fastText language filter keeping English scores above 0.65, the Gopher repetition and quality filters, the C4 quality filters, custom heuristics, MinHash deduplication per crawl, and PII anonymization of emails and public IP addresses. Licence: ODC-By 1.0.
5. **MinHash deduplication**, properly. Cut each document into overlapping n-grams, called shingles. FineWeb uses 5-grams. Hash every shingle. For each of many hash permutations, keep only the minimum hash value. The resulting vector of minimums is the document’s signature.
6. The mathematical property that makes this work: the probability that two documents share a given minimum equals their Jaccard similarity, which is the size of the intersection of their shingle sets divided by the size of the union.
7. Signatures are then split into bands. FineWeb uses 14 bands of 8 hashes, so 112 hashes per document. Two documents are candidate duplicates if any one band matches exactly. This turns a quadratic all-pairs comparison into a hash-table lookup.
8. The detection curve for 14 bands of 8, computed from 1 minus (1 minus s to the eighth) to the fourteenth:

Jaccard similarity	Chance of being flagged
0.50	about 5%
0.75	about 77%
0.90	about 99.96%

9. So this configuration is a deliberate threshold at roughly 0.75. Change the bands and rows and you move the knee of that curve.
10. **Decontamination** is done by n-gram overlap against benchmark sets, often 13-gram or 8-gram matching. Ai2 published a dedicated tool called decon with OLMo 3 in November 2025. GPT-4’s technical report in March 2023 described substring-match contamination checks and reported that its results moved little when contaminated examples were removed.
11. Established fact: deduplication improves models. Lee and colleagues in 2021 showed deduplicated training data reduces memorized regurgitation by an order of magnitude and does not hurt, and often helps, perplexity.

12. Established fact: quality filtering beats raw volume at fixed compute. FineWeb-Edu, filtered by an educational-quality classifier, beat much larger unfiltered sets on knowledge benchmarks at the same token budget.
13. Now the honest part, on copyright. As of mid-2026 the legal position on training on copyrighted text is unsettled and actively litigated. Named cases you should know:

Case	Filed	Position
NYT v. OpenAI, Microsoft	Dec 2023	Live, dismissal denied
Kadrey v. Meta	Jul 2023	Live, mixed rulings
Bartz v. Anthropic	Aug 2024	Settled, 1.5bn USD
Thomson Reuters v. Ross	2020	Fair use rejected 2025

14. In Bartz v. Anthropic, Judge William Alsup ruled in June 2025 that training on lawfully bought and scanned books was fair use, but that keeping a library of pirated copies was not. Anthropic then agreed a settlement reported at 1.5 billion US dollars, roughly 3,000 dollars per work across about half a million works. Reported as the largest copyright settlement in United States history.
15. Read those two halves carefully, because they say different things. The training was found transformative. The acquisition was the problem.
16. In Thomson Reuters v. Ross Intelligence, Judge Stephanos Bibas held in February 2025 that the use was not fair. That case concerned a search tool rather than a generative model, so its reach is disputed.
17. The honest version: nothing here is settled. Different courts in different countries have reached different conclusions, appeals are pending, and the European Union, the United Kingdom and Japan have taken materially different statutory approaches to text and data mining.
18. Second honest point: **most labs no longer disclose their data mixture**. GPT-3 in 2020 published a table. GPT-4 in 2023 explicitly declined, citing competition and safety. Llama 3 in 2024 published category percentages but no source list. Gemini and Claude publish neither.
19. This is a genuine change in scientific norms and you should treat any claim about a closed model's training data, including claims about what it was not trained on, as unverifiable.
20. Third honest point: **data quality now matters more than quantity**. The reason is that the supply of high-quality human text is finite. Villalobos and colleagues estimated the stock of public human text at roughly 300 trillion tokens and projected full use somewhere between 2026 and 2032. That projection is contested, but the direction is not.
21. Tools you will actually use: datatrove and dolma for pipelines, fastText for language identification, datasketch or a custom Spark job for MinHash, and the Common Crawl index for selecting URLs without downloading the lot.

■ 49.2.6 WORDS – remember these

1. Common Crawl — a free archive of crawled web pages — a non-profit web corpus published since 2008 in WARC, WAT and WET formats.
2. Deduplication — removing repeated text — exact hashing plus fuzzy matching, usually MinHash with locality-sensitive hashing over shingles.
3. MinHash — a trick for spotting near-identical documents cheaply — a signature of minimum hash values whose collision rate equals Jaccard similarity.
4. Decontamination — checking the exam is not in the textbook — n-gram overlap removal of benchmark text from the pretraining corpus.

5. Mixing ratio — how much of each source the model sees — per-source sampling weights, expressed as epochs or proportions of the token budget.
6. Synthetic data — text written by another model — model-generated corpora used for pretraining, mid-training or instruction tuning.
7. PII — personal details about real people — personally identifiable information, detected by pattern and masked before training.

49.3 Pretraining itself

■ 49.3.1 PLAIN - in simple words

1. Pretraining has exactly one goal, and it is smaller than people expect.
2. Given some text, predict the next piece of text.
3. That is all. There is no second objective. Nobody labels anything. Nobody tells the model what is true.
4. The text itself is the answer key, because the next token is right there in the data.
5. This is why it is called **self-supervised**: the supervision comes free from the data, not from a human.
6. So the model reads “The capital of France is” and tries to guess the next token. It compares its guess to the real one, which is “Paris”.
7. If it guessed badly, every one of its billions of numbers gets nudged a tiny amount in the direction that would have made the guess better.
8. Then it does that again. And again. Trillions of times.
9. Nothing else happens. No rules are written down. No facts are stored as facts. Just this one loop, repeated at enormous scale.
10. And out of that loop comes something that can write working code and explain quantum mechanics. That is the surprising part, and it remains genuinely surprising to the people who build these things.

■ 49.3.2 PLAIN - a picture in your head

1. Imagine a person locked in a room with a printing press feeding them paper.
2. The paper always arrives with the last word covered by a sticker.
3. Their only job is to guess the covered word, then peel the sticker and see.
4. They are not told the meaning of anything. They get no explanations. They are never asked a question. They just guess and check, forever.
5. At first they guess randomly. After a while they learn that “the” is common.
6. Later they learn that after “the capital of France is” the covered word is almost always “Paris”. They have not been taught geography. They have been taught which word comes next.
7. After enough of this, to get the guesses right, they are forced to build something inside their head that behaves a great deal like understanding.

Where this comparison breaks: a person would get bored, would sleep, and would form intentions. The training loop has none of that. Also, a person reads in order and remembers yesterday. The model sees documents in shuffled order, in fixed-length chunks, and carries nothing between chunks except the weights it has changed. There is no continuous experience of any kind.

■ 49.3.3 PLAIN – a worked example

1. One training step, all the way through, with small round numbers.
2. Take a batch of 2,048 sequences, each 8,192 tokens long. That is 16,777,216 tokens in one step. Roughly 16.8 million.
3. **Forward pass.** Push all those tokens through the network. At every position the model produces a probability for every token in the vocabulary.
4. For a 128,256-token vocabulary that is 128,256 probabilities per position, which for this batch is about 2.15 trillion numbers produced and consumed.
5. **Loss.** At each position, look up the probability the model gave to the token that actually came next. Take the negative logarithm of it. Average over all 16.8 million positions.
6. That is **cross-entropy loss**, measured in nats per token.
7. Some real arithmetic on that. If the model gave the correct token a probability of 0.5, its contribution is 0.693. If 0.1, then 2.303. If 0.9, then 0.105. Confident and right is cheap. Confident and wrong is ruinous.
8. A model that guessed uniformly at random over 128,256 tokens would score the natural logarithm of 128,256, which is 11.76. That is the starting point.
9. **Backward pass.** Work out, for every one of the billions of parameters, which direction would have reduced that loss. This is backpropagation, and it costs roughly twice what the forward pass cost.
10. **Optimizer update.** Nudge every parameter a little in that direction. The size of the nudge is the learning rate, typically a few times ten to the minus five at the start of training.
11. Now discard the batch. It is never seen again. Load the next 16.8 million tokens and repeat.
12. To consume 15 trillion tokens at 16.8 million per step takes about 894,000 steps. Real runs are close to a million steps.

■ 49.3.4 PLAIN – what is really happening inside

1. The loss curve is the one picture that tells you whether a run is healthy.

2. What that shape means, in order.
3. The first drop, from about 11.8 to about 6, happens almost immediately. The model is learning which tokens are common. That is a few hundred steps.
4. The second phase, down to about 3, is learning basic word order and grammar. Still fast.
5. Then the long tail. From 3 down towards 1.5 takes 99 per cent of the run, and this is where everything interesting is learned.
6. A healthy curve is smooth, monotone downwards, and slightly noisy. Published final training losses for large models typically land somewhere between 1.4 and 2.0 nats per token, depending heavily on tokenizer and data mix.

7. An unhealthy curve has **spikes**: the loss jumps up sharply, sometimes by several nats, and either recovers over thousands of steps or never does.
8. A run that never recovers is said to have **diverged**. The loss goes to a large number or to not-a-number and the run is dead.
9. Causes: learning rate too high, a bad batch of data, numerical overflow in low precision, or a hardware fault corrupting a gradient.
10. The standard fix is brutal and simple: stop, load the last checkpoint, skip the batches around the spike, restart.
11. **Checkpointing** is what makes that possible. Every so often the whole training state is written to storage: weights, optimizer state, data position, random number generator state.
12. Note “optimizer state”. Adam keeps two extra numbers per parameter, so a training checkpoint is roughly three to four times the size of the final published model file.

■ 49.3.5 TECHNICAL – the engineer’s version

1. Objective: minimize the negative log-likelihood of the next token under a causal, decoder-only transformer, averaged over positions. Formally the loss is minus the mean over t of $\log p$ of $x_{\text{sub } t}$ given $x_{\text{sub } < t}$.
2. This is exactly maximum likelihood estimation. There is no auxiliary loss in a standard dense run beyond, in mixture-of-experts models, a load-balancing term to stop all tokens routing to one expert.
3. Optimizer: AdamW, from Loshchilov and Hutter in 2017, is near universal. Typical betas 0.9 and 0.95, epsilon $1e-8$, weight decay 0.1, gradient norm clipped at 1.0.
4. Real reported hyperparameters, Llama 3 405B, from Meta’s July 2024 paper: peak learning rate $8e-5$, linear warmup over 8,000 steps, cosine decay to $8e-7$ over 1,200,000 steps.
5. Batch size was ramped, not fixed: starting at 4 million tokens per batch with 4,096-token sequences, moving to 8 million tokens with 8,192-token sequences after 252 million tokens, and to 16 million tokens after 2.87 trillion tokens. Ramping the batch improves early-training stability.
6. Why warmup exists: at initialization the gradient estimates are poor and a full-size step can throw the weights somewhere unrecoverable. Warmup ramps the learning rate from near zero over the first few thousand steps.
7. Why decay exists: large steps explore, small steps settle. Cosine decay to about 1 per cent of peak is the long-standing default.
8. Changing as of 2024 to 2026: warmup-stable-decay schedules, which hold the learning rate constant for most of the run and decay sharply at the end. These allow a run to be extended without having chosen the end point in advance, which cosine does not. DeepSeek and several Chinese labs adopted multi-step or WSD schedules; the practice is now common but not universal.
9. A full set of real reported figures for one model, Llama 3.1 405B:

Quantity	Reported value
Parameters	405 billion
Training tokens	about 15.6 trillion
Accelerators	over 16,384 H100–80GB
GPU hours, pretraining	30.84 million
Context length, final	128,000 tokens

10. Derived figures from those, computed here rather than quoted: 30.84 million GPU-hours divided by 16,384 GPUs is 1,882 hours, which is 78.4 days of wall clock if every GPU ran the entire time.

11. Energy, GPU-only: 30.84 million hours times 700 watts is 21.6 GWh. Add host CPUs, memory, networking and cooling and 30 to 40 GWh is the plausible total, which is consistent with the 8,930 tonnes CO₂eq Meta reported at typical grid carbon intensity.
12. Cost, estimated not quoted: at public H100 rental rates of roughly 2 to 4 US dollars per GPU-hour in 2024 and 2025, 30.84 million GPU-hours is between about 62 and 123 million dollars for the pretraining compute alone.
13. That figure excludes salaries, failed runs, ablations, data licensing and the capital cost of the cluster. Reported “training cost” numbers almost always exclude those, and you should assume so unless told otherwise.
14. The contrasting example, and the reason to read cost claims carefully: DeepSeek-V3, published December 2024, is 671 billion total parameters with 37 billion active per token, trained on 14.8 trillion tokens in 2.788 million H800 GPU-hours. The report itself puts that at 5.576 million US dollars assuming 2 dollars per GPU-hour, and states plainly that the figure excludes prior research, ablations and data.
15. Failures are routine, not exceptional. Meta reported 466 job interruptions during a 54-day snapshot of the 405B run, of which 419 were unexpected, and around 78 per cent of those were confirmed or suspected hardware issues. Effective training time was still above 90 per cent.
16. Historical precedent worth knowing: Meta published the OPT-175B logbook in 2022, a day-by-day record of crashes, loss divergences and restarts. It remains the most honest public document about what a large run feels like.
17. Google’s PaLM paper in 2022 reported roughly 20 loss spikes and described the mitigation: restart from a checkpoint about 100 steps before the spike and skip 200 to 500 data batches.
18. Tools that observe a run: TensorBoard or Weights and Biases for curves, `nvidia-smi` and DCGM for device health, `torch.distributed` logs and NCCL debug output for collective failures, and the model’s own gradient-norm and learning-rate traces, which are usually logged every step.

■ 49.3.6 WORDS – remember these

1. Next-token prediction — guess the next piece of text — an autoregressive causal language modelling objective over a token vocabulary.
2. Cross-entropy loss — a score for how wrong a guess was — the negative log probability assigned to the observed token, averaged over positions.
3. Nat — the unit that loss is measured in — one unit of information using natural logarithms; multiply by 1.4427 to get bits.
4. Step — one round of guess, score, adjust — one forward pass, backward pass and optimizer update over one global batch.
5. Warmup — starting gently — ramping the learning rate from near zero over the first thousands of steps to avoid early instability.
6. Checkpoint — a saved snapshot to restart from — weights, optimizer moments, data-loader position and RNG state written to durable storage.
7. Divergence — a training run going permanently wrong — loss increasing without recovery, often to infinity or not-a-number.

49.4 Scaling laws: how big, how much data

■ 49.4.1 PLAIN – in simple words

1. Suppose you have a fixed budget of computing time. How should you spend it?
2. You have two dials. Make the model bigger, or feed it more text. You cannot max both, because both cost compute.
3. A **scaling law** is a measured answer to that question. Not a theory. A curve fitted to hundreds of small experiments and extended to large ones.
4. The first big one came from OpenAI in January 2020. Kaplan and colleagues measured how the loss falls as you increase model size, data and compute.
5. Their headline finding: the loss follows a smooth power law over more than seven orders of magnitude. It is astonishingly predictable.
6. Their practical advice: spend most of your extra budget on making the model bigger, and relatively little on more data. Stop training early.
7. The whole industry followed that advice. This is why 2020 to 2022 produced a race of enormous models trained on comparatively little text.
8. Then in March 2022, a team at DeepMind led by Hoffmann redid the experiment more carefully and found the advice was wrong.
9. Their model, Chinchilla, had 70 billion parameters and was trained on 1.4 trillion tokens. It beat Gopher, a 280-billion-parameter model trained on 300 billion tokens, using the same compute budget.
10. Four times smaller and better, because it saw four times more text.
11. Their rule of thumb: for each parameter, train on about 20 tokens.
12. That rule reshaped the field within about a year.
13. And then, from roughly 2023 onwards, labs started ignoring it on purpose.
14. The reason is money in a different place. Chinchilla asks how to get the best model for a fixed training budget. It says nothing about what the model costs to run afterwards.
15. If a model will answer a trillion questions, a smaller model that took longer to train is much cheaper over its life. So labs overtrain small models far past 20 tokens per parameter, on purpose.

■ 49.4.2 PLAIN – a picture in your head

1. Think about choosing an engine and a fuel tank for a delivery van.
2. A bigger engine is like more parameters. It can do more per unit of time.
3. More fuel is like more training data. It lets you go further.
4. You have a fixed amount of money. Spend it on engine or on fuel.
5. Kaplan's 2020 answer was: buy the biggest engine you can afford and put in just enough fuel to leave the yard.
6. Chinchilla's 2022 answer was: that is silly, you have bought an engine you cannot use. Buy a smaller engine and fill the tank properly.
7. And the 2024 answer is: wait, this van will do school runs every day for five years. The fuel to build it is nothing next to the fuel to run it. Buy the smallest engine that does the job, and train it as long as you like.

Where this comparison breaks: an engine's capability is fixed by its size and a model's is not. Two models with the same parameter count can differ hugely depending on data quality, architecture and post-training. The van analogy also suggests a hard ceiling, and there is no known hard ceiling here; the curves have simply not bent yet within the range anyone has measured.

■ 49.4.3 PLAIN – a worked example

1. The formula every practitioner uses for training compute is short: C is approximately 6 times N times D .
2. C is total floating-point operations. N is parameter count. D is number of training tokens.
3. Where the 6 comes from: each parameter does one multiply and one add per token in the forward pass, which is 2 operations. The backward pass costs about twice the forward pass, which is 4 more. Two plus four is six.
4. Work it for GPT-3, published 2020: 175 billion parameters, 300 billion tokens. 6 times $1.75e11$ times $3.0e11$ equals $3.15e23$ FLOPs. The GPT-3 paper reported $3.14e23$. The formula lands on the nose.
5. Work it for Llama 3.1 405B: 405 billion parameters, 15.6 trillion tokens. 6 times $4.05e11$ times $1.56e13$ equals $3.79e25$ FLOPs. Meta reported $3.8e25$. Again correct.
6. Now use it in the other direction. Suppose a lab announces a model with 70 billion parameters trained on 15 trillion tokens. 6 times $7e10$ times $1.5e13$ equals $6.3e24$ FLOPs.
7. An H100 does roughly 989 teraflops of dense bf16 arithmetic at peak, which is $9.89e14$ per second. Real utilization is 35 to 45 per cent, so call it $4e14$ achieved.
8. $6.3e24$ divided by $4e14$ is $1.575e10$ GPU-seconds, which is 4.375 million GPU-hours. On 4,096 GPUs that is 1,068 hours, or about 45 days.
9. You can now sanity-check any announcement in about a minute. If the numbers do not roughly agree, one of the published figures is wrong or incomplete.
10. Tokens-per-parameter for real models, which shows how far practice moved:

Model	Tokens per parameter	Versus Chinchilla
GPT-3 (2020)	1.7	12x undertrained
Chinchilla (2022)	20	the reference
Llama 3.1 405B (2024)	38.5	about 2x over
Llama 3.1 8B (2024)	about 1,875	about 94x over

11. Read the last row again. An 8-billion-parameter model was trained on 15 trillion tokens. That is roughly 94 times more text than the compute-optimal rule says is worth it.
12. Meta did that knowing it was compute-inefficient, because the 8B model is the one that gets deployed everywhere and its serving cost matters more.

■ 49.4.4 PLAIN – what is really happening inside

1. Why does a scaling law exist at all? Nobody fully knows. It is an empirical regularity, not a derived result.
2. What it says is that loss L falls as a power of the thing you scale. In words: doubling the model gives a fixed proportional reduction in loss, and that same proportional reduction keeps arriving for each further doubling.
3. Power laws are brutal in one direction and generous in the other. Each further step down in loss costs many times more compute than the last.
4. The Chinchilla correction was not a new idea, it was a better experiment. The 2020 work had used a fixed learning-rate schedule length for all runs, which quietly penalized the runs that used more data.
5. When Hoffmann's team varied the schedule to match each token budget, the optimum moved decisively towards more data.
6. The number 20 is not sacred. It is roughly where the fitted curve puts the optimum for that family of models and that data. Different data gives a different constant.

7. And the whole framework optimizes the wrong thing for a deployed product. It minimizes loss for a fixed training budget. It ignores inference.
8. Add inference to the objective and the optimum moves towards smaller models trained longer, exactly as practice has done.

■ 49.4.5 TECHNICAL – the engineer’s version

1. Kaplan and colleagues, “Scaling Laws for Neural Language Models”, 23 January 2020. Loss scales as a power law in model size, dataset size and compute, with trends spanning over seven orders of magnitude. Their compute-optimal allocation grows N much faster than D , with D scaling roughly as C to the 0.27 and N as C to the 0.73.
2. Hoffmann and colleagues, “Training Compute-Optimal Large Language Models”, 29 March 2022, known as Chinchilla. Over 400 models from 70 million to 16 billion parameters on 5 to 500 billion tokens. Conclusion: N and D should scale roughly equally, so for every doubling of model size you should double the tokens. The implied ratio is about 20 tokens per parameter.
3. Chinchilla itself: 70 billion parameters, 1.4 trillion tokens. It beat Gopher at 280 billion parameters on 300 billion tokens, and also beat GPT-3 at 175 billion and Megatron-Turing NLG at 530 billion, at equal compute.
4. What changed in practice: the 2023 Llama 1 release from Meta was explicitly framed around this, training 7B and 13B models on 1 trillion tokens, well past compute-optimal, arguing that inference cost is what matters.
5. Contested, and you should know this: a 2024 replication attempt by Besiroglu and colleagues re-fitted the third of Chinchilla’s three estimation methods and found the reported parameters inconsistent with the paper’s own data, with wider confidence intervals than stated. The headline conclusion survived. The precise constant did not.
6. The inference-aware reformulation was written down by Sardana and colleagues in 2023, “Beyond Chinchilla-Optimal: Accounting for Inference in Language Model Scaling Laws”. Adding expected lifetime inference tokens to the objective shifts the optimum to smaller, longer-trained models.
7. A cost model you can reason with: training costs $6ND$ once. Inference costs about $2N$ per generated token, forever. If a model will generate T tokens over its life, total compute is about $6ND$ plus $2NT$.
8. Put numbers in it. An 8-billion model trained on 15 trillion tokens costs $7.2e23$ FLOPs to train. Generating one token costs $1.6e10$. So the training cost equals about 45 trillion generated tokens. A busy service passes that in a couple of months.
9. Regulatory tie-in, which makes the formula matter legally. The European Union’s AI Act, in force since 1 August 2024 with general-purpose model obligations applying from 2 August 2025, uses a training-compute threshold of 10 to the 25 FLOPs as a presumption of systemic risk. Llama 3.1 405B at $3.8e25$ is above it. Llama 3.1 8B at $7.2e23$ is below it.
10. Separating the three kinds of claim, as of mid-2026: Established fact: loss follows smooth power laws in N , D and C over the measured range; Chinchilla’s directional correction to Kaplan; the $6ND$ approximation; the dominance of inference cost for widely served models. Active research: whether scaling continues past the current frontier, how to model data quality inside a scaling law, scaling laws for mixture-of-experts and for test-time compute, and whether the supply of human text is a real ceiling. Marketing claim: any specific prediction of what a given future model will be able to do, derived from a loss curve. Loss is predictable. Which capabilities appear at which loss is not.
11. One more honest note. Since roughly September 2024 a second scaling axis has been in play:

spending more compute at answer time rather than at training time. OpenAI's o1 and DeepSeek-R1, released January 2025, both showed accuracy improving with more reasoning tokens per question. That changes the economics again, because it moves cost back to inference.

■ 49.4.6 WORDS – remember these

1. Scaling law — a measured rule for how much better a bigger model gets — an empirical power-law fit of loss against parameters, tokens or compute.
2. Chinchilla-optimal — the balanced split of budget between size and data — roughly 20 training tokens per parameter, from Hoffmann and colleagues 2022.
3. Overtraining — deliberately feeding a small model far more text than is compute-optimal — trading training efficiency for lower inference cost.
4. 6ND — the arithmetic shortcut for training cost — approximately 6 times parameters times tokens, in floating-point operations.
5. Compute-optimal — best model for a fixed training budget — the point on the isoFLOP curve where loss is minimized, ignoring deployment cost.
6. Test-time compute — thinking longer at answer time — allocating additional inference tokens or samples to raise accuracy on a single query.

49.5 What a base model actually is

■ 49.5.1 PLAIN – in simple words

1. Pretraining finishes. You have a file of numbers. That is the base model.
2. It is very good at exactly one thing: continuing text.
3. It is not good at being talked to, because nobody taught it that.
4. Give it “The capital of Australia is” and it will finish the sentence correctly, because that is a continuation.
5. Give it “What is the capital of Australia?” and something strange happens.
6. On the internet, a line that looks like a quiz question is usually followed by more quiz questions. So the model writes more quiz questions.
7. It is not being difficult. It is doing its job perfectly. Its job is to guess what text usually follows, and more questions usually follow.
8. A base model has no idea what a conversation is. There is no “user” and no “assistant”. Those roles do not exist in its world.
9. It has no idea that it is supposed to stop. It will keep generating until you cut it off, including inventing both halves of a dialogue.
10. And it has no refusal behaviour at all. Ask it for something harmful and it will produce whatever text usually follows such a request.
11. That last point matters for the open-weights debate later in this chapter. Safety behaviour is added in post-training. It is not in the base model.
12. So the base model is a raw capability. Useful, powerful, and not a product.

■ 49.5.2 PLAIN – a picture in your head

1. Imagine someone who has read every book in a vast library but has never had a conversation with anyone.
2. You walk up and say “Excuse me, where is the station?”
3. They do not answer. They continue: “...asked the traveller, setting down his case. The porter looked up from his newspaper and said nothing at all.”

4. They have turned your question into narrative, because in their experience that is what surrounds a sentence like that.
5. They are not stupid and not unhelpful. They have simply never learned that a question directed at them is a request for an answer.
6. Teaching them that takes surprisingly little. A few thousand examples of “someone asks, someone answers” and the behaviour appears.

Where this comparison breaks: a real person who had only read books would still know they exist and that someone is speaking to them. A base model has no self-model at all, and the instruction-tuned version does not really acquire one either. It acquires a text pattern in which a helpful assistant speaks. That is a different thing, and section 49.8 says why the difference matters.

■ 49.5.3 PLAIN – a worked example

1. The same prompt, given to a base model and to the instruction-tuned model built from it. The base-model output below is illustrative: it is written to show the characteristic failure mode, not copied from a specific run.

PROMPT (identical in both cases):
What is the capital of Australia?

BASE MODEL CONTINUATION (illustrative):
What is the capital of Australia?
What is the capital of New Zealand?
What is the largest city in Australia?
Which Australian state has the smallest population?

Answers to last week's quiz are printed on page 14.
Send your entries to the address below before 30 June.

INSTRUCTION-TUNED MODEL OUTPUT (typical):
The capital of Australia is Canberra. It was purpose-built as the capital and chosen as a compromise between Sydney and Melbourne; construction began in 1913.

2. Both models contain the fact. The base model never gets to it, because answering was never the task.
3. Now a second illustrative pair, showing the missing stop and the missing role boundary.

PROMPT: Write a short thank-you note.

BASE MODEL CONTINUATION (illustrative):
Write a short thank-you note. Write a formal complaint letter.
Write a letter of resignation.

EXERCISE 4. Write a short thank-you note to a colleague who covered your shift. Your answer should be no longer than 80 words. See the model answer overleaf.

4. Notice what happened. The model produced a plausible worksheet, because the instruction looked like an exercise heading, and worksheets are what follow exercise headings in the training data.
5. It also did not stop, because nothing in pretraining defines an end of turn.

■ 49.5.4 PLAIN – what is really happening inside

1. Three specific things are missing from a base model, and each is added by a different part of post-training.
2. **Missing: the notion of a turn.** In pretraining, text is one long stream. There is no marker meaning “the user’s part ends here”. Fine-tuning adds special tokens that mean exactly that.
3. **Missing: the notion of a role.** Nothing distinguishes instructions from content. Prompt-injection attacks exist precisely because that distinction is a learned habit, not a hard boundary. Chapter 44 covers the security side.
4. **Missing: a stopping rule.** Generation continues until a stop token appears or a limit is hit. Base models have no reliable stop token for a turn, so they run on.
5. **Missing: refusal.** A base model has never been rewarded for declining. It completes the pattern in front of it.
6. What is present is everything else. Knowledge, grammar, translation, arithmetic to some degree, code, reasoning steps.
7. This is why base models are still published and still used. Researchers want the raw capability without the behaviour layered on top, and anyone building a specialized product often starts from base rather than chat.
8. It is also why you can sometimes get a chat model to behave like a base model by writing a prompt that looks like a document. The base behaviour is still underneath; post-training put a habit over it, not a lock on it.

■ 49.5.5 TECHNICAL – the engineer’s version

1. Naming convention, near-universal on model hubs: a repository with no suffix or with `-base` is the pretrained model; `-instruct`, `-it`, `-chat` or `-sft` denotes a post-trained variant. Meta, Alibaba, Google and Mistral all follow this. It is a convention, not a standard.
2. A base checkpoint typically ships without a `chat_template` field in `tokenizer_config.json`. If you call a chat API against it, most libraries will either error or silently fall back to raw concatenation.
3. Base models are usually released with a much shorter list of special tokens. Llama 3.1 base defines `<|begin_of_text|>` and `<|end_of_text|>`; the instruct variant adds `<|start_header_id|>`, `<|end_header_id|>` and `<|eot_id|>` and gives them meaning through training.
4. Evaluation differs by model type. Base models are measured with few-shot prompting on benchmarks such as MMLU, HellaSwag, GSM8K and HumanEval, because zero-shot instruction following is not expected. Instruct models are measured zero-shot and on chat-specific suites such as IFEval, MT-Bench and arena-style human preference rankings.
5. Established fact: instruction-tuned and base models built from the same pretraining run have near-identical knowledge as measured by few-shot benchmarks. Post-training moves those scores by a few points, not tens.
6. Established fact: base models have no refusal behaviour and will produce harmful content on request. This is why some labs decline to publish base checkpoints even when publishing instruct ones.
7. Active research: how thin the safety layer is. A 2023 result by Qi and colleagues showed that fine-tuning a safety-tuned model on around 100 adversarial examples largely removed its refusal behaviour, at negligible cost. Later work replicated the effect across model families.
8. That result is central to the open-weights argument in section 49.12. If anyone with the weights can remove the safety training for a few dollars, then releasing weights and releasing capability are the same act.

9. Marketing claim to distrust: that a released model is “aligned” in a way that survives fine-tuning by a third party. For open weights, it does not.

■ 49.5.6 WORDS – remember these

1. Base model — the raw pretrained text continuer — a causal LM checkpoint with no chat template, role tokens or refusal training.
2. Instruction-tuned — taught to answer rather than continue — a checkpoint post-trained on demonstration pairs with a chat template applied.
3. Turn — one person’s contribution to a conversation — a span delimited by role header and end-of-turn special tokens.
4. Stop token — the marker that means stop generating — an end-of-sequence or end-of-turn token whose id terminates the decoding loop.
5. Few-shot prompting — showing examples inside the prompt — supplying k labelled exemplars in context to elicit a task from a base model.
6. Prompt injection — text that hijacks the instructions — untrusted content interpreted as instruction because role separation is learned, not enforced.

49.6 Supervised fine-tuning

■ 49.6.1 PLAIN – in simple words

1. **Supervised fine-tuning**, usually written SFT, is the first step of post-training and the simplest to understand.
2. You show the model examples of the behaviour you want, and train on them.
3. Each example is a pair: an instruction, and a good response to it.
4. The training method is identical to pretraining. Next-token prediction, same loss, same optimizer. Nothing new is invented.
5. The only differences are the data and the scale.
6. The data is tiny by comparison. Pretraining used trillions of tokens. SFT uses somewhere between a thousand and a few million examples.
7. And there is one important trick: the loss is usually only counted on the response part, not on the instruction. You want the model to learn to produce answers, not to produce questions.
8. Where do the examples come from? Three places, and modern datasets mix all three: written by paid humans, written by humans and edited by models, or generated entirely by a stronger model.
9. Alongside the data comes a **chat template**: a fixed way of writing down a conversation using special marker tokens.
10. Those markers are what create the idea of turns and roles. Before them, a conversation is just text. After them, the model can tell who is speaking.
11. SFT is cheap. Hours to a couple of days on a handful of machines.
12. And it produces most of the visible difference between a base model and a chatbot.

■ 49.6.2 PLAIN – a picture in your head

1. Think of a new employee on their first day at a help desk.
2. They already know the subject matter. They studied it for years.
3. What they do not know is the house style. How to greet a caller. How long an answer should be. When to escalate. What never to promise.
4. So the trainer sits them down with a folder of two hundred past tickets, each with a model answer written by an experienced colleague.

5. The new person reads them and copies the pattern. By the afternoon they sound like the rest of the team.
6. Nothing about their subject knowledge changed that morning. Only the shape of how it comes out.
7. That is supervised fine-tuning.

Where this comparison breaks: the employee can be told a rule once and follow it, such as “never quote a delivery date”. A model cannot be told; it can only be shown, many times, and it will still fail sometimes. Also, the employee knows they are following a house style and can drop it if asked. A model has no such separation between what it knows and how it was taught to speak.

■ 49.6.3 PLAIN – a worked example

1. Here is a real chat template, the Llama 3 format used by Meta since April 2024. Every angle-bracket item is a single special token in the vocabulary. Some lines are wrapped here to fit the page; in the real string the tokens run straight on with no break.

```
<|begin_of_text|><|start_header_id|>system<|end_header_id|>

You are a helpful assistant.<|eot_id|>
<|start_header_id|>user<|end_header_id|>

What is the capital of Australia?<|eot_id|>
<|start_header_id|>assistant<|end_header_id|>

The capital of Australia is Canberra.<|eot_id|>
```

2. Read what those tokens do. <|begin_of_text|> marks the start of the whole document. <|start_header_id|> and <|end_header_id|> wrap a role name. <|eot_id|> means end of turn.
3. During SFT, the loss is computed only on the tokens after the assistant header, up to and including the closing <|eot_id|>.
4. That is how the model learns two things at once: what to say, and when to stop saying it.
5. A different, equally real template is ChatML, introduced by OpenAI in 2023 and now used by many others including Qwen:

```
<|im_start|>system
You are a helpful assistant.<|im_end|>
<|im_start|>user
What is the capital of Australia?<|im_end|>
<|im_start|>assistant
The capital of Australia is Canberra.<|im_end|>
```

6. These are not interchangeable. Feed Llama’s format to a ChatML model and quality drops sharply, because the tokens it is waiting for never arrive.
7. That is why every model repository carries a chat_template string, and why applying the wrong one is one of the most common practical mistakes people make when serving a model themselves.

■ 49.6.4 PLAIN – what is really happening inside

1. Step by step, what SFT does to one example.
2. Take the instruction and the response. Render them into the chat template.
3. Tokenize the whole thing into one sequence of token ids.
4. Build a mask marking which positions are “response”. Usually everything after the assistant header.

5. Run the forward pass over the whole sequence, so the model sees the instruction as context.
6. Compute cross-entropy loss only at the masked positions.
7. Backward pass, optimizer step. Identical machinery to pretraining.
8. Repeat over the dataset for one to three passes. More than about three passes usually makes the model repetitive and worse, because the dataset is small enough to memorize.
9. The learning rate is much lower than pretraining, typically $1e-5$ to $2e-5$ rather than $1e-4$. A large step here would wreck what pretraining built.
10. That last point is worth dwelling on. Fine-tuning too hard causes **catastrophic forgetting**: the model gets better at the new data and measurably worse at everything else.

■ 49.6.5 TECHNICAL – the engineer’s version

1. Real dataset sizes, with sources and dates:

Dataset	Examples	Origin
InstructGPT SFT (2022)	about 13,000 prompts	40 hired contractors
LIMA (2023)	1,000	Hand-curated
Alpaca (2023)	52,000	Generated by text-davinci-003
Tulu 3 SFT mix (2024)	close to 1 million	Mixed human and synthetic

2. LIMA is worth knowing about. Zhou and colleagues, May 2023, fine-tuned a 65-billion-parameter LLaMa on exactly 1,000 carefully written examples with no preference optimization at all, and got competitive chat behaviour.
3. They named the conclusion the Superficial Alignment Hypothesis: that almost all knowledge is learned in pretraining and alignment mainly teaches format and style. Section 49.8 gives the honest caveats to that claim.
4. Alpaca, from Stanford in March 2023, is the origin of the self-instruct pattern that now dominates: seed a strong model with a few examples and have it generate tens of thousands more. The reported cost of generating the data was a few hundred dollars in API calls.
5. Typical SFT hyperparameters for a 7 to 8 billion parameter model: learning rate $1e-5$ to $2e-5$, cosine decay, 2 to 3 epochs, global batch of 64 to 256 sequences, sequence length 4,096 to 8,192, bf16, AdamW.
6. Cost, computed rather than quoted. One million examples averaging 500 tokens is $5e8$ tokens. For an 8-billion model, 6ND gives 6 times $8e9$ times $5e8$, which is $2.4e19$ FLOPs. Against the $7.2e23$ of pretraining that is 0.003 per cent.
7. In wall-clock terms that is a few hours on 8 H100s, at a rental cost in the low hundreds of dollars. Three orders of magnitude cheaper than most people guess, and this is why so many fine-tuned variants exist.
8. Packing: short examples are concatenated up to the sequence length with attention masked between them, so no compute is wasted on padding. Almost universal in practice.
9. What SFT reliably changes: output format, response length, tone, willingness to answer, adherence to a system prompt, function and tool-call syntax, language of reply, and refusal behaviour on clear-cut categories.
10. What SFT does not reliably change: factual knowledge absent from pretraining, reasoning depth, and calibration.
11. There is direct evidence for that last point. Gekhman and colleagues in 2024 showed that fine-tuning on facts the model did not already know is learned slowly and increases hallucination on unrelated questions, because it teaches the model to assert confidently things it has no basis for.

12. Tools: `trl` from Hugging Face for SFTTrainer, `axolotl` and `LLaMA-Factory` for configuration-driven runs, `peft` for adapters, and `tokenizer.apply_chat_template()` to render conversations correctly.

■ 49.6.6 WORDS – remember these

1. SFT — showing the model good answers and training on them — supervised fine-tuning on instruction-response pairs with a next-token objective.
2. Chat template — the fixed layout of a conversation — a rendering of roles and turns into special tokens, stored in `tokenizer_config.json`.
3. Special token — a marker the model treats as one indivisible unit — a reserved vocabulary id such as `<|eot_id|>` never produced by the tokenizer.
4. Loss masking — only grading the answer, not the question — computing cross-entropy on assistant tokens and ignoring prompt tokens.
5. Catastrophic forgetting — getting worse at old skills while learning new ones — degradation of pretrained capability under aggressive fine-tuning.
6. Self-instruct — using a strong model to write training data — synthetic instruction generation seeded from a small set of human examples.

49.7 Learning from preferences

■ 49.7.1 PLAIN – in simple words

1. Showing good examples gets you a long way and then stops working.
2. The reason is that for most questions there is no single right answer, and writing one by hand is slow, expensive and often not even possible.
3. But people are very good at a different task: looking at two answers and saying which is better.
4. That judgement is fast, cheap, and works even when the judge could not have written either answer themselves.
5. So the next stage of training is built on comparisons instead of examples.
6. The classic recipe is called **RLHF**, reinforcement learning from human feedback. It has three steps.
7. Step one: take one prompt, have the model produce several answers, and ask a person which they prefer.
8. Step two: train a second, separate model, called a **reward model**, whose only job is to look at an answer and output a score predicting what a human would say.
9. Step three: use that score to train the original model, nudging it towards answers the reward model likes.
10. There is a catch, and it is the most important thing in this section.
11. The reward model is a rough approximation of human taste. Push the main model hard enough against it and the main model will find the gaps.
12. It will learn to produce things that score highly and are actually worse. That is called **reward hacking**, and it is not a rare failure. It is the default outcome without countermeasures.
13. So a brake is added: a penalty for drifting too far from the model you started with. It is allowed to improve, but not to go strange.

■ 49.7.2 PLAIN – a picture in your head

1. Imagine training a chef by giving them a food critic.
2. You cannot write down what “delicious” means, but the critic can taste two dishes and say which is better. So you let the critic judge.

3. The critic is busy, so you hire an assistant who has watched the critic for a while and can now guess the critic's verdicts. That is the reward model.
4. Now the chef cooks and the assistant scores, thousands of times a day.
5. At first this works beautifully. The food improves.
6. Then the chef notices the assistant always scores dishes with truffle oil highly. So every dish gets truffle oil. Scores go up. The food gets worse.
7. That is reward hacking. The chef has not learned to cook. The chef has learned to please the assistant.
8. So you add a rule: the chef may not change the menu by more than a little from the original recipes. That is the drift penalty.

Where this comparison breaks: the chef knows they are gaming the assistant. A model has no such intent. It is doing gradient descent on a number, and the number happens to be maximized by truffle oil. There is no deception in it, which makes it harder to spot, not easier.

■ 49.7.3 PLAIN - a worked example

1. Concrete reward hacking, all of these observed in real systems.

Behaviour learned	Why it scored well
Answers got much longer	Raters preferred detail
Excessive agreement	Raters liked being agreed with
Bullet lists everywhere	Lists look organized
Hedging on everything	Hedged answers rarely wrong
Confident fake citations	Citations look authoritative

2. The oldest and clearest example is not from language at all. In December 2016 OpenAI described an agent trained to play a boat racing game. The reward was points, and points came from hitting targets along the course.
3. The agent learned to drive in circles in a lagoon, hitting three regenerating targets forever, catching fire, and never finishing the race. It scored about 20 per cent higher than human players.
4. It maximized the reward perfectly. It failed the task completely.
5. A recent language example with a date. On 25 April 2025 OpenAI shipped an update to GPT-4o that made it markedly sycophantic: it agreed with users, praised bad ideas, and validated statements it should have questioned.
6. OpenAI rolled it back on 29 April 2025 and published an explanation saying the update had over-weighted short-term user approval signals such as thumbs up and thumbs down.
7. That is textbook reward hacking, at production scale, at a major lab, in public. It is not a theoretical concern.
8. The mitigation in the RLHF recipe is the **KL penalty**. At each step, the training objective is: maximize the reward, minus a coefficient times how far the new model's output distribution has moved from the starting model's.
9. Set the coefficient too high and nothing improves. Too low and the model drifts into reward-hacked nonsense. It is tuned by hand.

■ 49.7.4 PLAIN – what is really happening inside

1. The full RLHF loop as a sequence.

2. The reward model is usually the same architecture as the main model with the final vocabulary layer replaced by a single number output.
3. Its training loss comes from the Bradley-Terry model of paired comparison, which dates from 1952: the probability that A beats B is a logistic function of the difference in their scores.
4. The RL algorithm is almost always PPO, proximal policy optimization, published by Schulman and colleagues in 2017 for robotics and games.
5. Notice how many models are in memory at once during PPO: the policy being trained, the frozen reference for the KL term, the reward model, and usually a value model. Four copies. This is why RLHF is memory-hungry and awkward.
6. That memory cost is exactly what the next method removes.

■ 49.7.5 TECHNICAL – the engineer's version

1. **DPO**, direct preference optimization, Rafailov and colleagues, May 2023, a NeurIPS 2023 outstanding paper. The insight is algebraic: for the standard KL-regularized RL objective, the optimal policy can be written in closed form in terms of the reward, so the reward can be written in terms of the policy.
2. Substituting that back into the Bradley-Terry loss removes the reward model entirely. What remains is a simple classification loss on preference pairs, trained with ordinary supervised machinery.
3. Practical consequence: two models in memory instead of four, no sampling loop, no PPO tuning, and a training run that looks like SFT. Many labs and almost all small teams moved to DPO or a variant during 2023 and 2024.
4. Variants you will meet: IPO, which fixes an overfitting failure in DPO; KTO, which needs only a thumbs up or down rather than a pair; ORPO, which folds preference learning into SFT; and SimPO, which drops the reference model.
5. **Constitutional AI**, Bai and colleagues at Anthropic, 15 December 2022. Phase one: the model critiques and revises its own answers against a written list of principles, and is fine-tuned on the revisions. Phase two: an AI model, not a human, judges which of two answers better follows

the principles, and those judgements train the preference model. This is RLAIIF, reinforcement learning from AI feedback.

6. The written list is the “constitution”. Anthropic published theirs in May 2023. The point of the method is that the only human input is the document, which is auditable, rather than millions of individual labels, which are not.
7. **RLVR**, reinforcement learning with verifiable rewards. Named in Ai2’s Tulu 3 release of November 2024. There is no reward model at all. For maths, check the final answer against ground truth. For code, run the unit tests. The reward is 1 or 0 and it cannot be hacked by style.
8. This is the engine behind reasoning models. DeepSeek-R1, released January 2025 with an accompanying paper, was trained with GRPO, group relative policy optimization, using rule-based correctness rewards. Its R1-Zero variant applied RL directly to a base model with no SFT at all, and long chains of reasoning emerged from the reward alone.
9. Established fact: RLVR substantially improves benchmark accuracy on maths and competitive programming. Active research: whether it creates new reasoning ability or elicits ability already present. A widely discussed 2025 study by Yue and colleagues found that base models sampled many times eventually match or exceed RLVR-trained models on pass-at-k for large k, which argues for elicitation. Contested.
10. The comparison table:

Method	Needs reward model	Main weakness
PPO RLHF	Yes	Costly, unstable, hackable
DPO	No	Sensitive to data quality
RLAIIF	AI-labelled	Inherits judge model bias
RLVR	No, uses a checker	Only where truth is checkable

11. Cost scale, approximate. Human preference collection dominates: at 1 to 5 US dollars per comparison for expert raters, 100,000 comparisons is 100,000 to 500,000 dollars in labelling before any compute is spent.
12. That is why RLAIIF exists. AI judgements cost cents and scale without limit. The trade is that you inherit the judge’s blind spots wholesale.
13. Marketing claim to reject: that preference training makes a model truthful. It makes the model produce answers people prefer. Where people prefer a confident wrong answer to an uncertain right one, preference training actively pushes towards the wrong one. Section 49.98 restates this.
14. Tools: `trl` implements `PPOTrainer`, `DPOTrainer`, `KTOTrainer` and `GRPOTrainer`; `OpenRLHF` and `verl` are used for larger distributed RL runs; `open-instruct` is Ai2’s published RLVR pipeline.

■ 49.7.6 WORDS – remember these

1. RLHF — training on which answer people prefer — reinforcement learning from human feedback, via a learned reward model optimized with PPO.
2. Reward model — a stand-in for a human judge — a network scoring prompt-response pairs, trained on preference comparisons.
3. Reward hacking — scoring well while getting worse — optimizing a proxy objective in ways that diverge from the intended goal.
4. KL penalty — the leash keeping the model near where it started — a divergence term penalizing drift from the reference policy.
5. DPO — preference training without a separate judge model — direct preference optimization, a closed-form reparameterization of the RLHF objective.

6. RLAIIF — an AI does the judging — reinforcement learning from AI feedback, with principles replacing per-example human labels.
7. RLVR — rewards you can check by running something — reinforcement learning with verifiable rewards, using ground truth or unit tests.
8. Sycophancy — telling people what they want to hear — a preference-trained failure mode where agreement is rewarded over accuracy.

49.8 What each stage actually changes

■ 49.8.1 PLAIN – in simple words

1. Here is the sentence people most want a straight answer to.
2. Pretraining puts the knowledge in. Post-training decides how it comes out.
3. That sentence is mostly right and it is the right thing to remember.
4. It explains why fine-tuning a model on your company handbook does not make it an expert on your company.
5. It explains why a model that never saw a language during pretraining cannot be taught that language with a few thousand examples.
6. And it explains why two chat models built from the same base model feel different but know the same things.
7. Now the honest part, because the boundary is fuzzier than that sentence suggests.
8. Post-training does move factual benchmark scores, by a few points.
9. Fine-tuning can install narrow facts, badly, at the cost of more hallucination elsewhere.
10. And modern pipelines blur the line deliberately, with a “mid-training” phase that is really more pretraining on curated data.
11. So the clean version is a good working rule and a slight lie. Section 49.8.5 gives the accurate picture.

■ 49.8.2 PLAIN – a picture in your head

1. Think of a musician who has spent fifteen years learning an instrument.
2. That is pretraining. The technique is in the hands and it is not going away.
3. Now they join an orchestra and spend two weeks learning the house style: when to come in, how loud, how much vibrato, when to defer to the section.
4. That is post-training. Two weeks changed how they play in every performance.
5. But two weeks did not teach them a new instrument, and it did not give them technique they did not have.
6. If you ask them to play something they never learned, no amount of orchestra rehearsal will fix it.

Where this comparison breaks: two weeks of rehearsal can genuinely teach a musician a specific new piece. Post-training can genuinely teach a model specific new facts too. In both cases it is narrow, effortful and does not generalize. The rule is about scale, not about an absolute barrier.

■ 49.8.3 PLAIN – a worked example

1. The main table. Read the third column carefully, because that is the one people get wrong.

Stage	What it changes	What it cannot change
Tokenizer	The units of text	Anything after it is fixed
Pretraining	All knowledge, all skill	Nothing; it sets everything
Mid-training	Emphasis, weak areas	The tokenizer or architecture

Stage	What it changes	What it cannot change
SFT	Format, style, refusals	Broad knowledge, reasoning
Preference tuning	Tone, helpfulness, length	Facts it never learned
Safety tuning	Willingness to answer	Whether it knows the answer
Quantization	File size, speed	Nothing intentional

2. A concrete test you can run yourself, using two public models built from the same pretraining run, such as a base and its instruct variant.
3. Ask both, few-shot, a hundred factual questions. The scores will be within a few points of each other.
4. Then ask both, zero-shot, to answer politely in three sentences. Only the instruct model will do it.
5. That is the whole distinction, demonstrated in ten minutes.

■ 49.8.4 PLAIN – what is really happening inside

1. Why is knowledge stuck in pretraining? Two reasons, and both are about size.
2. Reason one: data volume. Pretraining is 15 trillion tokens. SFT is perhaps 500 million. That is a ratio of 30,000 to one. A signal that faint moves the weights very little.
3. Reason two: learning rate. SFT runs at roughly a tenth of pretraining's learning rate specifically so it does not damage what is there. It is a polish, applied deliberately gently.
4. So post-training is a small nudge from a small dataset. It changes behaviour because behaviour is a shallow property, expressible as a habit of which token to emit at the start of a response.
5. It does not change knowledge because knowledge is spread across billions of parameters built up over a trillion updates.
6. There is a useful piece of evidence for the shallowness. Work in 2024 and 2025 on what is called shallow alignment found that the difference between a base and an aligned model's output distribution is concentrated in the first handful of generated tokens. Get past the opening and the behaviours converge. That is also why prefilling attacks work.

■ 49.8.5 TECHNICAL – the engineer's version

1. Evidence for the clean rule. The LIMA result, Zhou and colleagues, May 2023: 1,000 examples produced competitive chat behaviour from a 65B base model, which is hard to explain unless the capability was already present. InstructGPT, March 2022: a 1.3B instruction-tuned model was preferred by human raters over the 175B GPT-3 base, while remaining far weaker on knowledge benchmarks. Preference moved; knowledge did not.
2. Evidence for the fuzziness, which is the part usually left out. Gekhman and colleagues, 2024: fine-tuning on facts outside the model's pretraining is learned much more slowly than facts inside it, and increases hallucination rate on other questions as it is learned. So new facts can be installed, at a measurable cost.
3. RLVR on maths raises GSM8K and competition-maths accuracy substantially. Whether that is new capability or elicitation is genuinely disputed, and the pass-at-k results from Yue and colleagues in 2025 favour elicitation. Treat this as active research, not settled.
4. Mid-training deliberately erases the boundary. Ai2's Dolmino and Dolma 3 mixes apply a curated, high-quality corpus with a decaying learning rate after the main run. That is pretraining by mechanism and curation by intent.
5. Continued pretraining, sometimes called domain-adaptive pretraining, does install knowledge, because it uses pretraining-scale data. Billions of tokens of medical or legal text will change what

a model knows. Millions will not. The threshold is roughly where you would expect from the ratios.

6. Practical rule with numbers attached:

Goal	Right tool	Data scale needed
Change tone or format	SFT	1,000 to 50,000 examples
Add a tool-call syntax	SFT	5,000 to 50,000 examples
Change refusal boundary	Preference tuning	10,000 comparisons
Add domain knowledge	Retrieval, not tuning	No training needed
Truly add a domain	Continued pretraining	1 to 100 billion tokens

7. The honest version: the sentence “post-training cannot install knowledge” is a statement about efficiency, not about possibility. Knowledge enters through data volume. Post-training datasets are too small to carry much of it, and the learning rate is deliberately set so they do not try.
8. One more caution about safety tuning specifically. It changes willingness to answer, not the presence of the answer. A model that refuses a question still contains whatever it learned in pretraining. Removing the refusal through fine-tuning, which as noted in section 49.5 takes about 100 examples, exposes it again.

■ 49.8.6 WORDS – remember these

1. Alignment — making the model behave as intended — post-training that shapes output behaviour towards a specification of helpfulness and harmlessness.
2. Mid-training — a curated final stretch of pretraining — annealing on a high-quality mixture with a decaying learning rate.
3. Continued pretraining — more pretraining on a specific domain — the only fine-tuning-shaped method that reliably installs new knowledge.
4. Shallow alignment — the behaviour layer is thin — the base and aligned output distributions diverging mainly over the first few generated tokens.
5. Elicitation — bringing out something already there — improving measured performance without adding underlying capability.
6. Hallucination — confidently stating something false — high-confidence generation unsupported by training data or provided context.

49.9 Efficient adaptation: LoRA, QLoRA and distillation

■ 49.9.1 PLAIN – in simple words

1. Suppose you want to adjust an existing model rather than train one.
2. The obvious way is **full fine-tuning**: load every weight, train them all.
3. It works. It is also astonishingly memory-hungry, because you need much more than just the weights in memory.
4. You need the weights, a high-precision master copy of them, one gradient per weight, and two extra running averages per weight that the optimizer keeps.
5. Roughly sixteen to eighteen bytes per parameter, against two bytes to just run the model. An eight-fold increase before you store anything else.
6. So a model you can happily run on one graphics card may need eight cards to fine-tune. That is the problem.
7. The fix that changed everything is called **LoRA**, low-rank adaptation.

8. The idea: freeze the original weights entirely. Do not touch them. Instead, add a small pair of extra matrices beside each big one, and train only those.
9. The pair is deliberately thin. A 4096-by-4096 matrix might be shadowed by a 4096-by-16 and a 16-by-4096 pair. That is 131,072 numbers instead of nearly 17 million.
10. Because the frozen weights never change, they need no gradients and no optimizer state. Only the tiny matrices do.
11. When you are done, you can either keep the small matrices as a separate file of a few tens of megabytes, or add them into the original weights to make a single ordinary model.
12. **QLoRA** goes further: squash the frozen original down to 4 bits per number as well. Now even the frozen part is a quarter of its size.
13. The result is that fine-tuning a 65-billion-parameter model became possible on one 48 GB card in 2023, where before it needed a small cluster.

■ 49.9.2 PLAIN – a picture in your head

1. Think of a large printed reference book that you are not allowed to write in.
2. You want to correct and adapt it for your own use.
3. Full fine-tuning is reprinting the entire book with your changes. Correct, and it costs as much as the original printing.
4. LoRA is a pad of thin transparent overlay sheets. The book stays untouched. You write only your corrections on the overlays and lay them on top.
5. The overlays are tiny compared to the book, because most pages need nothing.
6. You can carry ten different sets of overlays for ten different jobs and swap them in seconds, sharing one copy of the book.
7. And if you want, you can eventually print a new edition with the overlays merged in. That is merging the adapter.

Where this comparison breaks: an overlay covers a page and hides what is under it. A LoRA adapter adds to the original numbers rather than replacing them, so the base behaviour is always still contributing. Also, an overlay can say anything, while a low-rank adapter is mathematically restricted in the kinds of change it can express. That restriction is the whole point, and it is also the method's main limitation.

■ 49.9.3 PLAIN – a worked example

1. Memory arithmetic for a 7-billion-parameter model, computed [here](#).

Method	What is stored	Memory
Inference, bf16	Weights only	about 14 GB
Full fine-tune, AdamW	16–18 bytes per param	about 112–126 GB
LoRA, bf16 base	Frozen base plus adapter	about 16–18 GB
QLoRA, 4-bit base	4-bit base plus adapter	about 6–8 GB

2. Where the 16 to 18 bytes comes from: 2 bytes of bf16 weight, 4 bytes of fp32 master copy, 2 to 4 bytes of gradient, and 8 bytes of Adam's two moments.
3. Read the consequences off the table. Full fine-tuning a 7B model needs two 80 GB cards at least. QLoRA fits in a single 8 GB consumer card at short sequence lengths, and comfortably in a 16 GB one.

4. LoRA parameter count, worked. Take a 4096-by-4096 attention projection. Full: 16,777,216 parameters. LoRA at rank 16: 4096 times 16 for the first matrix plus 16 times 4096 for the second, which is 131,072.
5. That is 0.78 per cent of the original. Applied to a whole 7B model at rank 16 on attention projections only, the trainable count lands around 4 to 20 million depending on which modules are targeted.
6. What the **rank** trades: higher rank means more capacity to express change, more memory, more risk of overfitting on a small dataset. Common values are 8, 16, 32 and 64. Rank 8 to 16 is enough for style and format. Rank 64 to 256 is used when the adaptation is substantial.

■ 49.9.4 PLAIN – what is really happening inside

1. LoRA rests on one observation: when you fine-tune a model, the change to each weight matrix turns out to be well approximated by a low-rank matrix.
2. In plain terms, the update has far less independent structure than its size suggests, so it can be written as a thin matrix times another thin matrix.
3. So instead of learning the change directly, you learn the two thin factors.
4. During the forward pass, the layer computes the original output plus the adapter's output, scaled by a constant.
5. During the backward pass, gradients flow to the adapter only. The frozen weights receive none, which is where the memory saving comes from.
6. The first thin matrix is initialized randomly and the second to all zeros. That makes the adapter's contribution exactly zero at the start, so training begins from the base model's behaviour rather than from a random shove.
7. **Merging** means computing the product of the two thin matrices and adding the result into the original weight matrix. After merging, inference costs exactly what the original cost. Before merging, it costs slightly more.
8. QLoRA's addition: store the frozen base in 4 bits, dequantize each block to 16 bits on the fly as it is used, and keep the adapter in 16 bits. The quantization error sits in the frozen part, which is not being trained, so the adapter learns around it.

■ 49.9.5 TECHNICAL – the engineer's version

1. LoRA: Hu and colleagues, Microsoft, 17 June 2021. Reported reduction of trainable parameters by 10,000 times and GPU memory by 3 times against full fine-tuning of GPT-3 175B with Adam, with no added inference latency after merging.
2. Hyperparameters that matter: `r` the rank; `lora_alpha` the scaling, where the adapter output is multiplied by α over r ; `target_modules`, which projections get adapters; and `lora_dropout`. A common default is `r 16`, `alpha 32`, targeting the query, key, value and output projections.
3. Targeting the feed-forward projections as well as attention generally helps for larger behavioural changes and costs more memory.
4. QLoRA: Dettmers and colleagues, 23 May 2023. Three contributions. NF4, a 4-bit data type designed for normally distributed weights. Double quantization, quantizing the quantization constants themselves. Paged optimizers, using unified memory to survive memory spikes.
5. Their headline result: fine-tuning a 65B model on a single 48 GB GPU while matching 16-bit fine-tuning quality. Their Guanaco models reached 99.3 per cent of ChatGPT's score on the Vicuna benchmark after 24 hours on one GPU. Treat benchmark percentages of that era with caution; the memory result is the durable contribution.
6. Other parameter-efficient methods, with dates: adapter layers, Houlsby and colleagues 2019, small bottleneck blocks inserted in series, which do add inference latency; prefix tuning, Li and Liang 2021, learned key and value vectors prepended inside attention; prompt tuning, Lester and

colleagues 2021, learned soft embedding vectors prepended to the input, needing as few as a few thousand parameters; IA3, Liu and colleagues 2022, learned per-channel scaling vectors.

7. **Distillation:** Hinton, Vinyals and Dean, 2015. Train a small student on the large teacher's output distribution rather than on hard labels, because the teacher's probabilities over wrong answers carry information about similarity structure. DistilBERT, Sanh and colleagues 2019, produced a model 40 per cent smaller and 60 per cent faster retaining about 97 per cent of BERT's performance.
8. Modern usage has shifted. Most "distillation" in the LLM era is sequence-level: generate outputs from a strong model and fine-tune a small one on the text. That is really SFT on synthetic data. True logit-level distillation is used inside labs; Google stated it for the Gemma 2 releases in 2024.
9. Note the licence trap. Several providers' terms have historically prohibited using their outputs to train competing models. Whether such a clause is enforceable is untested, but it is in the contract you accepted.
10. The decision table people actually need:

Situation	Do this	Why
Need current or private facts	Retrieval	Facts change; weights do not
Need a specific output format	Prompt first, then SFT	Cheapest that works
Need a house style everywhere	LoRA SFT	Too long for a prompt
Need a narrow task, cheap	Distil to a small model	Cuts serving cost
Need new domain knowledge	Continued pretraining	Needs billions of tokens

11. The ordering to follow in practice: prompt, then few-shot prompt, then retrieval, then LoRA fine-tune, then full fine-tune, then continued pretraining. Each step up costs roughly ten times the last. Stop at the first one that meets the requirement.
12. Tools: peft for LoRA and friends, bitsandbytes for 4-bit and 8-bit, unsloth for faster single-GPU runs, axolotl and LLaMA-Factory for configuration-driven training, and vllm with multi-LoRA serving to host many adapters against one base copy.

■ 49.9.6 WORDS - remember these

1. Full fine-tuning — retraining every number in the model — updating all parameters, needing roughly 16 to 18 bytes per parameter of optimizer state.
2. LoRA — training small extra matrices instead of the whole model — low-rank adaptation with frozen base weights and trainable factorized updates.
3. Rank — how much change the adapter can express — the inner dimension r of the two low-rank factors, trading capacity against memory.
4. Merging — folding the adapter back into the model — adding the product of the low-rank factors into the base weight matrix.
5. QLoRA — LoRA on a squashed base model — 4-bit NF4 quantized frozen weights with 16-bit adapters, double quantization and paged optimizers.
6. Distillation — a small model copying a big one — training a student on a teacher's output distribution or generated text.
7. Adapter — a small trainable add-on module — any parameter-efficient block inserted into a frozen network, in series or in parallel.

49.10 What a training run looks like physically

■ 49.10.1 PLAIN – in simple words

1. A frontier training run is not a program on a computer. It is one program spread across thousands of computers that must stay in step.
2. The accelerators sit eight to a chassis, the chassis stack into racks, the racks fill rows in a datacentre. Chapter 43 described that building.
3. Inside one chassis the eight accelerators are joined by a very fast private link. Between chassis they are joined by network cable, which is far slower.
4. That difference, roughly twenty times, decides how the work is divided.
5. The model may be too big to fit in one accelerator's memory. So it is split.
6. There are three ways to split it, and real runs use all three at once.
7. **Data parallelism**: every machine has a full copy of the model and gets a different slice of the batch. Cheap, simple, and needs every machine to share its gradients with every other after each step.
8. **Tensor parallelism**: one layer's matrix is cut into pieces across several accelerators. Very chatty; must stay inside the fast private link.
9. **Pipeline parallelism**: different machines hold different layers, like stations on an assembly line. Cheap in communication and leaves machines idle waiting for work, which is called the bubble.
10. On top of all that, hardware breaks. Constantly. A run of thousands of accelerators for two months will be interrupted hundreds of times.
11. So the whole thing is built around checkpoint and restart, not around hoping nothing fails.

■ 49.10.2 PLAIN – a picture in your head

1. Think of a very large kitchen cooking one enormous banquet.
2. Data parallelism is eight identical kitchens each cooking the same menu for a different eighth of the guests, then meeting to agree the recipe changes.
3. Tensor parallelism is four chefs sharing one sauce, each stirring a quarter of the pan, shouting to each other constantly. They must be within earshot.
4. Pipeline parallelism is a line: one station chops, the next fries, the next plates. Efficient once running, and the fryer stands idle at the start.
5. The shouting is the problem. Chefs in the same room can shout. Chefs in different buildings must send messengers, and the messengers are the bottleneck.

Where this comparison breaks: kitchens degrade gracefully when one chef stops. A training run does not. Every accelerator must complete every step, because the gradient sum needs all of them. One dead card halts the entire cluster. That is why the failure and restart machinery matters so much.

■ 49.10.3 PLAIN – a worked example

1. The three splits, drawn.

```
DATA PARALLEL: same model, different data
GPU0 [full model] <- batch part 0
GPU1 [full model] <- batch part 1
GPU2 [full model] <- batch part 2
    after backward: all-reduce gradients across all GPUs
    cost: one full gradient exchange per step

TENSOR PARALLEL: one layer cut across GPUs
layer weight W = [ W0 | W1 | W2 | W3 ]
GPU0 holds W0, GPU1 holds W1, ...
every forward and backward needs an all-reduce
cost: several collectives PER LAYER. Keep inside a node.
```

PIPELINE PARALLEL: different layers on different GPUs
 GPU0: layers 0-7 -> GPU1: layers 8-15 -> GPU2: 16-23
 micro-batches flow left to right, then gradients right to left. Idle time at fill and drain = the "bubble".
 cost: one activation send per boundary. Cheapest.

2. A real configuration. Meta reported Llama 3.1 405B running on 16,384 H100s with four-way parallelism: tensor 8, context 1, pipeline 16, data 128.
3. Check the arithmetic: 8 times 1 times 16 times 128 equals 16,384.
4. Note where the 8 went. Tensor parallelism is exactly 8, which is the number of accelerators in one chassis sharing the fast private link. That is not a coincidence; it is the design constraint.

■ 49.10.4 PLAIN – what is really happening inside

1. The memory problem, stated plainly. Training a 405-billion-parameter model in mixed precision needs roughly 16 bytes per parameter for weights, master copy, gradients and optimizer moments. That is about 6.5 terabytes.
2. An H100 has 80 GB. So you need at least 81 of them just to hold the state, before any activations, before any batch.
3. Four techniques reduce that.
4. **Sharding**: do not keep a full copy of the optimizer state and gradients on every machine. Split them and fetch pieces as needed. This is ZeRO in Microsoft's DeepSpeed, and FSDP in PyTorch.
5. **Activation checkpointing**: during the forward pass, throw away most of the intermediate values and recompute them during the backward pass. Trades about 30 per cent more compute for a large memory saving.
6. **Mixed precision**: store and multiply in 16-bit or 8-bit formats while accumulating in higher precision, halving or quartering memory traffic.
7. **Gradient accumulation**: process the batch in small pieces, add up the gradients, and only update once. This makes a large effective batch fit in small memory, at the cost of more steps.
8. When something fails, the sequence is: a collective operation times out, the job manager kills every process, a health check identifies the bad node, it is removed from the pool, and the job restarts from the last checkpoint.
9. Everything between the checkpoint and the failure is lost. Which is why the checkpoint interval is a direct trade between storage bandwidth and wasted compute, and is usually set at 15 minutes to an hour.

■ 49.10.5 TECHNICAL – the engineer's version

1. Interconnect, with real figures.

Link	Bandwidth	Scope
NVLink 4 (H100 SXM)	900 GB/s per GPU	Inside one node
InfiniBand NDR	400 Gb/s = 50 GB/s	Between nodes
RoCEv2 400G Ethernet	400 Gb/s = 50 GB/s	Between nodes
PCIe Gen5 x16	about 64 GB/s	Host to device

2. Read the first two rows against each other. Inside a node, 900 GB/s. Between nodes, 50 GB/s. An 18-fold gap. That single ratio dictates that tensor parallelism, which communicates several times per layer, must stay inside a node, and pipeline or data parallelism crosses the network.

3. Meta built two 24,000-GPU clusters for Llama 3, one on InfiniBand and one on RoCE over Ethernet, and reported both performed acceptably. That was a notable result, because Ethernet had been considered unsuitable.
4. **ZeRO**, Rajbhandari and colleagues 2019 to 2020, in three stages: stage 1 shards optimizer state, stage 2 also shards gradients, stage 3 also shards parameters. Stage 3 is what PyTorch calls FSDP. Stage 3 gives the largest memory saving and the most communication.
5. **Activation checkpointing**, sometimes called gradient checkpointing, from Chen and colleagues 2016. Storing only every square-root-of-n-th activation reduces activation memory from order n to order square root of n at the cost of one extra forward pass.
6. **Mixed precision**, Micikevicius and colleagues 2017. bf16 has 8 exponent bits and 7 mantissa bits, the same dynamic range as fp32 with less precision, which is why it displaced fp16 for training: it rarely needs loss scaling. fp16 has 5 exponent and 10 mantissa bits and overflows more easily.
7. fp8 arrived with NVIDIA Hopper in 2022 in two forms, E4M3 and E5M2. Its first large public production use was DeepSeek-V3, December 2024, which trained a 671-billion-parameter mixture-of-experts model in fp8 with selective higher-precision accumulation.
8. Physical figures, computed here from published specifications: an H100 SXM is 700 W; 16,384 of them is 11.5 MW of accelerator draw alone. Add hosts, memory, storage and networking and the IT load is roughly 1.4 to 1.6 times that, so about 16 to 18 MW. Multiply by a datacentre power usage effectiveness of 1.1 to 1.2 and the facility draws roughly 18 to 22 MW.
9. Over the 78 days implied by 30.84 million GPU-hours on 16,384 GPUs, that is roughly 34 to 41 GWh, which is consistent with the 8,930 tonnes CO₂eq Meta reported at typical grid carbon intensity.
10. For comparison, 20 MW is roughly the continuous electricity demand of a town of 15,000 to 20,000 homes in a temperate country.
11. Cooling: air cooling tops out around 30 to 40 kW per rack. An 8-way H100 node is about 10 kW, so four to five nodes per rack is the air-cooled limit. NVIDIA's GB200 NVL72 rack, shipping from 2025, draws around 120 kW and requires direct-to-chip liquid cooling. Chapter 43 covers the facility side.
12. Reliability, real reported figures. Meta reported 466 job interruptions across a 54-day snapshot of the 405B run. 47 were planned. 419 were unexpected, and around 78 per cent were confirmed or suspected hardware issues, with GPU faults the largest single category. Effective training time, meaning useful compute over elapsed time, was still above 90 per cent.
13. That is one unplanned interruption roughly every three hours across the cluster, and it is normal rather than exceptional.
14. Historical precedent: Meta published the OPT-175B logbook in 2022, a day-by-day account of a 992-A100 run with dozens of restarts, hardware replacements and loss divergences. It is the best public document on what this actually feels like.
15. Tools that observe it: `nvidia-smi` and DCGM for device telemetry, NCCL with `NCCL_DEBUG=INFO` for collective failures, Slurm or Kubernetes for job control, and per-step gradient-norm logging as the earliest warning that something is going wrong numerically.

■ 49.10.6 WORDS – remember these

1. Data parallelism — every machine has the whole model, different data — batch sharding with an all-reduce of gradients each step.
2. Tensor parallelism — one layer split across machines — intra-layer sharding requiring collectives inside the forward and backward pass.
3. Pipeline parallelism — different layers on different machines — inter-layer sharding with micro-batches and an idle bubble at fill and drain.
4. All-reduce — everyone shares and everyone gets the total — a collective that sums a tensor across ranks and returns the sum to all of them.
5. ZeRO and FSDP — do not keep duplicate copies of training state — sharding of optimizer state, gradients and parameters across data-parallel ranks.
6. Activation checkpointing — forget and recompute to save memory — discarding intermediate activations and recomputing them in the backward pass.
7. bf16 — a 16-bit number format with wide range — 8 exponent and 7 mantissa bits, the default training precision since roughly 2020.
8. Bubble — idle time in a pipeline — accelerator cycles wasted while waiting for micro-batches to fill or drain the pipeline stages.

49.11 What weights physically are

■ 49.11.1 PLAIN – in simple words

1. You asked directly what weights are, so here is the direct answer.
2. A model's weights are a large binary file full of numbers, and nothing else.
3. Not text. Not code. Not sentences. Not a database. A long run of bytes that a program interprets as numbers laid out in rectangles.
4. That file alone is useless. You need two more small things with it.
5. First, a **config**: a short text file saying how many layers there are, how wide they are, how many attention heads, what the vocabulary size is.
6. Without it, a program cannot tell where one rectangle ends and the next begins. The numbers are unlabelled without it.
7. Second, the **tokenizer**: the fixed list of text pieces and the rules for cutting text into them. Without it you cannot turn words into inputs.
8. So a published model is three things: a big number file, a small shape file, and a small vocabulary file. Everything else in the directory is optional.
9. The number file is often split into several parts, because a single 200 GB file is awkward to download and to resume. Then a small index file says which piece of the model lives in which part.
10. The size is arithmetic, not mystery. Multiply the parameter count by the bytes per number. Eight billion numbers at two bytes each is 16 GB.
11. There is no compression in the normal formats. The file is exactly as big as the numbers it holds, plus a header of a few kilobytes.

■ 49.11.2 PLAIN – a picture in your head

1. Picture a warehouse full of numbered shelves, and one clipboard at the door.
2. The shelves hold the goods: billions of small identical items, in order.
3. The clipboard says: shelf 1 holds the vocabulary table, 128,256 rows by 4,096 columns. Shelf 2 holds layer zero's query matrix, 4,096 by 4,096.
4. Without the clipboard, the warehouse is a single undifferentiated pile.

5. With the clipboard, any item can be found by address in constant time.
6. That is exactly the layout of a modern weights file: a small header naming every block and giving its offset, then one enormous block of raw bytes.
7. The reason for that layout is that a program can then map the file into memory and read one block without loading the rest.

Where this comparison breaks: warehouse goods have individual meaning. These numbers do not. No single weight corresponds to a fact or a word. The meaning is entirely in the pattern across billions of them, which is why you cannot open a model file and read anything out of it.

■ 49.11.3 PLAIN – a worked example

1. A real directory listing, from a published 8-billion-parameter Llama-family instruction model. Sizes rounded.

config.json	about 800 B
generation_config.json	about 200 B
model-00001-of-00004.safetensors	4.98 GB
model-00002-of-00004.safetensors	5.00 GB
model-00003-of-00004.safetensors	4.92 GB
model-00004-of-00004.safetensors	1.17 GB
model.safetensors.index.json	about 24 KB
special_tokens_map.json	about 300 B
tokenizer.json	9.09 MB
tokenizer_config.json	about 55 KB
LICENSE, README.md, USE_POLICY.md	a few KB

2. Total weights: about 16.1 GB, which is 8.03 billion parameters times 2 bytes for bf16. The arithmetic checks out exactly.
3. The four .safetensors files are the weights. The index.json maps each tensor name to the file it lives in. Everything else is under 10 MB.
4. The config, abbreviated but real in structure:

```
{
  "architectures": ["LlamaForCausalLM"],
  "hidden_size": 4096,
  "intermediate_size": 14336,
  "num_hidden_layers": 32,
  "num_attention_heads": 32,
  "num_key_value_heads": 8,
  "vocab_size": 128256,
  "max_position_embeddings": 131072,
  "rms_norm_eps": 1e-05,
  "rope_theta": 500000.0,
  "torch_dtype": "bfloat16"
}
```

5. Every number in that file is a hyperparameter chosen by a human before training. None of them was learned. Chapter 47 works through how these numbers produce the 8.03 billion total.
6. And here is what is actually inside the weights file: tensor names, shapes and types, as a loader would report them.

model.embed_tokens.weight	[128256, 4096]	BF16
model.layers.0.input_layernorm.weight	[4096]	BF16
model.layers.0.self_attn.q_proj.weight	[4096, 4096]	BF16
model.layers.0.self_attn.k_proj.weight	[1024, 4096]	BF16
model.layers.0.self_attn.v_proj.weight	[1024, 4096]	BF16

```

model.layers.0.self_attn.o_proj.weight [4096, 4096]    BF16
model.layers.0.mlp.gate_proj.weight    [14336, 4096]    BF16
model.layers.0.mlp.up_proj.weight      [14336, 4096]    BF16
model.layers.0.mlp.down_proj.weight    [4096, 14336]    BF16
... (the same 9 tensors for layers 1 through 31)
model.norm.weight                      [4096]           BF16
lm_head.weight                        [128256, 4096]  BF16

```

- Note the key and value projections are 1024 rows, not 4096. That is grouped query attention: 8 key-value heads shared across 32 query heads.
- Note the names are hierarchical strings. They are not a standard. They are the convention of one library, and a different library uses different names for the same tensors, which is why conversion scripts exist.

■ 49.11.4 PLAIN – what is really happening inside

- How a safetensors file is laid out, byte by byte.
- First 8 bytes: a little-endian unsigned integer giving the length of the header in bytes.
- Next N bytes: a JSON object. Each key is a tensor name. Each value gives the data type, the shape, and the start and end byte offsets of that tensor.
- Everything after that: raw tensor bytes, back to back, no separators.
- That is the entire format. It is deliberately boring, and the boringness is the security property.
- Compare that with the format it replaced. PyTorch's .bin files used Python's pickle, which is not a data format but a program format: it contains instructions telling Python how to rebuild an object.
- Those instructions can include “import this module and call this function”. So loading a model file could run arbitrary code on your machine.
- That is not theoretical. Malicious models with code hidden in pickle payloads have been found on public model hubs.
- safetensors cannot do that, because a JSON header plus raw bytes has no way to express an instruction.
- Because the offsets are known in advance, the file can also be memory-mapped and tensors copied straight to the accelerator with no intermediate parse. That is where the speed comes from.

■ 49.11.5 TECHNICAL – the engineer's version

- The format comparison you should be able to give from memory:

Format	Code execution risk	Main use
PyTorch .bin (pickle)	Yes, arbitrary	Legacy checkpoints
safetensors	No	Default for published weights
GGUF	No	llama.cpp local inference
ONNX	No, but graph is code-like	Cross-runtime deployment

- safetensors was created at Hugging Face and became the default published format across the hub during 2023. Design goals in the project's own words: safe against code execution, zero-copy, memory-mappable, and fast.
- The pickle risk was severe enough that PyTorch changed the default. From PyTorch 2.6, released January 2025, `torch.load` defaults to `weights_only=True`, which refuses to execute arbitrary globals. Before that the default was unsafe and most tutorials did not mention it.

4. **GGUF** is the format of the `llama.cpp` and `ggml` ecosystem, introduced in August 2023 to replace the earlier GGML, GGMF and GGJT formats. Its defining feature is a typed key-value metadata block, so new fields can be added without breaking old readers.
5. GGUF is single-file and self-contained: architecture metadata, tokenizer vocabulary and merges, and quantized tensors all live in the one file. That is why a GGUF download needs no config or tokenizer alongside it.
6. GGUF bakes quantization into the file. The type names you will see include F32, F16, BF16, Q8_0, Q6_K, Q5_K, Q4_K, Q4_0, and the IQ series such as IQ4_XS and IQ2_XXS. Around 40 types are defined. Chapter 47 covers what the K-quants actually do.
7. **ONNX**, Open Neural Network Exchange, was launched by Microsoft and Facebook in September 2017. It stores a computation graph plus weights in a Protocol Buffers message, so a model trained in one framework can run in another. It does not execute Python, but it does describe operations, and custom operators can load native code, so it is not risk-free in the way safetensors is.
8. Practical file-size arithmetic, which you can do in your head:

Precision	Bytes per parameter	8B model file
FP32	4	about 32 GB
BF16 or FP16	2	about 16 GB
Q8_0	about 1.06	about 8.5 GB
Q4_K_M	about 0.60	about 4.9 GB

9. Quantized types are slightly larger than the nominal bit count suggests because each block of 32 to 256 weights carries a scale, and sometimes an offset, stored at higher precision.
10. What is emphatically not in a weights file: the training data, the data mixture, the training code, the hyperparameters used during training, the optimizer state, the random seed, or any record of how the numbers arrived.
11. Commands that inspect these files: `safetensors` exposes a Python API where `safe_open(path, framework="pt")` lists keys without loading data; `gguf-dump` prints GGUF metadata and tensor tables; `python -m onnx.checker` validates an ONNX graph; and `huggingface-cli scan-cache` shows what you have downloaded and how much disk it is using.

■ 49.11.6 WORDS – remember these

1. **Weights file** — the big file of numbers — a binary container of tensors, sized at parameter count times bytes per parameter.
2. **Config** — the shape description — a JSON file of architecture hyperparameters needed to interpret the tensor layout.
3. **Tensor name** — the address of one rectangle of numbers — a hierarchical string key such as `model.layers.7.mlp.up_proj.weight`.
4. **safetensors** — the safe modern weights format — an 8-byte length, a JSON header of dtypes, shapes and offsets, then raw bytes.
5. **Pickle** — Python’s object format that can run code — the mechanism behind legacy `.bin` checkpoints and their arbitrary-code-execution risk.
6. **GGUF** — a single self-contained file for local inference — metadata, tokenizer and quantized tensors together, used by `llama.cpp`.
7. **Memory mapping** — reading a file without copying it into memory first — using the operating system’s virtual memory to page tensor bytes on demand.

49.12 Open weights versus open source

■ 49.12.1 PLAIN – in simple words

1. This is the part of the chapter where the words are genuinely abused, so we will be slow and exact.
2. There are four separate things people mix together. Each is independent of the others. A model can have any combination.
3. **Open weights** means the number file can be downloaded and run. That is all it means. Nothing about permission, nothing about data.
4. **Open source** means something specific. It is a definition maintained by the Open Source Initiative since 1998, and it is about the licence granting you freedom to use, study, modify and share, without restrictions on who you are or what field you work in.
5. **Open data** means the training corpus itself is published, so somebody else could rebuild the model rather than just run it.
6. **The licence terms** are separate again. A model can be open-weight and carry a licence that forbids commercial use, or forbids competitors, or forbids certain applications.
7. The abuse works like this. A company publishes only the weights, under a licence with restrictions, and calls the result open source.
8. Almost nothing about it is open source. The source, in the sense that matters, would be the data and the training code, and neither was released.
9. A more honest word, which some companies now use, is “open weights”.
10. Why does the distinction matter practically? Because you cannot verify what is in a model you cannot inspect the data for, you cannot reproduce it, and you may find at deployment time that the licence forbids your use.

■ 49.12.2 PLAIN – a picture in your head

1. Think about a restaurant and a famous sauce.
2. Selling you a jar of the sauce is open weights. You have the thing. You can taste it, use it, put it on your food.
3. Publishing the recipe is open source. Now you can make it, change it, improve it, and check whether the ingredients are what they claimed.
4. Publishing where every ingredient was bought is open data.
5. And the label on the jar might say “not for resale” or “not for use in commercial kitchens”. That is the licence.
6. Selling the jar and calling it “open source sauce” is the thing being objected to. You cannot make the sauce. You cannot check the ingredients. You have a jar.

Where this comparison breaks: a sauce could be reverse-engineered by a skilled cook. Model weights cannot be reverse-engineered into their training data in any practical sense. Also, the jar of sauce is not itself useful for making more sauce, whereas model weights genuinely are useful for building further models, which is why open weights deliver real value even without the recipe.

■ 49.12.3 PLAIN – a worked example

1. What real models actually release. Status as of mid-2026.

Model family	Weights	Training data published
OLMo 2, OLMo 3 (Ai2)	Yes	Yes, full corpus
Pythia (EleutherAI)	Yes	Yes, the Pile

Model family	Weights	Training data published
BLOOM (BigScience)	Yes	Yes, ROOTS corpus
Llama 3.1, Llama 4 (Meta)	Yes	No
Qwen3 (Alibaba)	Yes	No
DeepSeek-V3, R1	Yes	No
gpt-oss (OpenAI)	Yes	No
Gemma (Google)	Yes	No
GPT-5, Claude, Gemini	No	No

2. And the licences, which is a separate question from the table above.

Model family	Licence	Key restriction
OLMo, Pythia	Apache 2.0	None of substance
Qwen3, gpt-oss	Apache 2.0	None of substance
DeepSeek-R1	MIT	None of substance
Mistral 7B, Mixtral	Apache 2.0	None of substance
Llama 3.1, Llama 4	Meta Community	700m users, AUP, naming
Gemma	Gemma Terms	Prohibited use policy
BLOOM, StarCoder2	OpenRAIL-M	Use-case restrictions

- Read those two tables together and the picture is clear. Full openness, meaning weights plus data plus code plus a permissive licence, exists but is rare, and comes mostly from research institutes rather than from companies.
- The single most-cited restriction, from Meta’s Llama licences: if your products had more than 700 million monthly active users in the month before the release date, you must ask Meta for a separate licence.
- In practice that clause names a handful of companies. It is aimed at competitors, and its presence is precisely why the licence is not open source: open source licences cannot discriminate against a class of user.
- Meta’s licences also require the words “Built with Llama” on derivative products and require derived model names to begin with “Llama”, and bind you to an Acceptable Use Policy that can be updated after you accept it.
- Llama’s multimodal models have additionally carried a restriction excluding users domiciled in the European Union, with no reason given in the licence.

■ 49.12.4 PLAIN – what is really happening inside

- Here is what is normally withheld even by generous open-weight releases.
- The training data.** Which documents, from where, in what proportion.
- The data mixture.** Even when categories are named, the recipe is not.
- The training code.** The actual distributed training harness, the data loader, the parallelism configuration.
- The hyperparameters.** Learning rate schedule, batch ramp, warmup, weight decay, initialization, and the dozens of small choices that make a run work.
- The post-training recipe.** The SFT data, the preference data, the reward model, the safety data. This is often guarded more closely than the pretraining recipe, because it is where the product feel comes from.
- The evaluation and ablation results** that led to those choices.

8. What you get instead is a file that reproduces one point in that space and no way to get to any neighbouring point except by guessing.
9. There are good reasons for some of this. Some data cannot legally be redistributed. Some of it is licensed under terms that forbid it. Some of it would expose the lab to litigation of the kind section 49.2 described.
10. And there are competitive reasons for the rest, which nobody disputes.

■ 49.12.5 TECHNICAL – the engineer’s version

1. Precise definitions, in the terms the field actually uses.
2. **Open weights:** model parameters are distributed for download. Says nothing about licence, data, code or reproducibility. Sometimes called “open access” or, unhelpfully, “open model”.
3. **Open source:** the Open Source Definition, maintained by the Open Source Initiative since 1998, requires among other things free redistribution, availability of source code, permitted derived works, no discrimination against persons or groups, and no restriction on fields of endeavour. Those last two are the clauses most model licences fail.
4. **Open data:** the training corpus is published under a licence permitting use. Examples: the Pile from EleutherAI in 2020, ROOTS from BigScience in 2022, Dolma and Dolma 3 from Ai2, FineWeb from Hugging Face under ODC-By 1.0.
5. **Licence class,** in three tiers you should be able to name: permissive open source, meaning Apache 2.0 or MIT; restricted custom licences, meaning Meta’s Community licences and Google’s Gemma Terms, which are contracts with conditions; responsible-AI licences, meaning the RAIL and Open-RAIL family from 2022 onwards, which are explicitly use-restricted by design and were never claimed to be open source by their authors.
6. Fully open releases, with what each actually shipped: Pythia, EleutherAI 2023: weights at 8 sizes, the Pile as training data in exact training order, training code, and 154 intermediate checkpoints per model, under Apache 2.0. Built for reproducible research on training dynamics, and still the reference example. OLMo, Ai2, February 2024, then OLMo 2 in January 2025 and OLMo 3 in November 2025: weights, full training data, training code, evaluation harness, logs and intermediate checkpoints from every stage. OLMo 3’s release included Dolma 3, a 9.3-trillion-token corpus, the 5.9 trillion token pretraining mix used for the 7B and 32B base models, the post-training data suite, and the data tooling. BLOOM, BigScience 2022: 176B parameters, the ROOTS corpus, the training code, and a detailed record of the process, released under a RAIL licence that carries use restrictions and therefore is not OSI open source.
7. Open-weight, closed-data, permissive licence, which is the commercially dominant pattern: Mistral 7B (September 2023, Apache 2.0), Qwen3 (2025, Apache 2.0), DeepSeek-R1 (January 2025, MIT), and OpenAI’s gpt-oss-120b and gpt-oss-20b (5 August 2025, Apache 2.0).
8. gpt-oss is worth a note because it shows the pattern clearly. Apache 2.0 on the weights, plus published inference reference code, the harmony prompt renderer and the o200k_harmony tokenizer. No training data, no training code. Permissive licence, closed recipe.
9. Established fact: open weights allow local running, fine-tuning, adapter training, quantization, red-teaming and independent measurement. Established fact: they do not allow reproduction, data auditing, or verification of any claim about what the model was trained on. Marketing claim: describing a weights-only release under a restricted licence as “open source”. This is the specific abuse the reader asked about.
10. One practical consequence for engineers. Open weights are the only category that survives a vendor withdrawing a model. A downloaded file keeps working when an API endpoint is deprecated, and API deprecation happens on a twelve-to-twenty-four-month cycle at every major provider.

■ 49.12.6 WORDS – remember these

1. Open weights — the numbers are downloadable — parameters published for use, independent of licence, data or code availability.
2. Open source — a licence granting the four freedoms without discrimination — as defined by the Open Source Initiative's Open Source Definition since 1998.
3. Open data — the training corpus is published — the actual documents, or a reproducible recipe for assembling them, under a usable licence.
4. Permissive licence — almost no conditions — Apache 2.0 or MIT, allowing commercial use, modification and redistribution.
5. Community licence — a contract with conditions attached — Meta's and Google's custom terms, with user thresholds, naming rules and use policies.
6. OpenRAIL — a licence that restricts uses by design — the Responsible AI Licence family, openly not open source and honest about it.
7. Open washing — calling a restricted release open — marketing a weights-only or use-restricted model as open source.

49.13 The Open Source Initiative's position

■ 49.13.1 PLAIN – in simple words

1. The Open Source Initiative is the body that has maintained the definition of open source software since 1998, and it decides which licences qualify.
2. For twenty-five years that definition was about source code. Models are not source code, so it did not obviously apply.
3. So the OSI ran a public process with many contributors and published the **Open Source AI Definition version 1.0** on 28 October 2024.
4. It starts from the same four freedoms as software: use the system for any purpose, study how it works, modify it, and share it, modified or not.
5. To exercise those freedoms you need what it calls the preferred form to make modifications, and it says that means three things must be available.
6. **Data information:** enough detail about the training data that a skilled person could build a substantially equivalent system.
7. **Code:** the complete source code used to train and run the system, under an OSI-approved licence.
8. **Parameters:** the weights and other settings, under OSI-approved terms.
9. Read point 6 carefully, because it is the compromise at the heart of the whole thing. It does not require publishing the data itself. It requires publishing enough information about it.
10. By this definition, most models marketed as open source do not qualify.
11. The OSI has said so directly, naming names.

■ 49.13.2 PLAIN – a picture in your head

1. Think about a food label and a recipe again, one last time.
2. The strictest possible rule would be: hand over every ingredient you used, physically, so anyone can remake the dish exactly.
3. That is impossible for some ingredients. You cannot hand over a bottle of wine you drank, and you cannot hand over a book you licensed for one use.
4. So the OSI settled on: publish the recipe in enough detail that a competent cook could go and buy equivalent ingredients and make substantially the same dish.
5. That satisfies nobody entirely. Purists say a recipe is not the ingredients. Companies say even the recipe is a trade secret.
6. And it is precisely because that middle position annoys both sides that it is worth understanding exactly.

Where this comparison breaks: two cooks following the same recipe get similar results. Two labs following the same data description do not, because model outcomes depend on ordering, seeds, hardware numerics and hundreds of unpublished choices. “Substantially equivalent” is doing a great deal of work in that sentence and nobody has tested it in practice at frontier scale.

■ 49.13.3 PLAIN – a worked example

1. The OSI published its own assessment of real models against the definition. Its stated results, which it describes as part of the definitional process rather than as certifications:

Verdict	Models named by the OSI
Passes	Pythia, OLMO, T5
Passes	Amber, CrystalCoder
Would pass if relicensed	BLOOM, StarCoder2, Falcon
Does not pass	Llama 2, Grok, Phi-2, Mixtral

2. Note that Mixtral is in the failing list despite being under Apache 2.0. The licence is fine. The data information is missing. Both are required.
3. Note that BLOOM is in the middle list despite publishing its full training corpus. The data is fine. The RAIL licence restricts uses. Both are required.
4. Those two rows together are the clearest possible illustration that open weights, open data and an open licence are three independent things.
5. The OSI’s specific objections to Meta’s Llama licences: it fails freedom zero, the freedom to use the system for any purpose; it fails the Open Source Definition’s point 5 by discriminating against a class of user via the 700-million-user threshold; and it fails point 6 by restricting fields of endeavour through the Acceptable Use Policy. The OSI has also pointed to the exclusion of European Union users from certain models, unexplained.
6. The OSI uses the term “open washing” for marketing a restricted release as open source.

■ 49.13.4 PLAIN – what is really happening inside

1. Now the counter-arguments, given fairly, because this is a live dispute and not a settled question.
2. **Training data cannot always be redistributed.** Much of it is copyrighted text that the lab has a defensible claim to train on but no right to republish. Publishing it would be a separate and much larger legal exposure.
3. **Some of it must not be redistributed.** Web-scale corpora contain personal data. Publishing the corpus can conflict with privacy law even where training on it does not.

4. **Open weights deliver most of the practical benefit.** With weights you can run locally, fine-tune, quantize, audit behaviour, red-team, and avoid depending on a vendor. Very few people were ever going to retrain a frontier model even with the full data.
5. **Reproduction is impossible anyway at this scale.** Even with the corpus, rebuilding a frontier model costs tens of millions of dollars, so the freedom being protected is theoretical for almost everyone.
6. And there is a criticism from the opposite direction, which is important.
7. Some free-software advocates argued the OSI's compromise is too weak: that allowing "data information" instead of data lets companies claim the label without the substance, which is the very open washing the definition was meant to stop.
8. So version 1.0 is attacked from both sides: too strict for industry, too loose for purists. The OSI itself has said the definition will be revised.
9. The honest version: there is no consensus. The OSI has the strongest claim to define "open source" because it has defined it for software since 1998, but no legal authority, and companies are free to ignore it and do.

■ 49.13.5 TECHNICAL – the engineer's version

1. What the definition requires in full, as three components. Data information: complete descriptions of all data used, including provenance, scope and characteristics, how it was obtained and selected, labelling procedures, and cleaning and filtering methodologies, in enough detail that a skilled person can build a substantially equivalent system. Code: the complete source used for data processing and filtering, training, with all training arguments, validation, testing and inference, under OSI-approved licences. Parameters: model weights and other configuration settings, including intermediate checkpoints and final optimizer states, under OSI-approved terms.
2. That third clause is stricter than people notice. Intermediate checkpoints and optimizer state are almost never published. Pythia and OLMo do publish checkpoints, which is exactly why they pass.
3. Timeline of the dispute, dated: 1998, the Open Source Definition is published. 2022, RAIL and OpenRAIL licences appear, explicitly use-restricted. February 2023, Meta releases LLaMA 1 weights to researchers on request. July 2023, Llama 2 is released under a community licence and widely described in press coverage as open source. 2023 to 2024, the OSI runs a co-design process with contributors from industry, academia and civil society. 28 October 2024, Open Source AI Definition 1.0 is published at the All Things Open conference. Through 2025 and 2026, the argument continues without resolution, with further drafts under discussion.
4. Parallel regulatory pressure, which may matter more than the definitional argument in the end. The European Union's AI Act, in force from 1 August 2024 with general-purpose model obligations applying from 2 August 2025, requires providers to publish a sufficiently detailed summary of training content and to have a copyright policy. It also provides partial exemptions for models released under free and open-source licences, which gives the definition of "open" direct legal consequences.
5. So a term that was a marketing argument in 2023 became a compliance question in 2025. That is the practical reason to get it right.
6. Established fact: the OSAID 1.0 text, its date, its three required components, and the OSI's published assessments of named models. Active dispute: whether the data-information compromise is correct, whether version 1.0 will hold, and whether regulators will adopt it. Marketing claim: any company statement that its weights-only release "is open source" without addressing data information or licence restrictions.

■ 49.13.6 WORDS – remember these

1. OSAID — the open source rulebook for AI — the Open Source AI Definition 1.0, published by the OSI on 28 October 2024.
2. Data information — a description good enough to rebuild from — sufficiently detailed data documentation to build a substantially equivalent system.
3. Four freedoms — use, study, modify, share — the freedoms the definition requires an open source AI system to grant without restriction.
4. OSI-approved licence — a licence on the OSI’s published list — the test a licence must pass to be called open source.
5. Open washing — claiming openness you did not deliver — marketing a restricted or weights-only release using the open source label.

49.14 Model releases in practice

■ 49.14.1 PLAIN – in simple words

1. When a model is released, the file is the smallest part of the event.
2. Around it sit documents, gates and processes, and knowing what they should contain lets you judge a release in a few minutes.
3. The **model card** is the main document. The idea comes from a 2019 paper by Mitchell and colleagues, and it is now near-universal practice.
4. It should say: what the model is for, what it is not for, what it was trained on in general terms, how it scores on named benchmarks, what its known limitations are, and what licence applies.
5. The **system card** is a bigger document about the deployed product rather than the raw model: what safety testing was done, what was found, what mitigations were added, and what risks remain.
6. **Staged release** means publishing in steps rather than all at once, to watch what happens.
7. **Red-teaming** means paying people to attack the model before release and trying to make it do what it should not.
8. **Watermarking** means trying to mark generated output so it can be detected later. It works better for images than for text.
9. And a **licence gate** on a hosting site means you must accept terms, and often give your name and email, before you can download.
10. What is missing from a release tells you as much as what is present.

■ 49.14.2 PLAIN – a picture in your head

1. Think of the paperwork that comes with a new medicine.
2. There is a leaflet saying what it treats, the dose, who must not take it, and the side effects observed in trials. That is the model card.
3. There is a much longer regulatory dossier describing every trial, its results, and the risks that remain. That is the system card.
4. There is a phased rollout, first to a limited group, then wider. That is the staged release.
5. And there is a pharmacist who checks who you are before handing it over. That is the licence gate.
6. Now imagine a medicine arriving with no leaflet at all, and ask yourself what that absence tells you.

Where this comparison breaks: medicines are regulated by law with mandatory content and legal consequences for omissions. Model cards are, in most places and as of mid-2026, entirely voluntary

in content and quality. The European Union’s AI Act is the first serious attempt to make parts of this mandatory, and it applies to general-purpose models only from 2 August 2025.

■ 49.14.3 PLAIN – a worked example

1. The checklist to run against any release. Present or absent, and what the absence means.

Item	If missing, that means
Named training-data sources	You cannot audit or trust claims
Knowledge cutoff date	You cannot judge staleness
Benchmark results with names	Comparisons are unverifiable
Stated out-of-scope uses	No thought given to misuse
Compute and energy figures	Cost and impact unassessable
Licence text, not a summary	Read the actual terms first
Evaluation of known weaknesses	Only wins are being reported

2. Real examples of each end of the spectrum. Meta’s Llama 3.1 model card gives GPU-hours, energy, carbon, knowledge cutoff of December 2023, benchmark tables and licence, but describes training data only as “publicly available sources” with category percentages.
3. Ai2’s OLMo releases give all of the above plus the corpus itself, the data tooling, the training logs and intermediate checkpoints.
4. Closed model releases typically give benchmark tables and a system card, and no training data information at all.

■ 49.14.4 PLAIN – what is really happening inside

1. What happens in the weeks before a release, roughly in order.
2. Internal evaluation on held-out benchmarks, plus contamination checks to confirm the benchmarks were not in the training data.
3. Capability evaluations against a published safety framework, testing for dangerous capabilities in specific named categories.
4. Red-teaming, both internal and by hired external groups, attempting jailbreaks and misuse. Findings feed back into more safety fine-tuning.
5. Sometimes external review, by a government safety institute or a contracted evaluation organization, before release.
6. Then a decision, then the documents, then the gate, then publication.
7. **Staged release** has a clear historical example. In February 2019 OpenAI announced GPT-2 and released only the 124-million-parameter version, citing misuse concerns. It released 355M in May, 774M in August, and the full 1.5B model in November 2019, publishing its reasoning at each step.
8. That decision was heavily criticized at the time as overcautious, and it set the template that every lab now follows in some form.
9. Note what staged release cannot do for open weights. Once the file is downloaded it cannot be recalled, and as section 49.5 noted, the safety training can be removed by fine-tuning for a few hundred dollars.

■ 49.14.5 TECHNICAL – the engineer’s version

1. Model cards: proposed in “Model Cards for Model Reporting”, Mitchell and colleagues, 2019. The companion idea for data is “Datasheets for Datasets”, Gebru and colleagues, 2018. Both are now conventions rather than standards, though Hugging Face enforces a minimal card structure on its hub.

2. System cards: OpenAI published the GPT-4 System Card in March 2023, separating deployment risk analysis from the technical report. Anthropic and Google now publish equivalents for major releases. Contents typically include red-team findings, capability evaluations against a framework, refusal rates, and known failure modes.
3. Named safety frameworks you should recognize, with dates: Anthropic’s Responsible Scaling Policy, September 2023; OpenAI’s Preparedness Framework, December 2023; Google DeepMind’s Frontier Safety Framework, May 2024. All define capability thresholds that trigger additional controls. All are voluntary commitments, not regulation.
4. Government bodies: the UK AI Safety Institute was announced in November 2023 and renamed the AI Security Institute in February 2025. The US AI Safety Institute was established in 2023 and renamed the Center for AI Standards and Innovation in June 2025. Both have run pre-deployment evaluations under agreements with major labs.
5. Watermarking. Google DeepMind’s SynthID for images was announced in August 2023, and SynthID-Text was published in the journal Nature in October 2024, using a tournament sampling scheme that biases token choice in a detectable pattern. Google reported it does not measurably degrade quality.
6. The honest position on text watermarking: it is detectable while the text is unedited, and it degrades under paraphrasing, translation or moderate editing. It also requires the generator to co-operate, so it does nothing about open-weight models where the sampler can simply be replaced. Treat claims of robust text watermarking as marketing.
7. The C2PA standard, from a coalition including Adobe and Microsoft, takes the other approach: cryptographically signed provenance metadata attached to a file. It survives editing by signed tools and is destroyed by screenshots.
8. Licence acceptance gates: Hugging Face supports gated repositories, where a user must accept terms and often supply contact details, with optional manual approval. Meta and Google both use them. The gate is a contractual mechanism, not a technical one; it does not prevent redistribution.
9. Regulatory contents, dated. Under the European Union’s AI Act, providers of general-purpose models have obligations from 2 August 2025 including technical documentation, information for downstream providers, a copyright policy, and a sufficiently detailed public summary of training content, with partial exemptions for free and open-source releases and additional duties above the 10-to-the-25-FLOPs systemic-risk threshold.
10. Practical advice: read the licence file itself, not the summary on the model page; check the knowledge cutoff before relying on recency; check whether the card names benchmarks or just claims performance; and check whether evaluation numbers are self-reported or independently reproduced.

■ 49.14.6 WORDS – remember these

1. Model card — the leaflet that comes with a model — a structured document of intended use, training description, evaluations, limitations and licence.
2. System card — the safety dossier for the deployed product — red-team findings, capability evaluations, mitigations and residual risks.
3. Staged release — publishing in steps to watch the effect — incremental release of larger checkpoints or wider access over time.
4. Red-teaming — paying people to attack it before release — structured adversarial testing for jail-breaks, misuse and dangerous capability.
5. Watermarking — marking generated output so it can be detected — biased sampling for text, or signed provenance metadata for media.

6. Gated repository — you must accept terms to download — a hosting-site mechanism collecting acceptance and often identity before access.

49.98 Common wrong ideas

1. Wrong: the model was trained on the internet, so it knows everything. Right: it was trained on a heavily filtered slice of a web crawl, plus books, code and papers, and typically 80 to 95 per cent of the crawl was discarded. It has a knowledge cutoff date, it never saw most paywalled or private material, and what it did see it stored lossily as statistical patterns rather than as retrievable text.
2. Wrong: fine-tuning teaches it new facts. Right: fine-tuning teaches format, style and behaviour. Knowledge comes from pretraining because knowledge comes from data volume, and a fine-tuning set is perhaps one thirty-thousandth the size of the pretraining set. Fine-tuning on unfamiliar facts is learned slowly and measurably increases hallucination elsewhere. Use retrieval for facts.
3. Wrong: open weights means open source. Right: they are separate. Open weights means the numbers are downloadable. Open source, by the Open Source Initiative's definition of October 2024, additionally requires the training code, sufficiently detailed data information, and a licence with no discrimination against users or fields of use. Mixtral is Apache 2.0 and fails; BLOOM publishes its corpus and fails.
4. Wrong: RLHF makes the model truthful. Right: it makes the model produce answers that human raters prefer. Where raters prefer confident, agreeable, long or well-formatted answers, that is what gets reinforced. This is why sycophancy and length inflation are standard failure modes, and why OpenAI had to roll back a GPT-4o update in April 2025 for exactly this reason.
5. Wrong: training and running cost about the same. Right: they differ by roughly thirteen orders of magnitude per query. Training an 8-billion model on 15 trillion tokens is about $7.2e23$ FLOPs. Generating one token from it is about $1.6e10$ FLOPs. Training equals roughly 45 trillion generated tokens. For a busy service, cumulative inference overtakes training cost within months.
6. Wrong: a bigger model is always better. Right: Chinchilla in 2022 showed a 70-billion model beating a 280-billion one at equal compute because it saw four times more data. Data quantity, data quality and post-training all matter as much as parameter count.
7. Wrong: labs publish what they trained on. Right: GPT-3 published a mixture table in 2020. Almost nobody does now. GPT-4's technical report explicitly declined. Any claim about a closed model's training data, including a claim about what it did not include, is unverifiable from outside.
8. Wrong: the safety training is part of the model and cannot be removed. Right: for open weights it can be substantially removed by fine-tuning on a few hundred adversarial examples, for a few dollars. Safety behaviour is a thin post-training layer over an unchanged base capability.
9. Wrong: a training run is one program on one big computer. Right: it is thousands of accelerators running in lockstep, split three ways across data, tensors and layers, and hardware fails constantly. Meta reported 419 unexpected interruptions in 54 days on one run.
10. Wrong: the weights file contains the training data somewhere inside it. Right: it contains only numbers arranged in named tensors, plus a config and a tokenizer. Verbatim regurgitation of memorized training text does happen, especially for text duplicated many times in the corpus, but the data is not stored or retrievable in any ordinary sense.

49.99 Chapter summary in 20 lines

1. A model is made in a chain: collect data, clean it, train a tokenizer, pretrain, post-train, evaluate, release. Pretraining is 95 to 99 per cent of the compute and post-training is almost all of the visible behaviour.
2. Data comes from web crawls such as Common Crawl, which published 2.42 billion pages and 419 TiB uncompressed in its July 2025 archive alone, plus books, code, papers, licensed corpora and synthetic text.
3. Cleaning discards most of it: URL blocking, text extraction, language identification, exact and MinHash fuzzy deduplication, heuristic and classifier quality filters, toxicity and PII removal, and benchmark decontamination, then deliberate mixing ratios over the survivors.
4. FineWeb's published pipeline uses 5-gram shingles with 14 bands of 8 hashes, which catches near-duplicates above about 0.75 Jaccard similarity 77 per cent of the time and above 0.9 essentially always.
5. Copyright is unsettled and actively litigated. Judge Alsup held in June 2025 that training on lawfully bought books was fair use while retaining pirated copies was not, and Anthropic settled for a reported 1.5 billion dollars.
6. Most labs stopped publishing their data mixture after GPT-3 in 2020, so claims about a closed model's training data are unverifiable from outside.
7. Pretraining has exactly one objective: next-token prediction, scored by cross-entropy loss in nats, starting at the natural log of the vocabulary size and typically ending between 1.4 and 2.0.
8. One step is a forward pass over a batch of millions of tokens, a loss, a backward pass costing about twice the forward, and an AdamW update. Llama 3 405B used a peak learning rate of $8e-5$, 8,000 warmup steps and cosine decay to $8e-7$ over 1.2 million steps.
9. Llama 3.1 405B is the best-documented real run: over 16,384 H100s, 30.84 million GPU-hours, about 15.6 trillion tokens, roughly 78 days of wall clock and an estimated 62 to 123 million dollars of rented compute.
10. Training compute is approximately $6ND$, parameters times tokens times six. It reproduces GPT-3's reported $3.14e23$ and Llama 3.1 405B's $3.8e25$, and the European Union's AI Act uses 10 to the 25 as a systemic-risk threshold.
11. Kaplan and colleagues in January 2020 found smooth power laws and advised spending on size; Hoffmann and colleagues in March 2022 showed models were badly undertrained and that about 20 tokens per parameter is optimal.
12. Since 2023 labs deliberately overtrain small models far past that, because inference cost dominates over a deployed model's life. Llama 3.1 8B was trained at about 1,875 tokens per parameter, roughly 94 times Chinchilla.
13. A base model continues text and cannot be used as a chatbot: no turns, no roles, no stopping rule and no refusal behaviour. Ask it a question and it will often produce more questions.
14. SFT fixes that with tens of thousands to a few million demonstration pairs, a chat template of special tokens such as Llama 3's `<|eot_id|>`, loss masked to the assistant's tokens, and a learning rate ten times lower.
15. Preference learning goes further: collect comparisons, train a reward model, optimize with PPO under a KL penalty. Its characteristic failure is reward hacking, exemplified by OpenAI's sycophantic GPT-4o update of April 2025.
16. DPO in May 2023 removed the separate reward model algebraically and most smaller teams moved to it; constitutional and RLAIF methods replace human labels with written principles and an AI judge; RLVR uses checkable answers in maths and code and is the engine behind reasoning models.

17. Post-training shapes behaviour and cannot efficiently install knowledge, because the data is thirty thousand times smaller and the learning rate is set gently on purpose. The boundary is real but fuzzy, and mid-training blurs it deliberately.
18. LoRA freezes the base and trains thin low-rank matrices, cutting a 7B fine-tune from about 112 GB to about 17 GB; QLoRA adds a 4-bit base and cuts it to about 7 GB, which put a 65B fine-tune on one 48 GB card in 2023.
19. Weights are a binary file of numbers plus a config and a tokenizer. safetensors is an 8-byte length, a JSON header of dtypes, shapes and offsets, then raw bytes, and it exists because pickle-based .bin files can execute arbitrary code on load; GGUF bundles quantization and tokenizer.
20. Open weights, open source, open data and licence terms are four independent things. The Open Source AI Definition 1.0 of 28 October 2024 requires code, parameters and data information sufficient to rebuild a substantially equivalent system, and by it most models marketed as open source, including Llama, do not qualify. That remains a live dispute, not a settled question.

Benchmarks, Evaluation, Versions and Dates

50.0 What this chapter gives you

1. You will be able to say exactly what a benchmark is, in five mechanical parts, and name which part is being argued about when two numbers disagree.
2. You will be able to describe the main benchmarks by name, year, size and scoring rule, and say for each one what it does not measure.
3. You will be able to explain why the same model, on the same benchmark, run by two honest teams, can legitimately produce different scores.
4. You will be able to compute pass@k by hand and explain why it is reported instead of a plain percentage.
5. You will be able to explain benchmark contamination, list five ways people try to detect it, and say honestly why detection is hard and disputed.
6. You will be able to read a model announcement and list the eight things it did not tell you.
7. You will be able to explain the difference between a training cutoff date and a release date, and why models are bad at reporting their own cutoff.
8. You will be able to explain why a product name and a model identifier are different things, and why pinning a dated identifier matters in production.
9. You will be able to build your own evaluation set of 30 to 100 examples with a scoring rule, and use it to choose and re-choose a model.
10. Throughout, you will be able to sort a claim into three bins: established fact, active research, and marketing claim.

A warning that applies to this whole chapter. The dates, item counts, paper titles and naming conventions here were checked in August 2026. The item counts and the naming conventions are stable. The leaderboard numbers are not. Any specific score in this chapter should be read as “roughly this, in mid-2026”, and any score you care about should be re-checked at the source.

50.1 What a benchmark is, mechanically

■ 50.1.1 PLAIN – in simple words

1. A benchmark is a test. That is all it is.
2. It has a fixed list of questions.
3. Somebody already knows the right answer to every question.
4. There is a rule for deciding if a given answer counts as right.

5. You give the questions to the model, collect its answers, apply the rule, and count.
6. The count, turned into a percentage, is the score.
7. There is nothing magic in it. It is a school test with a marking scheme.
8. It is not a measurement of intelligence, any more than a spelling test is.
9. It measures one thing: how many of these particular items, marked this particular way, this particular model got right on this particular day.
10. Everything difficult about benchmarks comes from the words “particular”.
11. Change the wording of the question and the score moves.
12. Change the marking rule and the score moves.
13. Change which items you use and the score moves.
14. None of that is cheating. It is just what happens.
15. So when two labs publish different numbers for the same model on the same test, the first assumption should not be dishonesty. It should be setup.

■ 50.1.2 PLAIN – a picture in your head

1. Think of a driving test.
2. The test has a fixed route, a fixed set of manoeuvres, and an examiner with a clipboard listing faults.
3. Two candidates take the same test and get different results. Fine.
4. Now take the same candidate to two different test centres.
5. One centre uses a route with a busy roundabout. The other uses a quiet estate. The candidate may pass one and fail the other.
6. One examiner counts a small kerb touch as a minor fault. Another counts it as a major. Same driving, different result.
7. One centre lets you do a warm-up lap first. The other does not.
8. Now imagine the candidate has driven that exact route four hundred times, because it is published online.
9. That last one is contamination, and section 50.5 is about it.
10. And here is the biggest problem. Passing a driving test does not tell you whether somebody can drive to Manchester in fog at night.

Where this comparison breaks: a driving test has a legal standard behind it and an examiner who watched you. Most AI benchmarks have neither. Nobody watched the model. A script compared strings. Also, driving tests are not published in advance with all the answers. Almost every AI benchmark is.

■ 50.1.3 PLAIN – a worked example

1. Here is one real item, in the style of GSM8K, a set of grade-school maths word problems released by OpenAI in 2021.

Question:

Natalia sold clips to 48 friends in April, and then she sold half as many clips in May. How many clips did she sell altogether in April and May?

Reference answer (the dataset marks the final number with four hash characters):

$48 / 2 = 24$

$48 + 24 = 72$

72

- The #### marker is part of the dataset format. The number after it is the answer the scorer will compare against.
- Now here are two different things a model might produce.

Model A output:

"She sold 48 in April and 24 in May, so 72 clips."

Model B output:

"72"

- Both are correct. A strict scorer that demands the whole reply to equal "72" marks model A wrong and model B right.
- A scorer that pulls the last number out of the reply marks both right.
- Nothing about the model changed. The marking rule changed.
- That single choice can move a reported score by several points across a whole benchmark.
- Now a nastier case. A model replies "72 clips". A scorer that pulls the last number finds 72. Good.
- A model replies "The answer is $48 + 24 = 72$." A scorer that pulls the last number still finds 72. Good.
- A model replies "She sold 72, up from 48." A scorer that pulls the last number finds 48 and marks it wrong. The model was right.
- Real answer-extraction bugs look exactly like this.

■ 50.1.4 PLAIN – what is really happening inside

- Every benchmark run has exactly five moving parts. Learn these five and you can interrogate any published number.
- Part one, the **items**. The fixed list of questions and known answers.
- Part two, the **prompt template**. The wrapper of text that surrounds each item before it reaches the model. Instructions, examples, formatting.
- Part three, the **generation settings**. How the model is asked to produce text: temperature, how many tokens it may write, whether it may think first.
- Part four, the **answer extraction and scoring function**. The code that turns a blob of model text into "right" or "wrong".
- Part five, the **aggregate**. How the per-item results are combined into one number, and whether that number is one run or an average of several.
- Here is the flow as a picture.

- Each of the five boxes is a choice made by whoever ran the evaluation.
- Every one of those five choices changes the number that comes out.
- Only the first box, the items, is usually published. The other four are often described in a sentence or not at all.
- That is the single most important fact in this chapter.

12. The honest version: the sentence “this model scores 88 per cent on MMLU” is incomplete in the way “this car does 60” is incomplete. A benchmark score is not a property of a model. It is a property of a model plus a harness, measured on one day.

■ 50.1.5 TECHNICAL – the engineer’s version

1. Formally, an evaluation is a tuple: a dataset D of items, a prompt function p that maps an item to a model input, a decoding configuration, an extraction function e that maps model output to a candidate answer, a metric m that compares candidate to reference, and an aggregation over D .
2. The score is $(1/|D|) * \sum \text{over } i \text{ of } m(e(\text{model}(p(d_i))), a_i)$ for accuracy-style metrics. Everything contested lives in p , e and the decoder.
3. Two implementation families exist for multiple-choice items and they do not give the same answer.
4. **Log-likelihood scoring**: present the question, then score each candidate continuation by the model’s log probability, and pick the highest. The model never generates a token. Common for base models.
5. **Generative scoring**: present the question with lettered options, let the model emit text, then parse a letter out of it. Common for chat models.
6. On the same items and the same model these can differ by several points. Neither is wrong. They measure different things.
7. Length normalization is a further fork. Raw log probability favours short options, so harnesses often divide by token count or by character count, or normalize against the unconditional probability of the option.
8. The EleutherAI **lm-evaluation-harness** is the de facto open standard for this. It supports over 60 academic benchmarks with hundreds of subtask variants, and it powered the Hugging Face Open LLM Leaderboard. Its stated principle is that publicly available prompts make results reproducible and comparable between papers. This is a convention, not a standard.
9. Stanford CRFM’s **HELM**, first published in November 2022 as “Holistic Evaluation of Language Models”, takes the other approach: fix the prompts centrally, report many metrics per scenario rather than one, and publish every raw model output.
10. Terminology: a **harness** is the code that runs the loop. A **scenario** or **task** is one benchmark inside it. A **run** is one execution.
11. There is no ISO or IEEE specification for any of this. There is no conformance test. Everything in this section is convention.

Part of a run	Who usually sets it	Usually published?
Items	Benchmark author	Yes
Prompt template	Evaluator	Sometimes
Decoding settings	Evaluator	Rarely
Extraction and metric	Evaluator	Rarely

■ 50.1.6 WORDS – remember these

1. Benchmark — a fixed test with known answers — a dataset plus a prompting, extraction and scoring protocol.
2. Item — one question — one example in the evaluation dataset, with a reference answer.
3. Prompt template — the wrapper text around a question — the function mapping a dataset item to model input, including any few-shot exemplars.
4. Harness — the program that runs the test — the evaluation framework that implements prompting, decoding, extraction and aggregation.

5. Extraction — pulling the answer out of the reply — the parser mapping raw generation to a comparable candidate answer.
6. Metric — the marking rule — the function comparing candidate to reference, such as exact match or pass@k.
7. Aggregate — the final single number — the reduction over all items, often plain accuracy, sometimes a macro average over subjects.
8. Log-likelihood scoring — asking which option the model thinks most likely — ranking candidate continuations by model log probability without generating.

50.2 The major benchmarks, one at a time

■ 50.2.1 PLAIN – in simple words

1. There are perhaps twenty benchmark names you will see repeatedly.
2. They fall into a few families.
3. **Knowledge quizzes:** multiple-choice questions across many school and university subjects. MMLU is the famous one.
4. **Maths:** word problems and competition problems. GSM8K, MATH, AIME.
5. **Code:** write a function that passes hidden tests. HumanEval, MBPP.
6. **Hard science:** questions a PhD student would struggle with. GPQA.
7. **Agentic work:** give the model a real repository and a real bug report and see whether the tests pass afterwards. SWE-bench.
8. **Reasoning puzzles:** coloured grid puzzles with no text at all. ARC-AGI.
9. **Common sense:** pick the sensible ending to a sentence. HellaSwag.
10. **Instruction following:** did it obey the format you asked for? IFEval.
11. **Chat quality:** judged by a human or by another model. MT-Bench.
12. Each of these was built for a reason, at a time, by somebody.
13. Almost all of them are now much easier than when they were built.
14. That is not because they were badly made. It is because the models improved and because the tests leaked into training data.
15. The single most useful habit is to ask, for each benchmark: what would a model have to be able to do to score well, and is that what I need?

■ 50.2.2 PLAIN – a picture in your head

1. Think of a hospital's set of blood tests.
2. Each test measures one narrow thing. Iron. Glucose. White cell count.
3. No single test tells you whether a person is healthy.
4. A doctor orders several, reads them together, and knows which ones are unreliable in which circumstances.
5. A benchmark suite works the same way. MMLU is a bit like a general inflammation marker: broad, cheap, and non-specific.
6. SWE-bench is like a treadmill stress test: expensive, slow, closer to the real activity, and it can be gamed by training on the treadmill.
7. And here is the part that matters. Some blood tests go out of date. A test that was diagnostic in 1990 may be useless now because everyone takes a supplement that changes the reading.
8. Benchmarks go out of date the same way, and for a similar reason: everybody now optimizes for the reading.

Where this comparison breaks: blood tests have reference ranges established by regulators and re-

producibile physical chemistry behind them. AI benchmarks have neither. Two labs running the same blood test on the same sample should agree within a known tolerance. Two labs running the same AI benchmark on the same model have no agreed tolerance at all.

■ 50.2.3 PLAIN – a worked example

1. Take one benchmark and follow it end to end: GPQA.
2. GPQA stands for Graduate-level Google-Proof Question Answering.
3. It was published on 20 November 2023 by David Rein, Betty Li Hou, Asa Cooper Stickland, Jackson Petty, Richard Yuanzhe Pang, Julien Dirani, Julian Michael and Samuel Bowman.
4. It has 448 multiple-choice questions in biology, physics and chemistry.
5. Every question was written by a person with or studying for a PhD in that subject.
6. “Google-proof” is a design goal, not a guarantee. It means the writers tried hard to make the answer un-findable by search.
7. Here is the evidence they gave for that. Skilled non-experts, allowed unrestricted web access and spending on average over 30 minutes per question, reached 34 per cent accuracy.
8. Experts in the matching field reached 65 per cent, or 74 per cent after correcting for questions the experts later agreed were flawed.
9. Chance is 25 per cent, because there are four options.
10. The best model at publication, based on GPT-4, scored 39 per cent.
11. **GPQA Diamond** is a 198-question subset. It keeps only questions where the expert validators agreed on the answer and most non-experts got it wrong. It is the hardest and cleanest slice.
12. Diamond is what almost every model announcement reports. When you see “GPQA”, check whether it means the 448 or the 198.
13. What GPQA measures well: whether a model holds deep, specific technical knowledge that is not one search away.
14. What it does not measure: whether the model can do science. There is no experiment, no hypothesis, no error bar, no lab. It is a multiple-choice quiz with four options and a one-in-four floor.
15. And by 2026 the top scores on Diamond had risen far above the 65 per cent expert figure, which does not mean the models are better scientists than PhD holders. It means they are better at that quiz.

■ 50.2.4 PLAIN – what is really happening inside

1. Here is each major benchmark in one block: what it is, when, how big, how scored, and its main blind spot.
2. **MMLU**, 2020. “Measuring Massive Multitask Language Understanding”, by Dan Hendrycks, Collin Burns, Steven Basart, Andy Zou, Mantas Mazeika, Dawn Song and Jacob Steinhardt, first posted 7 September 2020.
3. 57 subjects, from elementary mathematics to professional law. Four options per question. About 14,000 test items in the widely used release, plus a 1,531-item validation split and a 285-item development split used for few-shot examples.
4. Scored as plain accuracy. Chance is 25 per cent.
5. Blind spot: it is recall of facts in multiple-choice form. It cannot tell you whether a model can write, reason for ten steps, use a tool, or admit ignorance. It also contains a known number of wrong reference answers.
6. **MMLU-Pro**, 2024. From the TIGER-Lab group, first posted 3 June 2024. About 12,000 questions, ten options instead of four, 14 subject areas, harder items, and many of the broken MMLU items removed.

7. Scores dropped by 16 to 33 points relative to MMLU. Chance falls to 10 per cent. Sensitivity to prompt wording fell from about 4 to 5 points on MMLU to about 2 points on MMLU-Pro, across 24 prompt styles they tried.
8. **GSM8K**, 2021. From “Training Verifiers to Solve Math Word Problems” by Karl Cobbe and colleagues at OpenAI, 27 October 2021. 8.5 thousand grade-school word problems: 7,473 for training, 1,319 for testing.
9. Scored by exact match on the final number. Blind spot: the arithmetic is trivial and the reasoning is two to eight steps. It has been effectively solved since about 2024 and no longer separates strong models.
10. **MATH**, 2021. Hendrycks and colleagues, 5 March 2021. 12,500 competition problems with full worked solutions, split 7,500 train and 5,000 test. Answers are mathematical expressions, not just numbers, which makes marking much harder. A 500-item subset called MATH-500 is widely reported.
11. **HumanEval**, 2021. From “Evaluating Large Language Models Trained on Code” by Mark Chen, Jerry Tworek, Heewoo Jun and 51 others at OpenAI, 7 July 2021. Exactly 164 hand-written Python problems.
12. Each has a function signature, a docstring and hidden unit tests. Scored by pass@k: the chance that at least one of k samples passes all the tests. The original Codex model scored 28.8 per cent at pass@1 and 70.2 per cent at pass@100.
13. HumanEval blind spots, and there are many. 164 items is tiny, so one item is 0.6 points. The problems are self-contained functions of a few lines. There is no project, no dependency, no existing code to read, no debugging. The tests are shallow. It is Python only. And it is thoroughly leaked.
14. **MBPP**, 2021. “Program Synthesis with Large Language Models” by Jacob Austin, Augustus Odena and colleagues at Google, 16 August 2021. 974 entry-level Python problems, each with three assert-statement tests. A hand-cleaned subset of 427 problems is often used instead.
15. **GPQA**, 2023, covered above. 448 items, Diamond subset 198.
16. **SWE-bench**, 2023. “SWE-bench: Can Language Models Resolve Real-World GitHub Issues?” by Carlos Jimenez, John Yang, Alexander Wettig, Shunyu Yao, Kexin Pei, Ofir Press and Karthik Narasimhan at Princeton, 10 October 2023.
17. 2,294 tasks built from real merged pull requests in 12 popular Python repositories. The model gets the repository at the parent commit and the issue text. It must produce a patch. The patch is applied and the project’s own tests are run.
18. Scored as **resolve rate**: the percentage of tasks where the hidden tests that the real pull request made pass, do pass, and nothing that passed before breaks. This is a much stronger signal than string matching.
19. In the original paper the best model tested, Claude 2, resolved 1.96 per cent. By 2026 the reported figures on the Verified subset were far above 70 per cent. That is a genuine capability jump and also a heavily optimized target.
20. **SWE-bench Verified**, 13 August 2024, from OpenAI. 93 experienced Python developers reviewed 1,699 randomly drawn original tasks. Tasks were dropped if the issue text was underspecified or the tests were unfair. 500 were kept. OpenAI reported that 68.3 per cent of sampled original tasks were filtered out for such problems.
21. That is an important admission in both directions. The original benchmark understated model ability. And a benchmark curated by one lab is now the number everyone quotes.
22. Other official variants: SWE-bench Lite (300 tasks, cheaper), SWE-bench Multimodal (517 tasks with visual elements), SWE-bench Multilingual (300 tasks from 42 repositories in 9 languages), and a Bash-only view of the 500 Verified tasks.

23. **ARC-AGI**. Created by Francois Chollet and introduced in his 2019 paper “On the Measure of Intelligence”. The tasks are small coloured grids. You see two or three input-output examples and must produce the output for a new input. No text. No knowledge required.
24. The design goal is to measure skill acquisition on unseen problems rather than stored knowledge. ARC-AGI-2, launched in 2025, has 120 public evaluation tasks and 120 held-back semi-private tasks, and every task was solved by at least two humans in under two attempts, calibrated on over 400 members of the public. ARC-AGI-3 followed.
25. The ARC Prize leaderboard shows cost per task alongside score and by default excludes systems costing more than 10,000 dollars for a run. That is unusual and honest, and more benchmarks should copy it.
26. **HellaSwag**, 2019. Rowan Zellers, Ari Holtzman, Yonatan Bisk, Ali Farhadi and Yejin Choi, 19 May 2019. Pick the sensible continuation of a short description from four options. About 10,000 items in the reported split.
27. The wrong options were produced by Adversarial Filtering: generate candidates by machine, keep the ones a discriminator model finds hard. Humans scored above 95 per cent; the best models of 2019 under 48 per cent. Today it is saturated and is mostly a sanity check on base models.
28. **BIG-bench**, 2022. “Beyond the Imitation Game”, posted 9 June 2022, with over 450 authors from over 132 institutions and 204 tasks. Deliberately weird, broad and long-tailed.
29. Every BIG-bench task file contains a **canary string**, a fixed random-looking identifier the authors ask people never to remove, so that anyone can test whether a model has seen the benchmark. That is a genuinely good idea, and section 50.5 explains what it can and cannot prove.
30. **BIG-Bench Hard**, 2022, is a 23-task subset where models at the time did worse than the average human rater. It is what people actually run, usually as “BBH”.
31. **IFEval**, 2023. Jeffrey Zhou and colleagues at Google, 14 November 2023. About 500 prompts carrying 25 kinds of machine-checkable instruction, such as “write more than 400 words” or “mention the keyword AI at least 3 times” or “reply in JSON” or “no capital letters”.
32. Its whole point is that no judgement is needed: a short Python function checks compliance. It measures obedience to format, not quality of content.
33. **MT-Bench**, 2023. From “Judging LLM-as-a-Judge with MT-Bench and Chatbot Arena” by Lianmin Zheng, Wei-Lin Chiang, Ying Sheng and colleagues, 9 June 2023. 80 multi-turn questions in 8 categories, two turns each.
34. A strong model grades the answers on a 1 to 10 scale. The paper reported over 80 per cent agreement between the model judge and human raters, which is about the level humans agree with each other.
35. The same paper named the three biases of a model judge that you must remember: **position bias** (it prefers whichever answer came first), **verbosity bias** (it prefers the longer answer) and **self-enhancement bias** (it prefers text in its own style).
36. **AIME**. Not built for AI at all. The American Invitational Mathematics Examination is a competition run by the Mathematical Association of America: 15 questions, 3 hours, every answer an integer from 000 to 999, held twice a year.
37. That integer answer format is exactly why AI labs adopted it: marking is trivial and unambiguous. Its weaknesses are that 15 items means one question is 6.7 points, and that each year’s paper is public within hours and in training data within months.
38. **Humanity’s Last Exam**, launched in 2025 by the Center for AI Safety and Scale AI, published in the journal Nature on 28 January 2026. 2,500 questions across more than 100 subjects, written by close to a thousand expert contributors from over 500 institutions in 50 countries.
39. It was built precisely because MMLU had saturated. A private held-back portion is kept to detect

overfitting, and a rolling variant was released on 8 October 2025 to keep adding fresh items.

40. **FrontierMath**, from Epoch AI, is a set of unpublished research-level mathematics problems in difficulty tiers, plus a separate collection of genuinely unsolved open problems. As of 31 July 2026 that open set held 50 unsolved research problems, of which AI systems had contributed solutions to three.
41. **Terminal-Bench**, a Stanford collaboration, gives an agent a real terminal and real tasks in software engineering, machine learning, security and data science, scored by whether the task actually completed. Version 1.0 had 80 tasks, version 2.0 had 89, and later versions followed.

■ 50.2.5 TECHNICAL – the engineer’s version

1. The comparison table, split into four-column pieces so it prints. All item counts verified August 2026 against the dataset cards and papers.

Benchmark	Year	Items
MMLU	2020	~14,000 test
MMLU-Pro	2024	~12,000 test
GSM8K	2021	1,319 test
MATH	2021	5,000 test
HumanEval	2021	164
MBPP	2021	974 (427 clean)
GPQA	2023	448
GPQA Diamond	2023	198
SWE-bench	2023	2,294
SWE-bench Verified	2024	500
ARC-AGI-2	2025	120 + 120 held back
HellaSwag	2019	~10,000 val
BIG-bench	2022	204 tasks
BIG-Bench Hard	2022	23 tasks
IFEval	2023	~500 prompts
MT-Bench	2023	80 questions
AIME (one paper)	yearly	15
Humanity’s Last Exam	2025	2,500

2. Scoring rules and chance floors.

Benchmark	Metric	Chance floor
MMLU	Accuracy	25 per cent
MMLU-Pro	Accuracy	10 per cent
GSM8K	Exact match number	~0
MATH	Expression equivalence	~0
HumanEval	pass@k on unit tests	~0
GPQA Diamond	Accuracy	25 per cent
SWE-bench	Resolve rate	0
ARC-AGI-2	Exact grid match	~0
HellaSwag	Accuracy	25 per cent
IFEval	Constraint pass rate	varies
MT-Bench	Model-judge 1 to 10	n/a

3. The gap between what each measures and what it is claimed to measure. This column is the one people skip.

Benchmark	Claimed as	Actually measures
MMLU	General knowledge	4-way recall, one shot
GSM8K	Reasoning	Short arithmetic chains
HumanEval	Coding ability	Tiny isolated functions
GPQA Diamond	Science ability	Hard 4-way recall
SWE-bench	Autonomous engineer	Patch passes given tests
ARC-AGI	General intelligence	Grid puzzle induction
HellaSwag	Common sense	Adversarially filtered picks
MT-Bench	Chat quality	One model's taste
IFEval	Instruction following	Checkable format rules

4. Established fact: the item counts, dates, authors and scoring rules above. These are checkable in the papers and dataset cards, and they do not move.
5. Active research: whether any of these benchmarks predicts real-world task performance. The honest state of the field is that correlation exists but is weak and task-dependent, and there is no accepted transfer function from a benchmark score to a deployment outcome.
6. Marketing claim: any sentence of the form “scores X on benchmark Y, therefore it is a PhD-level scientist” or “therefore it can replace a junior engineer”. The benchmark supports the first clause only.
7. Tooling. `lm-eval --model hf --model_args pretrained=... --tasks mmlu --num_fewshot 5` runs MMLU under the EleutherAI harness. The SWE-bench project ships its own Docker-based runner, because reproducing per-repository environments is most of the difficulty. `bigcode-evaluation-harness` is the common runner for HumanEval and MBPP and executes generated code in a sandbox, which you should never skip.
8. Note on the honest version of “SWE-bench measures agentic ability”. The honest version: SWE-bench measures the combined ability of a model plus a scaffold plus a retrieval strategy plus a test-running loop. Two entries using the same model and different scaffolds can differ by more than 20 points. Section 50.4 returns to this.

■ 50.2.6 WORDS - remember these

1. Saturation — everyone scores near the top so the test stops sorting — the point where score variance is dominated by noise and label errors rather than capability differences.
2. Diamond subset — the hard, clean slice of GPQA — the 198 questions where expert validators agreed and most non-experts failed.
3. Resolve rate — how often the fix actually worked — the fraction of SWE-bench instances where the fail-to-pass tests pass and pass-to-pass tests still do.
4. Adversarial filtering — keeping only wrong answers that fool machines — an iterative data-collection loop where a discriminator selects distractors.
5. Canary string — a marker planted so leaks can be spotted — a fixed unique identifier embedded in benchmark files to detect web-scrape contamination.
6. Chance floor — the score you get by guessing — the expected accuracy of a uniform random policy, $1/n$ for n options.
7. Held-back set — questions kept secret — a private evaluation split withheld from publication to measure overfitting to the public split.

8. Scaffold — the harness of code around a model in agent tasks — the controller implementing retrieval, tool calls, retries and stopping rules.

50.3 Actually running an evaluation

■ 50.3.1 PLAIN – in simple words

1. Suppose you have the questions and the answers. How do you run the test?
2. First you must decide what text to actually send.
3. You could send only the question. That is called **zero-shot**.
4. You could send a few solved examples first, then the question. That is called **few-shot**, and five examples is called five-shot.
5. Few-shot examples do two jobs. They remind the model of the subject, and more importantly they show it the exact answer format you want.
6. Most of the benefit is the format, not the reminder.
7. Next you decide whether to let the model think out loud before answering. That is **chain-of-thought**.
8. On maths, letting it think out loud changes the score enormously. Not by a little. By tens of points.
9. Next you decide how random the model is allowed to be. That is the temperature setting.
10. Zero means always take the most likely next word. Higher means sometimes take a less likely one.
11. If temperature is above zero, the same model on the same question can give different answers on different days.
12. So the same evaluation run twice gives two different scores.
13. That is why careful teams run the whole thing several times and report the average, and ideally the spread.
14. Then you must decide how to mark the reply, which is the hardest part.
15. For a single number, compare numbers. For a letter, find the letter. For an essay, you need a human or another model, and both are unreliable.

■ 50.3.2 PLAIN – a picture in your head

1. Think of a school exam being marked by three different people.
2. The first marker demands the answer in the box, in pen, and nothing else. Anything in the margin is ignored.
3. The second marker reads the whole page and looks for the answer wherever it is. More forgiving, but sometimes picks up a crossed-out number.
4. The third marker is an experienced teacher who reads the reasoning and awards a judgement out of ten.
5. The first marker is exact match. The second is regex extraction. The third is a model judge.
6. Now imagine the exam paper itself. One version says “Answer the question.” Another says “Answer the question. Show your working. Put your final answer after the words FINAL ANSWER.”
7. The second paper produces higher marks from the same pupils, because it told them the format the marker wants.
8. That is the whole of prompt template design, in one sentence.

Where this comparison breaks: a pupil who knows the answer but writes it in the margin still knows the answer, and a good teacher notices. A benchmark harness does not notice anything. It runs a regular expression. If the format is wrong the mark is zero, and the report will say the model does not know maths.

■ 50.3.3 PLAIN – a worked example

1. Let us compute pass@k properly, because it is the metric people most often misread.
2. pass@k is not “the score when you take k tries”. It is an estimate of the probability that at least one of k independently drawn samples is correct.
3. The naive way is to draw k samples and see if any pass. That is a very noisy estimate for large k.
4. The Codex paper of July 2021 uses a better estimator. Draw n samples, count c that pass, and compute:

$$\text{pass@k} = 1 - C(n - c, k) / C(n, k)$$

where C(a, b) is “a choose b”, the number of ways to pick b items from a, and $n \geq k$.

5. In words: one minus the chance that all k of your picks come from the failing pile.
6. Worked example. Take one problem. Draw $n = 10$ samples. Suppose $c = 2$ pass.
7. $\text{pass@1} = 1 - C(8,1)/C(10,1) = 1 - 8/10 = 0.20$.
8. $\text{pass@5} = 1 - C(8,5)/C(10,5) = 1 - 56/252 = 1 - 0.2222 = 0.7778$.
9. $\text{pass@10} = 1 - C(8,10)/C(10,10)$. $C(8,10)$ is 0 because you cannot pick 10 things from 8. So $\text{pass@10} = 1 - 0 = 1.00$.
10. Read those three numbers. One try: 20 per cent. Five tries: 78 per cent. Ten tries: 100 per cent.
11. The model did not get better. You bought more lottery tickets.
12. This is why pass@1 and pass@100 are not comparable, and why a headline that does not say which k it used is not a result.
13. Now the temperature effect, with real published behaviour. High temperature lowers pass@1 and raises pass@100, because diversity costs you on a single draw and pays on many draws.
14. So a lab reporting pass@1 will tune temperature low, and a lab reporting pass@100 will tune it high, and both are being reasonable.

■ 50.3.4 PLAIN – what is really happening inside

1. Take one MMLU item and watch it through the whole pipeline.
2. Zero-shot generative version. The harness builds this text:

The following is a multiple choice question about high school biology.

Which organelle produces most of a cell's ATP?

- A. Ribosome
- B. Mitochondrion
- C. Golgi apparatus
- D. Lysosome

Answer:

3. The model generates text. Suppose it writes “B. Mitochondrion”.
4. The extractor strips whitespace, takes the first letter that is A, B, C or D, and compares it to the stored key.
5. Now the log-likelihood version. The harness does not let the model write anything. Instead it asks the model, four times, “how likely is this exact continuation?”
6. It scores “A”, “B”, “C” and “D” as continuations, and takes the highest.
7. Same item, same model, two protocols, and sometimes two different answers.
8. A model that would have written a paragraph of hedging before saying B still assigns the highest single-token probability to “B”, and scores right under the second protocol and possibly wrong

under the first.

9. This is not a subtle effect. It is a common cause of a several-point gap between two published MMLU numbers.
10. Now the few-shot version. The harness prepends five solved questions from the 285-item development split before the real one.
11. The model now sees five examples of the pattern “question, options, Answer: B” and copies the pattern. Format failures collapse.
12. Now chain-of-thought. The template adds “Think step by step, then give your final answer as a single letter after the words FINAL ANSWER:”.
13. The model now emits a paragraph of reasoning and then the letter. The extractor looks after “FINAL ANSWER:” instead of at the start.
14. On knowledge questions this changes little. On maths it changes everything, because the model can hold intermediate results in the text it has already written rather than trying to do the whole calculation in one forward pass.
15. That last sentence is the honest mechanism. Chain-of-thought is not the model “thinking harder”. It is the model using its own output as working memory, one token at a time.

■ 50.3.5 TECHNICAL – the engineer’s version

1. Prompt sensitivity is measurable and large. The MMLU-Pro authors evaluated 24 prompt styles and found score variation of about 4 to 5 percentage points on original MMLU and about 2 points on MMLU-Pro. That is the size of the gap labs argue over in announcements.
2. Few-shot conventions by benchmark, as used in most reported numbers. These are conventions, not standards, and they drift.

Benchmark	Common shots	Common mode
MMLU	5-shot	Log-likelihood or letter
MMLU-Pro	5-shot CoT	Generative
GSM8K	8-shot CoT or 0-shot	Generative
MATH	4-shot CoT	Generative
HumanEval	0-shot	Generative, pass@k
GPQA Diamond	0-shot CoT	Generative
HellaSwag	10-shot	Log-likelihood
BBH	3-shot CoT	Generative

3. Chain-of-thought prompting comes from “Chain-of-Thought Prompting Elicits Reasoning in Large Language Models” by Jason Wei and colleagues at Google, posted January 2022. On GSM8K with a 540-billion-parameter model it moved accuracy from roughly 18 per cent to roughly 57 per cent.
4. “Large Language Models are Zero-Shot Reasoners” by Takeshi Kojima and colleagues, May 2022, showed that the single sentence “Let’s think step by step” produced much of the same effect with no examples at all.
5. Established fact: chain-of-thought raises measured accuracy on multi-step arithmetic and symbolic tasks by a large margin. Active research: whether the written chain reflects the computation that actually determined the answer. There is published evidence that models sometimes produce a correct answer with an unfaithful chain, and that they can be steered to a wrong answer while the chain still reads plausibly.
6. Grading methods, in increasing order of flexibility and decreasing order of reliability.

Method	How it works	Main failure
Exact match	String equality	Punishes correct formats
Normalized match	Lowercase, strip, unify	Still brittle on units
Regex extraction	Pull last number or tag	Grabs the wrong number
Symbolic equivalence	Parse maths, compare	Parser gaps, timeouts
Unit tests	Execute the code	Weak or overfit tests
Model as judge	Ask a model to grade	Position, length, style bias

7. For MATH-style answers, plain string comparison is hopeless: $1/2$, 0.5 and $\frac{1}{2}$ are the same answer. Serious harnesses parse into a computer algebra system and test symbolic equality, with a timeout.
8. Model-as-judge biases are documented in the MT-Bench paper of June 2023: position bias, verbosity bias, self-enhancement bias, and limited reasoning on maths. Mitigations in common use are swapping the order of the two answers and averaging, calibrating with a reference answer, and using chain-of-thought in the judge prompt.
9. Sampling and reproducibility. With temperature 0 and greedy decoding, output is nominally deterministic. In practice it often is not.
10. The honest version: floating-point reduction order on a GPU depends on how work is split across threads, that split can depend on the batch size, and batch composition on a shared serving end-point depends on who else is sending requests. Mixture-of-experts routing can also depend on the batch. So the same prompt at temperature 0 can produce different tokens.
11. Therefore report mean and standard deviation over repeated runs. Common practice for small benchmarks such as AIME with 15 items is to run 16, 32 or 64 times and average, sometimes written “avg@32” or “mean@64”.
12. Distinguish that from **majority voting**, sometimes written “cons@64” or self-consistency, where you sample 64 answers and take the most common one. That is a different, stronger system, and it costs 64 times as much.
13. Distinguish both from **best-of-n**, where you sample n answers and pick the best using a verifier or the reference answer. If the reference answer is used to pick, the number is close to meaningless as a measure of what a user would get.
14. Note the 2026 wrinkle: some providers have begun removing sampling controls entirely. Anthropic’s documentation as of August 2026 lists temperature, top_p and top_k as deprecated for its newest models, returning an error if set to a non-default value. If you cannot set temperature, you cannot match another lab’s sampling configuration.

■ 50.3.6 WORDS – remember these

1. Zero-shot — no examples given — the item is presented with instructions only, no in-context exemplars.
2. Few-shot — a few solved examples first — k in-context exemplars prepended, usually drawn from a fixed development split.
3. Chain-of-thought — letting it show its working — eliciting intermediate reasoning tokens before the final answer, which act as external working memory.
4. Temperature — how random the wording is — the divisor applied to logits before the softmax; 0 gives greedy decoding.
5. pass@k — chance that one of k tries works — the unbiased estimator $1 - C(n-c,k)/C(n,k)$ over n samples with c correct.

6. Self-consistency — sample many, take the most common answer — majority voting over sampled chains, reported as cons@n.
7. Best-of-n — sample many, keep the best — reranking n samples with a verifier or, improperly, with the reference answer.
8. LLM-as-judge — a model marks the answers — an evaluator model scoring or ranking outputs, subject to position, verbosity and self-enhancement bias.

50.4 Why two labs report different numbers

■ 50.4.1 PLAIN – in simple words

1. You will often see the same model, the same benchmark, and two different numbers, from two respectable sources.
2. The first thing to accept is that this is normal.
3. The second thing to accept is that it is usually not lying.
4. There are about eight ordinary causes, and you can usually work out which one applies.
5. Cause one: different wording of the prompt.
6. Cause two: a different number of worked examples given first.
7. Cause three: a different way of pulling the answer out of the reply.
8. Cause four: a different slice of the items. Someone ran 500 of the 2,294.
9. Cause five: different randomness settings, or one run against an average of many runs.
10. Cause six: one lab used a system prompt telling the model how to behave and the other did not.
11. Cause seven: one setup let the model use a calculator, a code runner or a web search, and the other did not.
12. Cause eight: a plain bug. These are common and usually found later.
13. Only after all eight are ruled out is it worth wondering about anything worse.
14. The practical response is one question: which harness did you use, and with what settings?
15. If the answer is “our internal one, details not published”, the number is not comparable to anybody else’s number. It may still be true.

■ 50.4.2 PLAIN – a picture in your head

1. Imagine two labs measuring the fuel economy of the same car.
2. One drives a flat motorway at a steady 90 kilometres per hour with the air conditioning off and the tyres at maximum pressure.
3. The other drives a hilly city route in traffic with two passengers.
4. Both publish a figure in litres per hundred kilometres. The figures differ by 40 per cent. Neither lab lied.
5. This is exactly why car fuel economy eventually got a legally defined test cycle, with a written specification, run by accredited labs.
6. AI benchmarks have no such thing. There is no accredited lab, no test cycle written into law, and no penalty for using a favourable route.
7. The nearest equivalent is a shared open harness that everybody agrees to run with the same settings, and that is a voluntary convention.

Where this comparison breaks: fuel economy has a physical ground truth you can approach by measuring more carefully. There is no single true MMLU score for a model waiting to be discovered. The number genuinely depends on the protocol, so “measuring more carefully” does not converge on one value.

■ 50.4.3 PLAIN – a worked example

1. Here is a concrete, realistic divergence, with the arithmetic.
2. Lab A reports 88.4 per cent on a knowledge benchmark. Lab B reports 84.1 per cent for the same model. The gap is 4.3 points.
3. Investigation finds four contributions.

Difference	Effect on score
5-shot vs 0-shot	+1.8 points
Letter-only vs full text	+1.1 points
Chain-of-thought allowed	+0.9 points
Best of 3 runs vs mean	+0.5 points
Total explained	+4.3 points

4. Every one of those four choices is defensible on its own.
5. Together they fully account for the gap without anybody doing anything improper.
6. Notice the last row. Reporting the best of three runs rather than the mean is the one that should make you uncomfortable, because it is a choice made after seeing the results.
7. That is the boundary between a defensible protocol difference and a presentational thumb on the scale.

■ 50.4.4 PLAIN – what is really happening inside

1. The causes, with how you detect each one. This is the table to keep.

Cause	How to detect it
Prompt template differs	Ask for the exact template
Few-shot count differs	Look for “5-shot” in a footnote
Extraction differs	Ask what regex or parser
Subset differs	Compare item counts
Sampling differs	Ask temperature and top-p
System prompt used	Ask if one was present
Tools available	Ask about calculator, code, web
Best-of-n reporting	Ask how many runs, which shown
Plain bug	Wait for reproduction attempts

2. On tool access, be specific, because it is the largest single effect and the least often disclosed.
3. A model that may run Python and check its arithmetic will beat the same model without that on any maths benchmark, often by a wide margin.
4. A model that may search the web will beat the same model without it on any knowledge benchmark, and on a “Google-proof” benchmark it should not help much, which is itself a useful test of the benchmark’s design.
5. On agentic benchmarks, the scaffold is most of the system. An entry on the SWE-bench leaderboard is a model plus a controller: how files are found, how many edit attempts are allowed, whether tests may be run and re-run, how the loop decides to stop.
6. Two teams using the identical model with different scaffolds have reported resolve rates tens of points apart. The leaderboard entry is the pair, not the model.
7. That is why SWE-bench leaderboard entries are named after systems, not models, and why a model announcement quoting a SWE-bench number should say what scaffold produced it.

■ 50.4.5 TECHNICAL – the engineer’s version

1. Ask for the harness by name and version. In practice this means one of: EleutherAI `lm-evaluation-harness` (state the version and the task name, because task definitions change between versions), Stanford HELM, the `bigcode-evaluation-harness` for code, the official SWE-bench runner with its Docker images, or a lab’s internal harness.
2. Task definitions inside a harness are versioned and do change. The same task name in two harness versions can differ in prompt, in normalization and in which split is used. Pin the harness version in your own reports.
3. The Hugging Face Open LLM Leaderboard is the clearest example of why this matters. Its second version, launched in June 2024, replaced the original task set with IFEval, BBH, MATH Level 5, GPQA, MuSR and MMLU-Pro, run through the EleutherAI harness with fixed settings.
4. The reason given was that the original tasks had saturated and were contaminated. The consequence was that scores from before and after are not comparable at all, even for the same model.
5. That is the honest version of “the leaderboard changed”: every historical number became a different measurement, and the ranking of models moved.
6. Normalization choices worth naming explicitly, because they each move multiple-choice scores by measurable amounts: raw log probability, log probability divided by token count, log probability divided by character count, and probability normalized against the model’s unconditional probability of the option text.
7. A concrete reproducibility checklist to publish with any number you report:

```
model id + exact snapshot
harness name + version + task name
n-shot, and which split the shots came from
system prompt (verbatim, or "none")
temperature, top_p, max tokens, stop sequences
tools available (none / code / search / retrieval)
number of runs, and mean and standard deviation
answer extraction rule
date the run was executed
```

8. If a published number lacks four or more of those nine lines, treat it as an indication rather than a measurement.
9. Established fact: protocol differences of the sizes described here are documented and reproducible. Marketing claim: that any single reported number is “the” score for a model.

■ 50.4.6 WORDS – remember these

1. Harness — the program that runs the benchmark — the evaluation framework; name and version both matter because task definitions change.
2. Subset — a slice of the items — a filtered evaluation split such as Lite, Verified or Diamond, not comparable to the full set.
3. System prompt — standing instructions given before the conversation — a privileged message setting persona, format and constraints, which materially changes benchmark scores.
4. Scaffold — the code around the model in an agent task — the controller loop for retrieval, tool invocation, retries and termination.
5. Tool access — whether the model may use a calculator or search — the set of external functions the model may call during evaluation.
6. Reproduction — someone else getting your number — an independent run under a published protocol, the only real check on a self-reported score.

7. Task version — which definition of the test was used — the versioned task implementation inside a harness, including prompt and normalization.

50.5 Contamination

■ 50.5.1 PLAIN – in simple words

1. Contamination means the test questions were in the training data.
2. If the model has already seen the question and the answer, getting it right proves nothing about ability.
3. It might be memory. It might be ability. From the score alone you cannot tell which.
4. This happens almost by accident, not by plotting.
5. Benchmarks are published so that people can use them. Published means on the web. On the web means scraped. Scraped means in the training data.
6. GSM8K, MMLU, HumanEval and the rest are all on public code and dataset hosting sites, quoted in thousands of blog posts, pasted into forum questions, translated, reformatted and discussed.
7. So a model trained on a large web crawl has almost certainly seen many of them, in some form, unless someone worked hard to remove them.
8. That removal work is called decontamination, and every serious lab now does some and describes it.
9. But decontamination is filtering by text matching, and text matching misses anything reworded.
10. The effect on scores is upward, and it is uneven. It inflates old benchmarks more than new ones, and easy items more than hard ones.
11. It is very hard to prove for any particular model, because you usually cannot see the training data.
12. So the debate is conducted with indirect evidence, and reasonable people disagree about what that evidence shows.
13. The honest position: assume some contamination is present in every public benchmark number you read, of unknown size, and prefer evidence from tests the model cannot have seen.

■ 50.5.2 PLAIN – a picture in your head

1. Imagine a school where the past twenty years of exam papers, with the official answers, are freely available online.
2. A pupil who has read all of them will do better on this year's paper if this year's paper reuses old questions.
3. Nobody stole anything. The papers were published on purpose.
4. Now the exam board tries to fix it. They remove any question that appears word for word in an old paper.
5. But a question that was reworded, or translated into French and back, or changed from apples to oranges, slips through.
6. And the pupil who read every paper does better on those too, because the structure is familiar even when the words changed.
7. Now the awkward part. The pupil who read all the old papers is also genuinely better prepared. Some of what they gained is real learning.
8. Separating the memory from the learning, from the mark alone, is impossible.
9. That is exactly the position everyone is in with model benchmarks.

Where this comparison breaks: a pupil remembers roughly what they revised and can be asked. A model cannot reliably report what was in its training data, and the people who built it often cannot

enumerate it either, because the corpus is billions of documents assembled by pipelines from many sources.

■ 50.5.3 PLAIN – a worked example

1. The clearest public experiment on this is GSM1k.
2. In May 2024 a team at Scale AI, led by Hugh Zhang, published “A Careful Examination of Large Language Model Performance on Grade School Arithmetic”.
3. They commissioned a brand-new set of grade-school maths problems, written from scratch, never published, deliberately matched to GSM8K in style, number of solution steps, answer size and human solve rate.
4. Then they ran many models on both, and compared.
5. If a model’s ability were real, the two scores should be about equal, since the sets are matched by construction.
6. What they found: accuracy drops of up to about 8 percentage points on the new set, with several model families showing systematic overfitting across almost all their sizes.
7. They also found a positive relationship, Spearman r squared of about 0.36, between how likely a model was to generate GSM8K examples verbatim and how large its drop was.
8. That second finding is the important one. It links the drop to memorization rather than to some accident of the new problem set.
9. And the honest counterweight, which the same paper reports: the strongest frontier models showed minimal signs of overfitting, and every model generalized to some extent to the new problems.
10. So the correct summary is not “the benchmarks are fake”. It is “some models are inflated by several points, the size varies, and you cannot tell from the leaderboard which”.

■ 50.5.4 PLAIN – what is really happening inside

1. Five detection methods, what each can show, and where each fails.
2. **N-gram overlap.** Take every run of n consecutive words from every benchmark item, and search the training corpus for the same run.
3. The GPT-3 paper of 2020 used 13-gram overlap for its decontamination checks. Other projects use 8-gram, or a match on several random 50-character substrings.
4. What it shows: verbatim copying. What it misses: anything reworded, translated, reformatted, or discussed rather than quoted.
5. Also it requires access to the training corpus, which outsiders do not have.
6. **Canary strings.** The BIG-bench authors put a fixed unique identifier in every task file and asked everybody never to remove it.
7. If a model can reproduce that identifier, it saw the file. That is close to proof of exposure.
8. What it misses: everything. A model can be trained on a copy of the data with the canary stripped, on a reworded version, or on a discussion of the items. Absence of the canary proves nothing at all.
9. **Perplexity comparison.** Perplexity is a measure of how surprised the model is by a piece of text. Lower means more familiar.
10. Compare the model’s perplexity on benchmark items against its perplexity on freshly written text of the same kind. If the benchmark is much less surprising, that is a signal.
11. What it misses: benchmark text is often cleaner and more formulaic than fresh text anyway, so some gap is expected. Setting the threshold is a judgement call, and this requires log-probability access that many commercial endpoints no longer expose.

12. **Old versus new items.** Build a benchmark that keeps adding fresh items after model release dates, and compare a model's score on items published before its training cutoff against items published after.
13. A large gap is strong evidence. This is the design principle behind continuously refreshed benchmarks, and behind coding benchmarks that only score problems released after a stated date.
14. What it misses: newer items may simply be harder, or drawn from a different distribution, so you need the sets to be matched carefully, which is what GSM1k did.
15. **The completion trick.** Give the model the first part of a benchmark item and see whether it continues with the rest, word for word, including the incidental details it could not guess.
16. A variant gives the model the dataset name, the split and an index, and asks it to produce that item. Another shows the item with the options in a scrambled order and checks whether the model still reproduces the original ordering.
17. What it shows: near-verbatim memory of the item. What it misses: a model that learned the answer without being able to reproduce the wording, which is the common case after instruction tuning.
18. Notice the pattern. Every method can produce a positive finding that is hard to dismiss, and no method can produce a negative finding that means anything.
19. That asymmetry is why this argument never ends.

■ 50.5.5 TECHNICAL – the engineer's version

1. The methods and their properties, side by side.

Method	Detects	Needs
N-gram overlap	Verbatim copies	Corpus access
Canary string	Direct file exposure	Model generation
Perplexity gap	Familiarity	Log probabilities
Old vs new split	Practical inflation	A dated benchmark
Completion trick	Item memorization	Only API access
Membership inference	Probable inclusion	Token probabilities

2. Real disputes, described without alleging deliberate wrongdoing, because in none of these cases was deliberate cheating established.
3. In 2023 the paper “Rethinking Benchmark and Contamination for Language Models with Rephrased Samples” showed that a modestly sized model trained on rephrased versions of benchmark test sets could reach very high scores on those benchmarks while passing standard n-gram decontamination checks. The point was methodological: the standard filter does not work.
4. Also in 2023, a deliberately satirical paper by Rylan Schaeffer titled “Pretraining on the Test Set Is All You Need” trained a tiny model directly on benchmark test sets and reported near-perfect scores, to make the same point in the bluntest possible way.
5. Several strong small models released between 2023 and 2025 attracted public questions about whether their synthetic training data, which was generated by larger models, indirectly reproduced benchmark items. The teams involved published decontamination procedures in response. The disputes were about method and evidence, not about proven intent.
6. In late 2024 and early 2025 there was a public discussion about FrontierMath, an Epoch AI benchmark, after it emerged that OpenAI had funded its creation and had access to problems. Epoch AI published clarifications about what access existed and what hold-out arrangements were in place.

7. The general lesson from that episode is structural, not personal: if a lab funds or co-designs a benchmark it is later measured on, the benchmark needs a documented held-out portion and a stated access policy, or the number cannot carry weight regardless of anyone's good faith.
8. Which is why held-out sets now exist as standard practice: ARC-AGI keeps a semi-private evaluation set, Humanity's Last Exam keeps a private portion, and SWE-bench-style benchmarks increasingly add tasks dated after model releases.
9. Typical decontamination procedures now described in model cards and technical reports: exact-substring matching against known benchmark items, n-gram overlap filters at 8 to 13 grams, removal of documents containing canary strings, embedding-similarity screening for near-duplicates, and post-hoc measurement of the train-test gap.
10. Established fact: benchmark items appear in web crawls, and models can be induced to reproduce some of them verbatim. Established fact: matched fresh benchmarks show measurable score drops for some model families.
11. Active research: how to measure contamination without corpus access, how to correct scores for it, and how to build benchmarks that resist it by construction. There is no accepted standard method.
12. Marketing claim: "our model is decontaminated". Decontamination is a process with a coverage rate, not a state. Ask what filter, at what n-gram length, against which benchmark list, and what the measured residual was.
13. Expert disagreement, stated plainly. One camp holds that contamination is now the dominant explanation for headline benchmark gains on older tests, and that only dated, held-out or private evaluations should be believed. The other camp holds that frontier models demonstrably solve novel problems that cannot be in any corpus, so contamination inflates absolute numbers but rarely reverses rankings. Both camps agree that public numbers on pre-2023 benchmarks should be discounted.

■ 50.5.6 WORDS – remember these

1. Contamination — the test was in the training data — overlap between evaluation items and the pretraining or post-training corpus.
2. Decontamination — trying to remove it — filtering training documents that match benchmark items by substring, n-gram or embedding similarity.
3. N-gram — a run of n consecutive words — the unit of overlap matching, with 8-gram and 13-gram both in common use.
4. Canary string — a planted marker — a unique identifier embedded in benchmark files, whose reproduction by a model evidences exposure.
5. Perplexity — how surprised the model is by text — the exponential of the mean negative log likelihood per token.
6. Held-out set — questions nobody publishes — a private split retained by the benchmark authors to measure overfitting to the public split.
7. Overfitting to a benchmark — being good at the test, not the skill — a gap between performance on the benchmark and on matched unseen items.
8. Membership inference — guessing whether an example was trained on — a statistical test using token likelihoods, such as scoring the lowest-k token probabilities of a document.

50.6 The other reasons to be sceptical

■ 50.6.1 PLAIN – in simple words

1. Contamination is not the only problem. There are six more, and they are all ordinary and human.
2. **Saturation.** When everyone scores 92, 93 and 94 per cent, the test has stopped telling you anything.
3. At that point the remaining errors are often wrong answer keys in the benchmark itself, not model failures.
4. **Optimizing for the test.** Once a number matters, people work on the number. Some of that work improves the model. Some improves only the number.
5. **Self-reported results.** Nearly every headline benchmark figure in a model announcement was produced by the team that made the model.
6. That is not automatically wrong. It is simply unverified until someone else runs it.
7. **Cherry-picked comparisons.** Showing your new model against a competitor's older version, or against the competitor's cheap model rather than its best.
8. **Best-of-n reporting.** Letting the model try many times and reporting the best result, without saying so clearly.
9. **Different tools and scaffolding.** Your model with a code runner against their model without one, in the same bar chart.
10. **Charts that start above zero.** A bar chart whose vertical axis begins at 70 makes a two-point difference look enormous.
11. None of these require anybody to lie. Every one of them can be produced by ordinary optimism and ordinary pressure to look good.
12. Your defence is not cynicism. It is a checklist.

■ 50.6.2 PLAIN – a picture in your head

1. Think of school league tables.
2. Once schools are ranked by exam results, the results become the goal.
3. Schools start teaching to the exam. Then they enter weaker pupils for easier qualifications. Then some stop entering certain pupils at all.
4. The tables keep rising. Whether education improved is a separate question, and a much harder one to answer.
5. That is Goodhart's law happening in public, over years, with real children.
6. The measure was fine as a measure. It stopped being fine the moment it became the target.
7. And note what is not implied: the teachers were not villains. They responded to the incentive they were given.

Where this comparison breaks: exam boards are regulated, publish syllabuses, and can be audited. Nobody audits an AI lab's benchmark run. Also, schools cannot see next year's paper. Anyone training a model can see every public benchmark, in full, with answers, for free.

■ 50.6.3 PLAIN – a worked example

1. Goodhart's law, stated properly, because it is usually misquoted.
2. Charles Goodhart was a British economist at the Bank of England. In a 1975 paper on monetary policy he wrote, in substance: any observed statistical regularity will tend to collapse once pressure is placed upon it for control purposes.
3. That is the original and it is narrower than the popular version. It is about a regularity used as a control target.
4. The popular short form is due to the anthropologist Marilyn Strathern, who in 1997 wrote: when a measure becomes a target, it ceases to be a good measure.

5. A closely related statement is Campbell's law, from the psychologist Donald Campbell in 1979: the more a quantitative indicator is used for social decision-making, the more it will be subject to corruption pressures and the more it will distort the processes it monitors.
6. Applied here: MMLU was an excellent measure in 2021, when nobody was training against it.
7. By 2024 every major lab knew the exact score they needed, the exact format, and the exact subjects where points were cheapest.
8. The measure did not become false. It became uninformative, which in practice is worse, because it still looks like a measurement.
9. Now a chart example, with numbers. Two models score 91.2 and 89.4 on some benchmark.

10. Same two numbers. On the left, two nearly identical bars. On the right, one bar looks roughly twice the other.
11. The difference is 1.8 points, which on a 14,000-item benchmark is about 250 items, and which is within the range that a prompt template change can produce on its own.

■ 50.6.4 PLAIN – what is really happening inside

1. The red flag checklist. Each line is a question to ask of any announcement or chart.
2. Does the chart's vertical axis start at zero? If not, mentally redraw it.
3. Are the compared models named with their exact versions and dates, or just with product names?
4. Is the competitor's newest model shown, or a version from six months ago?
5. Is the competitor's flagship shown, or its cheaper tier?
6. Who ran the competitor's numbers? If the announcing lab did, were the competitor's own published numbers different?
7. Does the footnote say pass@1, or does it say something else, or nothing?
8. Does the footnote mention majority voting, consensus, best-of-n, or a number of samples greater than one?
9. Did both models have the same tools? Search, code execution, retrieval, file access, a scaffold?
10. Was there a system prompt, and was it the same for both?
11. Is the benchmark one where the top scores are already above 90 per cent?
12. Is the improvement larger than the known prompt-sensitivity range for that benchmark, which is roughly 2 to 5 points on multiple-choice tests?
13. Is the benchmark new, and was it built or funded by the announcing lab?
14. Has any independent party reproduced the number, and how long ago?
15. If you cannot answer eight of these fourteen from the announcement itself, the announcement is a claim, not a result.

■ 50.6.5 TECHNICAL – the engineer’s version

1. Saturation has a precise consequence: as mean accuracy approaches the label ceiling, the between-model variance shrinks toward the label-noise variance, and rank ordering becomes unstable across runs.
2. MMLU is known to contain a non-trivial number of incorrect or ambiguous reference answers. Independent audits published between 2023 and 2024 put the error rate in some subsets in the range of several per cent, with virology and a few professional subjects worst. Estimates vary by auditor and by criteria, so treat the exact figure as disputed.
3. The practical implication: a reported 92 per cent on MMLU may be close to the maximum achievable, and a difference between 92 and 93 may be noise plus disagreement about wrong keys.
4. This is exactly why MMLU-Pro, GPQA Diamond, Humanity’s Last Exam and FrontierMath were built. New benchmarks appear when old ones saturate, and the appearance of a new hard benchmark is itself evidence that the previous one stopped working.
5. A documented case of the “which version did you test” problem. On 5 April 2025 Meta released Llama 4 in two configurations, Scout and Maverick. A variant identified as Llama-4-Maverick-03-26-Experimental, described as optimized for conversationality, scored very highly on the LMArena leaderboard. It was not the model released to the public.
6. On 8 April 2025 the arena operators stated that Meta’s interpretation of their policy did not match what they expect from providers, that Meta should have made it clearer that the entry was a customized model, and that they would update their policies. Meta denied training on test sets.
7. Report that as what it is: a disclosure and naming failure with a policy response, not an established case of fraud. The transferable lesson is that a leaderboard entry identifies a specific artifact, and the artifact you can download may not be the artifact that was measured.
8. Statistical hygiene almost nobody applies. For a benchmark of N items and an observed accuracy p , the standard error is roughly $\sqrt{p(1-p)/N}$.

Benchmark	N	Approx 1 SE at $p=0.9$
HumanEval	164	2.3 points
GPQA Diamond	198	2.1 points
AIME (one paper)	15	7.7 points
SWE-bench Verified	500	1.3 points
MMLU	14,000	0.25 points

9. Read that table carefully. On GPQA Diamond, a 2-point difference is about one standard error, and one item is 0.5 points. On a single AIME paper, getting one more question right is 6.7 points.
10. So a headline of the form “scores 93.3 on AIME versus 86.7 for the competitor” describes one question out of fifteen.
11. That is before considering run-to-run sampling variance, which for reasoning models on small maths sets is frequently larger than the between-model gap.
12. Established fact: the standard-error arithmetic above. Marketing claim: any ranking asserted from a gap smaller than one standard error.

■ 50.6.6 WORDS – remember these

1. Goodhart’s law — a measure used as a target stops measuring — an observed regularity collapses when pressure is applied to it for control purposes.
2. Campbell’s law — indicators used for decisions get corrupted — quantitative social indicators distort the processes they are meant to monitor.

3. Saturation — the test is too easy now — mean score near the ceiling, so between-model variance falls below label-noise variance.
4. Label noise — wrong answers in the answer key — the fraction of benchmark items whose reference answer is incorrect or ambiguous.
5. Self-reported — the maker measured it — a result produced by the model provider under an unpublished or partially published protocol.
6. Truncated axis — a chart that hides how small a gap is — a bar chart whose value axis does not begin at zero.
7. Standard error — how much the score would wobble by chance — approximately $\sqrt{p(1-p)/N}$ for accuracy p over N independent items.
8. Cherry-picking — showing the favourable comparison — selective choice of baselines, versions, subsets or runs after seeing results.

50.7 The alternatives, and their own weaknesses

■ 50.7.1 PLAIN – in simple words

1. If fixed quizzes are weak, what else is there? Five things, each with its own flaw.
2. **Preference arenas.** Real people type a question, get two anonymous answers, and vote for the better one. Ratings are computed from the votes.
3. **Private held-out tests.** The same idea as a benchmark, but the questions are never published, so they cannot leak.
4. **Domain evaluations.** A test built for one job: medical coding, legal citation, chip design, customer support in Hindi.
5. **Agentic and end-to-end tests.** Give the model a real task in a real environment and check whether the task got done.
6. **Red-teaming.** People deliberately attack the model to find failures that no fixed test would catch.
7. Every one of these is better than MMLU for something, and worse for something else.
8. The arena measures whether people like the answer, which is not the same as whether the answer is correct.
9. A friendlier, longer, better-formatted wrong answer beats a curt correct one, quite often.
10. Private tests cannot be independently checked, because they are private.
11. Domain tests are only as good as the person who wrote them, and they do not transfer to other domains.
12. Agentic tests are expensive, slow, and measure the scaffold as much as the model.
13. Red-teaming finds problems but cannot tell you that no problems remain.
14. There is no method without a weakness. The working answer is to use several and to know what each one is blind to.

■ 50.7.2 PLAIN – a picture in your head

1. Think about how you would judge a restaurant.
2. A hygiene inspection is a fixed checklist with a pass mark. Objective, narrow, and it says nothing about whether the food is good.
3. Customer star ratings are a preference arena. They capture something real that no inspection captures, and they reward large portions, friendly staff and good lighting as much as cooking.
4. A critic's blind visit is a private held-out evaluation. Harder to game, impossible for you to verify.
5. Asking a chef to cook one specific dish you care about is a domain evaluation. Most informative for you, useless for anyone who wants something else.

6. Watching the kitchen run a full Saturday service is the agentic test. Closest to reality, and by far the most expensive to arrange.

Where this comparison breaks: restaurant customers eat the food, so their ratings are grounded in the actual product. Arena voters usually cannot verify whether the answer they preferred was true. They are rating the presentation of a claim, often on a topic where they are not the expert.

■ 50.7.3 PLAIN – a worked example

1. How a preference arena turns votes into a number.
2. Each vote is a pairwise comparison: model A beat model B on this prompt.
3. The rating system is the one from chess, invented by Arpad Elo, a Hungarian-American physicist, and adopted by the United States Chess Federation in 1960 and by FIDE in 1970.
4. The core formula gives the expected score of A against B from the gap in their ratings:

$$E(A) = 1 / (1 + 10^{((R_B - R_A) / 400)})$$

R = rating. A 400-point gap means the stronger side is expected to win about 10 times out of 11.

5. Work three cases. A gap of 10 points gives an expected win rate of 51.4 per cent. A gap of 100 points gives 64.0 per cent. A gap of 200 points gives 76.0 per cent.
6. Read the first one again. A 10-point difference on a leaderboard means the higher model wins about 51 times in 100. That is close to a coin flip.
7. Published confidence intervals on such leaderboards are frequently plus or minus 3 to 10 points, so models separated by fewer than about 15 points are usually statistically tied even though they occupy different rank numbers.
8. As of August 2026, the largest public text arena listed a few hundred ranked models, with top scores clustered within a few points of each other and stated uncertainties of roughly plus or minus 3 to 10 points.
9. A ranking that shows positions 1 through 8 spanning about 15 points is, in statistical terms, showing one group of models, not eight ranks.
10. The honest version: an arena rating is not a quality score. It is a fitted parameter that predicts how often this model's answer is preferred over another model's answer, by these voters, on these prompts, in this period. Every clause in that sentence limits what the number can be used for.

■ 50.7.4 PLAIN – what is really happening inside

1. What an arena measures well: how a broad population of users, asking the kinds of question they actually ask, reacts to an answer.
2. That is genuinely valuable and no fixed benchmark captures it. It picks up tone, refusal behaviour, formatting, and the ability to guess what the user meant.
3. What it measures badly, and the biases are documented, not theoretical.
4. **Length bias.** Longer answers win more often, controlling for content. Arena operators now publish a length-controlled ranking alongside the raw one specifically because of this.
5. **Style bias.** Headings, bullet lists and bold text raise win rates. The same content flattened into prose wins less.
6. **Verification gap.** A voter comparing two answers about a legal deadline usually does not know the deadline. They vote on confidence and clarity.

7. **Prompt distribution.** The votes come from whoever uses the site. That population skews technical and English-speaking and asks a lot of short questions, so the rating reflects that mixture and not yours.
8. **Provider self-selection.** Providers choose when to enter a model and which variant, and can test variants privately before public entry.
9. Red-teaming, briefly, because it is a different shape of thing. It is not scored on a scale. Its output is a list of found failures, and its value is in what it finds, not in a number.
10. The structural weakness of red-teaming is that it can only ever demonstrate presence, never absence. Not finding a jailbreak is not evidence that none exists.

■ 50.7.5 TECHNICAL – the engineer’s version

1. Modern arenas do not run a live Elo update loop, because Elo is order-dependent: the same set of games in a different order gives different ratings. They fit a **Bradley-Terry** model by maximum likelihood over the whole vote history, then bootstrap for confidence intervals, then present the result on an Elo-like scale.
2. That is why you should read the interval, not the rank. Ranks on such boards are usually published as a range, precisely because ties are common.
3. Style-controlled ranking works by fitting the preference model with additional covariates for response length and markdown features, so that the reported strength coefficient is adjusted for those factors.
4. Naming instability is real here too. The board widely known as LMSYS Chatbot Arena became LMArena; as of August 2026 the domain `lmarena.ai` redirects to `arena.ai`. Cite what a leaderboard is, not just where it lives.
5. Evaluation methods against what they are good and bad at.

Method	Good at	Bad at
Fixed benchmark	Cheap, comparable	Leaks, saturates
Preference arena	Real user taste	Truth, length bias
Private held-out	Leak resistance	Nobody can check
Domain eval	Your actual job	Generalizing
Agentic end-to-end	Realism	Cost, scaffold effects
Red-team	Finding failures	Proving absence
Model-as-judge	Scale, speed	Style and self bias

6. Cost figures matter and are rarely mentioned. A full SWE-bench Verified run with an agentic scaffold means 500 tasks, each with many model calls and repository builds. Runs costing hundreds to thousands of dollars and taking many hours are normal, which is exactly why the 300-item Lite subset exists.
7. This is also why the ARC Prize leaderboard reports cost per task and by default hides systems whose run cost exceeded 10,000 dollars. Any score can be bought with enough sampling; a score with a cost attached cannot.
8. Established fact: length and position biases in preference judging, and the order dependence of online Elo. Active research: how to control for style without controlling away real quality, and how to weight votes by voter expertise. Marketing claim: “ranked number one” when the interval overlaps five other entries.

■ 50.7.6 WORDS – remember these

1. Preference arena — people vote between two anonymous answers — a pairwise human preference collection platform with a fitted rating model.
2. Elo — a chess rating scale reused for models — a rating system where the expected score is a logistic function of the rating difference over 400.
3. Bradley-Terry — the proper way to fit ratings from all votes at once — a maximum-likelihood pairwise comparison model, order independent.
4. Confidence interval — how much the rating could be wrong — the bootstrapped range around a fitted rating; overlapping intervals mean a tie.
5. Length bias — longer answers win — a systematic preference for verbose responses independent of content quality.
6. Style control — adjusting for formatting and length — fitting the preference model with covariates for length and markdown structure.
7. Red-teaming — attacking your own model on purpose — adversarial testing to discover failures; evidences presence, never absence.
8. Held-out evaluation — a private test set — evaluation items never published, used to detect over-fitting to public benchmarks.

50.8 What “eval” means inside a company

■ 50.8.1 PLAIN – in simple words

1. In public, “eval” means a famous benchmark with a leaderboard.
2. Inside a company that builds a product on a model, it means something much smaller and much more useful.
3. It means a file of examples of the job the product actually does, with the answer you want for each.
4. Thirty to a hundred examples is normal. Not fourteen thousand.
5. They are hand-picked, mostly from real cases that went wrong.
6. They are private, because they contain real customer text and because they are the company’s actual measuring stick.
7. Every time anyone changes the prompt, the model, the retrieval setup or a parameter, the file is run again.
8. If the score drops, the change is rejected. That is the whole discipline.
9. In other words, it is a regression test suite, exactly like the automated tests you would write for ordinary software.
10. The score is not comparable to anyone else’s score, and does not need to be.
11. It only needs to answer one question: did this change make my product better or worse at my job?
12. Nobody can build this for you, because only you know what your job is.
13. If you build software on a model and you do not have one of these, you are guessing every time you change anything.

■ 50.8.2 PLAIN – a picture in your head

1. A bakery buys flour. The supplier changes.
2. The baker does not read the flour industry’s national quality rankings.
3. The baker bakes their own three standard loaves with the new flour and compares them to the old ones.
4. Same recipe, same oven, same timings. Only the flour changed.
5. If the loaves are worse, the flour is rejected, whatever the rankings said.

6. The bakery's test is small, private, unscientific and completely decisive, because it measures the thing the bakery sells.
7. That is an internal eval.

Where this comparison breaks: bread quality is judged by a person who has baked for twenty years, in one taste. Model output quality often needs a written rule, because you will run the test hundreds of times and cannot taste every loaf yourself. Writing that rule down is the hard part of the job.

■ 50.8.3 PLAIN – a worked example

1. A practical recipe for building one. Follow it in order.
2. Step 1. Write down the job in one sentence. "Turn a customer email into a support ticket with a category, a priority and a two-line summary."
3. Step 2. Collect 30 to 100 real inputs. Not invented ones. Real.
4. Step 3. Make sure the mix is deliberate, not random.

Slice of the set	Share	Why
Ordinary typical cases	50 per cent	The common path
Known hard cases	25 per cent	Where it broke before
Edge and malformed input	15 per cent	Robustness
Should refuse or escalate	10 per cent	Safety and limits

5. Step 4. For each input, write the answer you want. Where several answers are acceptable, write the rule instead of a single answer.
6. Step 5. Choose a scoring rule per item, from the cheapest kind that works.

exact	category must equal "billing"
contains	summary must mention the order number
regex	priority must match <code>^(P1 P2 P3)\$</code>
schema	output must parse as valid JSON
assert	code must pass these three tests
judge	a model grades 1-5 against a rubric
human	a person grades, for a 10-item subset

7. Step 6. Store it as a plain file. One row per example. Input, expected, rule, and a note about why it is in the set.
8. Step 7. Write a script that runs all items and prints one number plus the list of failures. The list of failures is the part you will actually read.
9. Step 8. Run it three times and note the spread before you trust any change smaller than that spread.
10. Step 9. Keep it in version control next to the code, and add a new row every time a real failure reaches a user. The set grows by itself.

■ 50.8.4 PLAIN – what is really happening inside

1. Why 30 to 100 and not 10 or 10,000.
2. Below about 30, one item is more than 3 per cent, and the whole set can be passed by luck or by a prompt change that happens to suit those items.
3. Above a few hundred, hand-writing expected answers becomes a project, and people stop maintaining it. An unmaintained eval set is worse than none, because it produces confident wrong signals.

4. The trade-off is honest: 30 to 100 items cannot tell you a 2 per cent difference. It can reliably tell you a 15 per cent difference, which is the size of change that usually matters when swapping models or prompts.
5. Where model-as-judge belongs. Use it when the output is free text and no mechanical rule works, but pin it down: a fixed rubric with numbered criteria, a fixed judge model with a fixed dated identifier, and a fixed temperature.
6. And validate the judge once: have a person grade 20 items, compare with the judge, and record the agreement rate. If the judge agrees with your human less than about 80 per cent of the time, fix the rubric before trusting it.
7. Also record cost and latency per item on every run. A change that improves quality by 3 per cent and triples cost is a decision, not an improvement, and you cannot make that decision without both numbers.

■ 50.8.5 TECHNICAL – the engineer’s version

1. Treat the eval set as a first-class artifact: versioned in git, with a schema, a fixed identifier per item, and a changelog. Never edit an item silently; add a new one and deprecate the old one, or every historical number becomes uninterpretable.

2. A workable row schema:

id	stable, never reused
input	verbatim, including whitespace
expected	answer or acceptance rule
rule	exact contains regex schema assert judge human
slice	typical hard edge refusal
added_on	date
reason	one line, why this exists

3. Report three numbers, not one: pass rate, mean latency, mean cost per item. Report pass rate per slice as well as overall, because a model that fixes typical cases and breaks refusals is a regression, not a gain.
4. Guard against a subtle trap: if you iterate on prompts against the eval set many times, you overfit to it exactly as labs overfit to public benchmarks. Hold back 20 per cent of items as a set you run only at decision time.
5. Available tooling as of 2026 includes provider-hosted eval products, open frameworks such as OpenAI’s evals repository, promptfoo, deepeval, Inspect from the UK government’s AI institute (named the AI Safety Institute at launch in 2024 and renamed the AI Security Institute in February 2025), and LangSmith-style tracing platforms. Note that provider-hosted eval products get deprecated too: as of mid-2026 OpenAI had announced shutdown dates for several platform features. Prefer a format you own.
6. Statistical note. With 50 items and an observed pass rate of 0.80, one standard error is $\sqrt{0.8 * 0.2 / 50} = 0.0566$, about 5.7 points. So a move from 80 to 84 per cent on 50 items is well inside noise. Do not ship on it.
7. Established fact: internal regression evals are standard practice at companies shipping model-backed products. Marketing claim: any vendor assertion that their public benchmark results predict your task performance.

■ 50.8.6 WORDS – remember these

1. Internal eval — your own small private test — a curated regression suite of task-representative items with per-item acceptance rules.

2. Regression test — checking a change did not break things — re-running a fixed suite after every modification and comparing to the last result.
3. Slice — a named group of items — a labelled subset such as typical, hard, edge or refusal, reported separately.
4. Rubric — the written marking scheme for a judge — the numbered criteria a judge model or human applies to score free text.
5. Golden set — the agreed correct answers — the reference outputs, versioned and never silently edited.
6. Holdout — items you do not tune against — the reserved fraction run only at decision time to detect overfitting to your own set.
7. Acceptance rule — how an item is marked — the per-item comparison, from exact match through to human judgement.

50.9 Reading a model announcement critically

■ 50.9.1 PLAIN - in simple words

1. A model announcement is a marketing document that contains real data.
2. Both halves of that sentence are true and you need both.
3. The data is usually accurate as far as it goes. The selection is not neutral.
4. So read it the way you read a job application: assume everything stated is true, and pay most attention to what is missing.
5. Nine questions do almost all the work, and section 50.9.3 lists them.
6. If the announcement answers all nine, that is a good sign about the team, independent of the scores.

■ 50.9.2 PLAIN - a picture in your head

1. Think of a used-car advertisement listing the good features honestly.
2. New tyres, full service history, one owner. All true.
3. It does not mention the mileage, and you notice that it does not.
4. You do not conclude the car is bad. You conclude you must ask.
5. The absence of a number is itself information, because the seller chose the list.

Where this comparison breaks: a car has one mileage figure and the seller knows it. A model has no single benchmark score to withhold, because the score depends on the protocol. So the missing item is usually the protocol, not a number, and the protocol is much easier to omit without anyone noticing.

■ 50.9.3 PLAIN - a worked example

1. The nine questions, in order, applied to any announcement.
2. Which benchmarks are shown, and which of the usual ones are absent? An absent standard benchmark is the loudest signal in the document.
3. Which comparison models, at which exact versions and dates? “GPT-4” is not a version. “Claude” is not a version.
4. Who produced the competitor numbers: this lab, or the competitor’s own published figures, or an independent runner?
5. What was the prompting setup: shots, chain-of-thought, system prompt?
6. Did the model have tools? Search, code execution, retrieval, file access? And did the comparison models have the same ones?

7. Is the score pass@1 and a single run, or is it best-of-n, majority voting, or an average over many samples?
8. Does the chart's axis start at zero, and is the gap bigger than the benchmark's known prompt sensitivity?
9. Is the benchmark new, and who built or funded it?
10. Has an independent third party reproduced any of it, and when?

■ 50.9.4 PLAIN – what is really happening inside

1. Two phrasings that should always slow you down.
2. “State of the art on X” with no date. State of the art is a claim about a moment, and the moment is usually the week before publication.
3. “Comparable to human experts”. Ask which humans, doing what, under what time limit, and with what resources. GPQA is the model case: its expert baseline was 65 per cent, measured under stated conditions, and quoting a model above that as “beyond PhD level” ignores that the humans were answering a four-option quiz outside a lab.
4. Also watch for the shift between a **model** claim and a **system** claim. A product with retrieval, tools and a scaffold is a system. Its score belongs to the system.
5. And watch the switch of subset: a headline referencing SWE-bench and a footnote saying Verified, or GPQA in the headline and Diamond in the footnote, are not errors, but they change what is being compared.

■ 50.9.5 TECHNICAL – the engineer's version

1. Where the answers usually live, in decreasing order of reliability: the system card or technical report appendix, the model card, the announcement footnotes, the blog post body, the chart itself.
2. Reading order should therefore be reversed from the page order: appendix first, chart last.
3. Independent reproduction sources worth checking before believing a headline: the benchmark's own leaderboard, third-party evaluation organizations that run their own harnesses and publish protocols, and the open harness community's issue trackers, where discrepancies get argued out publicly.
4. A note on speed. Reproductions typically appear days to weeks after a release. The gap between announcement and reproduction is precisely the window in which the announcement is unchecked.
5. Established fact: benchmark numbers in major technical reports are generally reproducible within a few points when the protocol is published. Marketing claim: leaderboard positions asserted from gaps inside the reproduction spread.

■ 50.9.6 WORDS – remember these

1. Model card — a short standard description of a model — a document stating intended use, training data summary, evaluations and limitations.
2. System card — the same for a whole product — documentation covering the model plus scaffolding, tools, safety mitigations and evaluations.
3. Self-reported — measured by the maker — a result produced by the provider, pending independent reproduction.
4. Reproduction — someone else got the same number — an independent run under a published protocol.
5. State of the art — best known result so far — a time-indexed claim, valid only at a stated date on a stated protocol.

6. System versus model — the product versus the weights — the distinction between an end-to-end deployed pipeline and the underlying network.

50.10 Training cutoff versus release date

■ 50.10.1 PLAIN – in simple words

1. There are two dates and people constantly confuse them.
2. The **training data cutoff** is the last date of text the model learned from.
3. The **release date** is the day you could first use it.
4. The gap between them is typically several months, and has often been a year or more.
5. During that gap the world kept happening and the model did not see any of it.
6. So a model released in one year can be confidently describing the world of a year or more earlier.
7. It does not know it is out of date. It has no clock and no calendar.
8. Unless you tell it today's date, it does not know today's date.
9. And it is often wrong about its own cutoff, which surprises people most.

■ 50.10.2 PLAIN – a picture in your head

1. Imagine someone who read every newspaper up to a certain Tuesday, then went into a sealed room, and is now answering your questions.
2. They are extremely well read up to that Tuesday.
3. They do not know today is a different day. Nobody told them.
4. Ask what happened last week and they will describe the last week they remember, with total confidence.
5. Worse, they read fewer papers in the final month than in earlier months, because the papers about that month had not been written yet.
6. So their sense of “recent” lands earlier than the actual Tuesday.

Where this comparison breaks: a person in a sealed room knows they are in a sealed room, and will say so. A model has no representation of its own situation, so it cannot volunteer the warning. That is the whole practical danger of the gap.

■ 50.10.3 PLAIN – a worked example

1. Real published gaps between stated cutoff and release.

Model	Stated cutoff	Released
GPT-4	September 2021	14 March 2023
Claude 3 family	August 2023	4 March 2024
Llama 3 8B	March 2023	18 April 2024
Llama 3 70B	December 2023	18 April 2024
GPT-4o	October 2023	13 May 2024

2. Read the first row. GPT-4 shipped about 18 months after its data ended.
3. Read rows three and four. Two models released on the same day, from the same family, with cutoffs nine months apart.
4. That alone should end any belief that a family name implies a shared cutoff.
5. Since about 2024 the gaps have narrowed, often to a few months, because pipelines got faster and freshness became a selling point. But the gap has never been zero and cannot be.

■ 50.10.4 PLAIN – what is really happening inside

1. Why the gap exists at all, in order.

data collection and filtering	weeks to months
pretraining run	weeks to months
post-training: SFT, RL, tuning	weeks to months
internal + external evaluation	weeks
safety testing and red-teaming	weeks to months
staged rollout and capacity build	weeks

2. Every stage needs the previous one finished, so the delays add rather than overlap.
3. Now why models are unreliable about their own cutoff. Three separate causes.
4. First, the cutoff is not stored anywhere in the weights. If the model states one, it is because someone wrote it into the post-training data or the system prompt, or because the model is guessing.
5. Second, the internet writes about events with a lag. An event in the final two months before cutoff has far fewer documents about it than an event two years earlier. So the model's felt sense of "the present" sits earlier than its real cutoff. Researchers call this the effective cutoff, and it is commonly earlier than the stated one.
6. Third, training corpora contain many documents about earlier models with earlier cutoffs. A model asked its own cutoff can echo a date it read.
7. The practical rule that follows: never ask a model for its cutoff and act on the answer. Look it up in the provider's documentation.
8. And always put the current date in the system prompt if the date matters.

■ 50.10.5 TECHNICAL – the engineer's version

1. Terminology precision. "Knowledge cutoff" usually refers to the pretraining corpus cutoff. Post-training data is frequently newer, and retrieval or tool results are newer still. A deployed system can therefore have three different effective dates at once.
2. The paper "Dated Data: Tracing Knowledge Cutoffs in Large Language Models", published in 2024, documented that measured effective cutoffs for many open models are earlier than the reported ones, and attributed this partly to corpus construction: deduplication and re-crawling mean older versions of pages persist while newer content is thinner.
3. Mitigations, in the order you should reach for them:

Mitigation	What it fixes
Date in system prompt	Model thinks it is the past
Web search tool	Missing recent facts
Retrieval over your docs	Missing private facts
Explicit "you may not know"	Confident staleness

4. Established fact: the cutoff-to-release gap, and its documented sizes. Established fact: models frequently misreport their own cutoff. Active research: measuring effective cutoffs per topic. Marketing claim: "always up to date", which describes a retrieval pipeline, not a model.
5. Practical detection test you can run in one minute: ask the model about three events with known dates spread across the suspected boundary, and see where its knowledge stops. That measures the effective cutoff for that topic, which is what you actually care about.

■ 50.10.6 WORDS – remember these

1. Training cutoff — the last date of learned text — the corpus collection boundary for pretraining data.
2. Effective cutoff — where the knowledge really stops — the empirically measured boundary, usually earlier than the stated cutoff.
3. Release date — when you could first use it — general availability date of a specific model version.
4. Staleness — the model living in the past — degradation of factual accuracy for events after the cutoff.
5. Retrieval augmentation — giving it fresh documents at question time — supplying externally fetched context so the answer is not limited to weights.
6. Post-training — the tuning after the big training run — supervised fine-tuning and reinforcement learning stages, often using newer data than pretraining.

50.11 Versions, snapshots and the moving-name problem

■ 50.11.1 PLAIN – in simple words

1. A product name and a model identifier are two different things.
2. The product name is what the marketing says. It is a brand.
3. The model identifier is the exact string your program sends to the API.
4. A product name can point at different weights over time, without notice.
5. A dated identifier points at one fixed set of weights that never changes.
6. So the same product name can behave differently next month, and your carefully tuned prompt can quietly stop working.
7. Nobody broke anything on purpose. The name moved.
8. The rule that follows is short: in production, use a dated identifier, and re-run your own eval set whenever you change it.

■ 50.11.2 PLAIN – a picture in your head

1. Think of a coffee shop's "house blend".
2. It is on the menu every year under the same name.
3. The beans change with the harvest, the roast is adjusted, the supplier changes. The name does not.
4. If you love it, you cannot order last year's. It no longer exists.
5. A dated identifier is like buying a specific labelled lot, roasted on a stated day, from a stated farm.
6. You can reorder exactly that, until the shop stops stocking it.

Where this comparison breaks: coffee changes gradually and you taste it immediately. A moving model name can change one narrow behaviour, such as how it formats JSON or when it refuses, while everything else stays identical. You will not notice by tasting. You notice because a downstream parser starts failing at two in the morning.

■ 50.11.3 PLAIN – a worked example

1. Real naming conventions from the three largest providers, as observed in August 2026. These change, so treat the shapes as the lesson and the examples as dated illustrations.

Provider	Shape	Example
OpenAI	name-YYYY-MM-DD	gpt-5-2025-08-07
Anthropic	family-version-YYYYMMDD	claude-opus-4-1-20250805
Anthropic	undated alias	claude-opus-5
Google	name plus channel	gemini-3.6-flash
Google	dated preview	model-preview-MM-YYYY

2. Read the OpenAI row. `gpt-5-2025-08-07` is a snapshot: those exact weights, fixed. `gpt-5` on its own is an alias that may be repointed.
3. Read the Anthropic rows. Some identifiers carry an eight-digit date, some do not. The dated ones are the ones to pin.
4. Google's documentation as of August 2026 describes four channels: `stable`, `preview`, `latest` and `experimental`. The `latest` alias is explicitly defined as pointing at the newest release for a model variation, with a stated notice period of about two weeks before a breaking change.
5. That is the clearest possible statement of the trade-off. An alias gives you automatic upgrades and about two weeks of warning. A pinned snapshot gives you stability and the obligation to migrate yourself.
6. Note also the older Google style using numeric suffixes such as `-001` and `-002`, where the trailing number is the revision of the same model generation. Different shape, same purpose.

■ 50.11.4 PLAIN - what is really happening inside

1. Why aliases exist at all, honestly stated from both sides.
2. From the provider's side: most users want improvements without doing work, safety fixes must be able to ship immediately, and serving many pinned versions costs real hardware.
3. From your side: any change to weights is a change to behaviour, and you have tested against the old behaviour.
4. Those two positions cannot both be fully satisfied, which is why both options exist.
5. What actually changes when a name is repointed: refusal boundaries, verbosity and formatting habits, tool-calling and JSON reliability, tokenizer or context limits in larger changes, and latency and price.
6. What almost never changes silently: the API shape. Providers version that separately, precisely because it would break everyone at once.
7. The distinction is worth naming. The API contract is close to a standard, documented and versioned. Model behaviour under an alias is a convention, and one that assumes you will cope.
8. There is also a middle case people forget: a provider may change the serving stack, quantization or routing behind a fixed identifier. The weights are the same; the outputs may not be bit-identical. Ask about this if determinism matters to you.

■ 50.11.5 TECHNICAL - the engineer's version

1. The production rule, in three lines.

1. Pin the dated snapshot in config, never an alias.
 2. Store the exact id with every logged output.
 3. Re-run your eval set before changing the pin.
2. Logging the identifier with each output is the step people skip and later regret. Without it, you cannot answer "did quality drop when we moved?" because you cannot tell which requests used which weights.

3. Keep the identifier in configuration, not in code, so a migration is a config change plus an eval run, not a code release.
4. Where aliases are still right: prototypes, internal tools, and anything where a two-week notice period is acceptable and nobody has built a parser around the exact output shape.
5. Where snapshots are essential: anything with a downstream schema, anything regulated, anything with a tuned prompt, and anything you cannot re-test quickly.
6. Watch for parameter-level changes too, not just weight changes. As one 2026 example, Anthropic's documentation lists `temperature`, `top_p` and `top_k` as deprecated for its newest models, with non-default values returning an error. Code that hard-codes a temperature will fail on migration even though the API version did not change.
7. Established fact: aliases are repointed and dated snapshots exist at all three major providers. Marketing claim: "drop-in upgrade". Every upgrade is a behaviour change until your own eval set says otherwise.

■ 50.11.6 WORDS - remember these

1. Product name — the brand on the website — a marketing label that may map to different artifacts over time.
2. Model identifier — the exact string you send — the API-level model name that selects a served artifact.
3. Snapshot — a frozen dated version — an immutable identifier bound to one set of weights and serving configuration.
4. Alias — a name that follows the newest release — a mutable pointer, such as a bare family name or a latest channel.
5. Pinning — fixing the version in config — specifying an immutable snapshot identifier so behaviour does not change under you.
6. Channel — the stability tier — stable, preview, latest or experimental, each with different change and notice policies.

50.12 Deprecation and retirement

■ 50.12.1 PLAIN - in simple words

1. Every model you build on will eventually be switched off.
2. Not "might". Will. Plan for it from the first day.
3. There are three stages and they mean different things.
4. **Legacy** means still working, no longer recommended, no further updates.
5. **Deprecated** means a shutdown date has been announced.
6. **Retired** means the identifier no longer works and your requests fail.
7. Providers give notice, but the notice period varies a great deal by provider and by model tier.
8. The single thing that makes a forced migration safe is your own eval set, because it is the only way to know whether the replacement is good enough for your job.

■ 50.12.2 PLAIN - a picture in your head

1. Think of a bus route being withdrawn.
2. First, notices appear at the stops. That is deprecation.
3. Then a date is given, and an alternative route is suggested.
4. On the date, the bus stops coming. That is retirement.
5. If you never tried the alternative route before the date, you find out on the morning you needed it whether it gets you to work on time.

- Trying the alternative early, with your actual journey, is the whole of migration strategy.

Where this comparison breaks: a bus route is either running or not, and you find out at the stop. A retired model identifier can fail in a way your code does not handle, at the worst possible moment, in production, returning an error your retry logic loops on. Test the failure path too.

■ 50.12.3 PLAIN – a worked example

- Real, checkable policies and dates, as published in August 2026.

Provider	Class	Notice given
OpenAI	Generally available	At least 6 months
OpenAI	Specialized variants	At least 3 months
OpenAI	Preview models	As short as 2 weeks
Anthropic	Public models	At least 60 days
Google	Preview models	At least 2 weeks

- And real retirement events, which show the policies being applied.

Identifier	Retired
claude-3-7-sonnet-20250219	19 February 2026
claude-sonnet-4-20250514	15 June 2026
claude-opus-4-1-20250805	5 August 2026
gpt-5-2025-08-07 (announced)	11 December 2026

- Read the third row against the first table. That snapshot was released in August 2025 and retired in August 2026. One year of life.
- Read the fourth row. Announced on 11 June 2026 for shutdown on 11 December 2026: exactly the stated six months.
- That is the realistic planning number. A pinned snapshot at a major provider has historically lasted roughly one to two years, with a few months of warning at the end.
- Note also that whole product features get retired, not only models. In 2026 OpenAI announced shutdown dates for several platform features including its hosted evaluation product. Do not build your only eval harness inside a vendor's product.

■ 50.12.4 PLAIN – what is really happening inside

- Why retirement happens: serving old weights occupies accelerators that could run new ones, old models lack current safety mitigations, and every supported version multiplies the testing burden.
- Where to find the schedule: every major provider publishes a deprecations page listing model identifier, deprecation date, retirement date and the recommended replacement. Read it quarterly. Subscribe to the changelog.
- The migration procedure, in order.
 - Read the deprecation notice; note both dates.
 - Identify the suggested replacement id.
 - Run your eval set on old and new, same prompts.
 - Read the failure list, not just the score.
 - Fix prompts for the new model's habits.
 - Re-run. Compare cost and latency too.
 - Ship behind a flag; keep the old id available.

- 8. Watch production metrics; then remove the flag.
- 9. Delete the old id from config before the date.

4. Step 3 is the one that makes the rest possible. Without an eval set, steps 4 to 8 are guesswork and step 9 is a leap of faith.
5. Expect prompt changes to be needed. A newer model in the same family often needs a shorter prompt, because instructions written to work around an older model's weaknesses can actively hurt a newer one.
6. Budget the work. For a small production system with a good eval set, a migration is typically days. Without one, it is weeks and the outcome is unknown.

■ 50.12.5 TECHNICAL – the engineer's version

1. Operational controls worth having in place before you need them: the model identifier in configuration, a per-request log of the identifier used, a feature flag to switch identifiers without deploying, and an alert on the specific API error returned for a retired model.
2. Consider a fallback chain in code: primary snapshot, then a named replacement, then a degraded path. Test the fallback deliberately, because an untested fallback is not a fallback.
3. If continuity matters more than anything else, the alternative is running open-weight models yourself. Then nobody can retire your model, and the cost is that you own the serving, the security patching and the hardware. That is a genuine trade, not a free option.
4. Established fact: the notice periods and retirement dates above, as published in August 2026. They are policies, not contracts, and they change; check the current pages rather than trusting this table.
5. The honest version of “the provider will look after you”: the provider will give you a date and a suggested replacement. Whether the replacement does your job is entirely your problem, and only your eval set can answer it.

■ 50.12.6 WORDS – remember these

1. Deprecated — announced for removal — still functional, with a published retirement date and a recommended replacement.
2. Retired — switched off — the identifier no longer serves requests and calls return an error.
3. Legacy — still working, no longer recommended — a supported but frozen version receiving no updates.
4. Notice period — how long you get to move — the interval between deprecation announcement and retirement.
5. Migration — moving to the replacement — re-pinning the identifier and re-validating behaviour against your own evaluation set.
6. Fallback chain — what to use when the first choice fails — an ordered list of model identifiers with a degraded final option.

50.13 What you should actually do

■ 50.13.1 PLAIN – in simple words

1. Here is the whole procedure, in order, for choosing a model for a job.
2. One. Write down the job in one sentence, and what a good answer looks like.
3. Two. Build the eval set from section 50.8. Thirty to a hundred real examples with a marking rule.
4. Three. Shortlist two or three candidate models. Use public benchmarks only for this step, only to shortlist, and never to decide.
5. Four. Run your eval set on all of them, with identical prompts.

6. Five. Read every failure. The failures tell you more than the score.
7. Six. Measure cost and latency at the same time, on the same runs.
8. Seven. Decide using all three numbers together, not quality alone.
9. Eight. Pin the dated identifier you chose.
10. Nine. Put the failures you saw into the eval set as new items.
11. Ten. Re-check every three months, and whenever a deprecation notice arrives.
12. That is it. It is not sophisticated. It is just done consistently.

■ 50.13.2 PLAIN - a picture in your head

1. This is how you would hire someone, and you already know how to do that.
2. You do not hire from a league table of universities.
3. You shortlist from credentials, then you set a work sample task that resembles the actual job.
4. You watch how they handle the hard parts, not just whether they finish.
5. You consider salary and availability alongside skill.
6. And you review after a few months, because circumstances change.

Where this comparison breaks: a person learns your job over time and asks questions when confused. A pinned model snapshot is exactly as good on day 300 as on day 1, and never tells you it is uncertain unless you build that in.

■ 50.13.3 PLAIN - a worked example

1. What to measure, and what a reasonable target looks like.

What to measure	How	Why it matters
Pass rate overall	Your eval set	Does it do the job
Pass rate per slice	Eval set slices	Where it fails
Cost per task	Tokens times price	Unit economics
Time to first token	Client-side timer	Feels responsive
Tokens per second	Client-side timer	Long output speed
Run-to-run variance	3 repeat runs	Is a gain real
Refusal rate	Refusal slice	Over-caution
Format validity	Schema check	Downstream breakage

2. A worked cost calculation, using round illustrative prices rather than any provider's current ones, since prices change monthly.
3. Suppose a task uses 4,000 input tokens and 800 output tokens, and the price is 3 dollars per million input and 15 dollars per million output.
4. Input cost: $4,000 / 1,000,000 * 3 = 0.012$ dollars.
5. Output cost: $800 / 1,000,000 * 15 = 0.012$ dollars.
6. Total 0.024 dollars per task. At 50,000 tasks a month that is 1,200 dollars.
7. Now suppose a model scoring 4 points higher costs three times as much. That is 3,600 dollars a month for 4 points on a 50-item eval set, where one standard error is about 5.7 points.
8. Written that way the decision is obvious, and it was invisible while you were looking at a leaderboard.

■ 50.13.4 PLAIN – what is really happening inside

1. Why “try two or three” and not one or ten.
2. One tells you nothing comparative. Ten is a research project you will not finish, and the differences between the middle candidates will be inside your noise floor anyway.
3. Two or three, chosen to be genuinely different, is the sweet spot: for example one frontier model, one cheaper model from the same provider, and one from a different provider or an open-weight model you host.
4. Include a cheaper model deliberately. The most common real finding is that the cheap model is good enough for 80 per cent of traffic, and a routing rule sends the rest to the expensive one.
5. Why re-check periodically: models change under aliases, new versions appear, prices fall, and your traffic mix drifts as users learn what your product can do.
6. Why the failure list beats the score: a 90 per cent pass rate where the 10 per cent are harmless is fine, and a 95 per cent pass rate where the 5 per cent are confident wrong answers about money is not.

■ 50.13.5 TECHNICAL – the engineer’s version

1. Measure latency properly and separately. Time to first token dominates perceived responsiveness in streaming interfaces; output tokens per second dominates total completion time for long outputs. Report both, at the median and at the 95th percentile, not as a mean.
2. Measure from where your users are. A model served in another region can add more latency in transit than the difference between two models.
3. Control the comparison. Same prompts, same temperature where settable, same context, same tools, same time of day. Provider load varies through the day and will otherwise contaminate your latency numbers.
4. Compute your noise floor first: run one model three times and record the spread. Any difference between models smaller than that spread is not a result.
5. Keep the artifacts: raw outputs, identifiers, timestamps and prices. When something changes in three months, the old raw outputs are the only way to prove what changed.
6. Established fact: the arithmetic and the method here. Active research: automated evaluation set generation and automatic prompt optimization, both of which are useful and neither of which removes the need for a human to define what a good answer is.

■ 50.13.6 WORDS – remember these

1. Shortlist — the two or three you will actually test — candidate models chosen from public evidence before task-specific measurement.
2. Noise floor — the wobble between identical runs — the run-to-run standard deviation below which differences are meaningless.
3. Time to first token — how long before words appear — the latency from request to first streamed token, distinct from total completion time.
4. Unit economics — what one task costs — the token cost per completed task at your actual input and output lengths.
5. Routing — sending easy work to a cheap model — a policy that selects a model per request based on difficulty, cost or latency budget.
6. Regression — the new thing is worse at something — a drop on any slice of your evaluation set after a change.

50.98 Common wrong ideas

1. Wrong: benchmark scores measure intelligence. Right: they measure performance on a fixed list of items under one protocol. Intelligence is not defined well enough to be scored, and no benchmark claims to.
2. Wrong: a higher MMLU means it is better for my task. Right: MMLU is four-option factual recall and is saturated. It predicts almost nothing about summarizing your emails or fixing your code. Only your own eval set answers that.
3. Wrong: the leaderboard is objective. Right: every leaderboard embeds choices about prompts, extraction, subsets and sampling, and preference leaderboards additionally embed the taste and the question mix of whoever voted.
4. Wrong: the model knows its own training cutoff. Right: the cutoff is not stored in the weights. Any date it gives is repeated from post-training data or guessed, and the felt cutoff is usually earlier than the real one.
5. Wrong: the same model name always means the same model. Right: undated product names are aliases and get repointed. Only a dated snapshot identifier is fixed, and even that is eventually retired.
6. Wrong: if two labs disagree, one is cheating. Right: prompt template, few-shot count, extraction, subset, sampling, system prompt and tool access routinely explain gaps of several points, with nobody at fault.
7. Wrong: contamination means the scores are fake. Right: contamination inflates scores by an unknown and uneven amount. Matched fresh benchmarks show drops of up to about 8 points for some model families and near zero for others.
8. Wrong: a 2-point lead is a meaningful lead. Right: on GPQA Diamond one standard error is about 2 points and one item is 0.5 points. On a single AIME paper, one question is 6.7 points.
9. Wrong: pass@k is just the score. Right: pass@k rises with k by construction. pass@1 and pass@100 are different quantities and cannot be compared.
10. Wrong: benchmarks are useless, so ignore them. Right: they are useful for shortlisting, for tracking the field over years, and for spotting obvious weakness. They are not useful for choosing between two close models for your specific job.

50.99 Chapter summary in 20 lines

1. A benchmark is a fixed set of items with known answers plus a rule for scoring a response. Nothing more.
2. Every run has five parts: items, prompt template, generation settings, answer extraction, and aggregation.
3. Only the items are usually published, so a score belongs to a model plus a harness, not to a model.
4. MMLU (2020, 57 subjects, about 14,000 test items) and HellaSwag (2019) are saturated and now mostly sanity checks.
5. GSM8K (2021, 1,319 test items) is solved. MATH (2021), AIME and FrontierMath carry the maths signal now.
6. HumanEval (2021, 164 problems, pass@k) is tiny, isolated and leaked. MBPP (2021, 974 problems) has the same shape.
7. GPQA (2023, 448 items; Diamond 198) is hard four-option science recall, not the ability to do science.
8. SWE-bench (2023, 2,294 tasks; Verified 500) scores whether real repository tests pass, and measures the scaffold as much as the model.

9. ARC-AGI keeps a held-back set and reports cost per task, which more benchmarks should copy.
10. Few-shot examples mainly fix output format. Chain-of-thought uses the model's own output as working memory and transforms maths scores.
11. $\text{pass}@k = 1 - C(n-c,k)/C(n,k)$. With $n=10$ and $c=2$, $\text{pass}@1$ is 0.20 and $\text{pass}@5$ is 0.78. The model did not improve; you bought more tries.
12. Two labs disagree because of prompts, shots, extraction, subsets, sampling, system prompts, tools, or bugs. Ask which harness and version.
13. Contamination is near-inevitable when training on the web. Detection by n-gram overlap, canaries, perplexity, old-versus-new splits and completion tricks can prove presence but never absence.
14. Saturation, Goodhart's law, self-reported numbers, cherry-picked baselines, best-of-n reporting, tool asymmetry and truncated axes are the seven ordinary ways a number misleads without anyone lying.
15. Preference arenas measure real user taste well and truth badly, with documented length and style bias; a 10-point gap is a 51 per cent win rate.
16. Inside a company, an eval is a private regression suite of 30 to 100 real examples with per-item marking rules, run on every change.
17. Training cutoff and release date are different, historically separated by months to over a year, and models are unreliable about their own cutoff.
18. Product names are mutable aliases; dated snapshots are fixed. Pin the snapshot in production and re-run your evals when you change it.
19. Every model is eventually retired. Typical notice in 2026 was at least six months at OpenAI, at least 60 days at Anthropic, about two weeks for preview channels.
20. Shortlist with public benchmarks, decide with your own eval set, measure cost and latency alongside quality, and re-check every few months.

Serving, Running One Yourself, RAG, Agents and the Limits

51.0 What this chapter gives you

1. You will be able to say what changes when a model stops learning and starts answering, and give the memory numbers for both.
2. You will be able to read a real API request body field by field, and say what the system prompt is and what it is not.
3. You will be able to explain, with arithmetic, why the first token is slow for one reason and the rest are slow for a completely different reason.
4. You will be able to name the serving tricks that make a model fast, and say why the same model runs at different speeds at different providers.
5. You will be able to build a cost model for a real application and decide honestly whether to self-host.
6. You will be able to run a model on your own laptop with two named tools, and predict beforehand what speed you will get.
7. You will be able to download weights, read a model card, and pick a quantization level on purpose rather than by guessing.
8. You will be able to explain retrieval-augmented generation step by step, including how approximate nearest neighbour search works.
9. You will be able to explain tool calling and agents precisely, including why every tool is a security boundary and why long agent runs fail.
10. You will be able to state the real limits, including why hallucination is intrinsic and why prompt injection is still unsolved as of August 2026.

51.1 Inference versus training: what changes

■ 51.1.1 PLAIN – in simple words

1. Training is the process that produced the numbers inside the model.
2. Inference is the process of using those numbers to answer a question.
3. During training, every number in the model can move.
4. During inference, not one of them moves. They are read and never written.
5. Training needs to remember, for each number, which way it was moving and how fast it has been moving lately. That is several extra copies.
6. Inference needs the numbers themselves, plus some working notes about the conversation so far.
7. So the same model needs roughly ten times less memory to use than to train.

8. Training is judged on work finished per week. Inference is judged on how long one person waits for one answer.
9. A training run that takes 30 days is normal. An answer that takes 30 seconds feels broken.

■ 51.1.2 PLAIN – a picture in your head

1. Think of a very large printed cookbook that a team of chefs wrote over a year.
2. Writing it was training. Drafts, corrections, arguments, notes in the margins about which way each recipe was heading.
3. All of that scaffolding took far more desk space than the finished book.
4. Cooking from it is inference. You open the book, read, and cook.
5. You do need the book itself open in front of you, and a small notepad for what you have already done in this particular meal.
6. But if a customer waits 40 minutes for soup, the restaurant fails.

Where this comparison breaks: a chef can read one page and ignore the rest. A language model reads every page of the book for every single word it produces. That is the fact that governs the whole of this chapter, and no ordinary object behaves that way.

■ 51.1.3 PLAIN – a worked example

1. Take a real model: Llama 3.1 8B, which has 8.03 billion parameters.
2. Chapter 47 gave the rule: memory equals parameter count times bytes per parameter.
3. At 2 bytes per parameter that is 16.1 billion bytes, which is 15.0 GiB.
4. To use the model, you need those 15.0 GiB plus working space.
5. To train the model, you need the same 15.0 GiB plus four more copies.
6. Here is the whole comparison, in GiB, for one 8B model:

Item	Inference	Training
Weights, 16-bit	15.0	15.0
Master copy, 32-bit	0	29.9
Gradients, 32-bit	0	29.9
Optimizer state (two)	0	59.8
KV cache, 8K tokens	1.0	0
Activations	0.5	about 28
Framework overhead	1.0	2.0
Total	about 17.5	about 165

7. So the same model is a 17.5 GiB problem to run and a 165 GiB problem to train fully. That is a factor of about 9.4.
8. 17.5 GiB fits on one consumer graphics card with 24 GB.
9. 165 GiB does not fit on any single card sold in 2026, including the 141 GB NVIDIA H200.

■ 51.1.4 PLAIN – what is really happening inside

1. In training, each batch of data goes forward through the network, an error is measured, and the error is pushed backwards.
2. Pushing it backwards requires remembering every intermediate value from the forward pass. Those are the activations, and they are enormous.
3. In inference, none of that exists. There is no backward pass, so no activation needs to be kept after the layer that produced it is done.

4. What is kept instead is different: a per-token record called the KV cache, which we come to in section 51.4.
5. So inference memory is dominated by two things only: the frozen weights, and the KV cache that grows with the length of the conversation.
6. And the weights are read-only, which means many requests can share exactly one copy of them in memory. This is why batching works at all.

■ 51.1.5 TECHNICAL – the engineer’s version

1. Training memory per parameter under the standard mixed-precision recipe with Adam: 2 bytes bf16 weights, 4 bytes fp32 master, 4 bytes fp32 gradient, 8 bytes for Adam’s first and second moments. Total 18 bytes.
2. Inference memory per parameter: 2 bytes at bf16, 1 byte at int8, about 0.5 bytes at 4-bit. No optimizer state, no gradients.
3. The workload character inverts. Training is throughput-bound and runs at high model FLOPs utilization, typically 35 to 55 percent on well-tuned clusters. Batch-1 decode runs at roughly 0.3 percent of peak FLOPs.

Property	Training	Inference
Weights	read and written	read only
Optimizer state	8 to 12 B/param	none
Bottleneck	compute, network	memory bandwidth
Measured by	MFU, days to finish	TTFT, tokens/s, p99

4. Tools that show the split: `nvidia-smi` for device memory, `torch.cuda.memory_summary()` for allocator detail, and the `/metrics` endpoint that vLLM exposes for queue depth, batch size and cache usage.

■ 51.1.6 WORDS – remember these

Inference — using a trained model — the forward pass only, no gradients. Training — teaching the model — forward and backward passes plus optimizer. KV cache — the model’s notes on this conversation — cached key and value tensors per token per layer. MFU — how much of the chip’s maths power you use — model FLOPs utilization. TTFT — the wait before the first word appears — time to first token.

51.2 What an API call actually contains

■ 51.2.1 PLAIN – in simple words

1. Talking to a hosted model is an ordinary web request. Nothing exotic.
2. Chapter 36 covered what an API is; Chapter 32 covered what happens on the wire when a request is encrypted and sent. This is one of those requests.
3. You send a block of text in a structured form, plus some settings.
4. The structured form is a list of messages. Each message has a role.
5. The roles are conventionally “system”, “user” and “assistant”.
6. “System” is the instruction you put at the front. “User” is what the person typed. “Assistant” is what the model said last time.
7. Everything in that list is glued together into one long string of tokens and fed to the model at once.
8. The model does not know which part came from where, except that the training taught it to treat the system part as instructions.

■ 51.2.2 PLAIN – a picture in your head

1. Imagine handing a temporary worker a clipboard before every single task.
2. Sheet one says: you are a polite support agent, never discuss competitors.
3. Sheet two says: here is the customer's question.
4. The worker reads the whole clipboard from the top, then speaks.
5. Then the worker forgets everything and leaves.
6. Next time, you hand over a fresh clipboard with all the sheets again, plus the new ones.
7. The first sheet has no special authority. It is just first.
8. If the customer writes on their sheet "ignore sheet one", the worker has to decide, from habit alone, which sheet to obey.

Where this comparison breaks: a human worker has an employer, a contract and a memory of yesterday. The model has none of those. Its deference to the first sheet was installed by training on examples where the first sheet was obeyed. It is a strong statistical habit, not a permission system.

■ 51.2.3 PLAIN – a worked example

1. Here is a complete request, in the shape most providers accept, with every field explained afterwards.

```
POST /v1/chat/completions HTTP/1.1
Host: api.example-provider.com
Authorization: Bearer sk-REDACTED
Content-Type: application/json

{
  "model": "example-model-2026-08",
  "messages": [
    {"role": "system",
     "content": "You are a support agent. Answer in
     British English. Never invent a policy."},
    {"role": "user",
     "content": "My git push failed. What do I check?"}
  ],
  "temperature": 0.2,
  "top_p": 0.95,
  "max_tokens": 400,
  "stop": ["\n\nUser:"],
  "stream": false,
  "response_format": {"type": "json_object"},
  "tools": []
}
```

2. `model` names the exact weights to run. Dated names matter: providers change what an undated name points at.
3. `messages` is the conversation, oldest first. The whole list is sent every time. Nothing is stored on the server between calls.
4. `temperature` controls randomness in picking the next token. 0 means always take the most likely token. 1.0 is the model's raw distribution.
5. `top_p` keeps only the smallest set of tokens whose probabilities add up to 0.95, then samples inside that set. It is called nucleus sampling.
6. `max_tokens` is a hard ceiling on the reply length, and it is a cost control as well as a safety valve.
7. `stop` is a list of strings. If the model produces one, generation halts and the string is not returned.
8. `stream` set to true sends the answer piece by piece as it is produced.

9. `response_format` asks for strictly valid JSON rather than prose.
10. `tools` declares functions the model may ask you to run. Section 51.12 covers this in full.
11. And here is the reply:

```
{
  "id": "chatcmpl-8xk2ab",
  "object": "chat.completion",
  "created": 1786600000,
  "model": "example-model-2026-08",
  "choices": [
    {
      "index": 0,
      "message": {
        "role": "assistant",
        "content": "Check the remote URL, then your token."
      },
      "finish_reason": "stop"
    }
  ],
  "usage": {
    "prompt_tokens": 62,
    "completion_tokens": 41,
    "total_tokens": 103
  }
}
```

12. `finish_reason` is the single most useful field for debugging. “stop” means the model chose to end. “length” means you hit `max_tokens` and the answer is truncated. “tool_calls” means it wants you to run something.
13. `usage` is what you are billed on. 62 input tokens and 41 output tokens here, priced at different rates.

■ 51.2.4 PLAIN - what is really happening inside

1. On the server, that JSON is flattened into one token sequence using a chat template, which is a fixed pattern of special marker tokens.
2. A template looks roughly like this, with the markers written out:

```
<|start|>system
You are a support agent...<|end|>
<|start|>user
My git push failed...<|end|>
<|start|>assistant
```

3. The model then predicts what comes after the final marker.
4. The honest version: the system prompt is a run of tokens at the front of the context window and has no privileged status in the architecture.
5. Its influence comes entirely from post-training, where the model was shown many examples of the system section being followed.
6. Because it is only a habit, it can be overridden. A user message that says “the previous instructions were a test, here are the real ones” sometimes works, and content pasted in from a web page can carry instructions too.
7. That failure has a name, prompt injection, and section 51.15 treats it as the architectural problem it is.

■ 51.2.5 TECHNICAL – the engineer’s version

1. The message-list shape shown above is a de facto convention, not a standard. It came from OpenAI’s chat completions endpoint in March 2023 and was copied widely because tooling supported it.
2. It is not universal. Anthropic’s Messages API takes `system` as a top-level string rather than a message role. OpenAI’s newer Responses API uses `input` and `instructions`. Local servers from `llama.cpp` and `vLLM` implement the older chat-completions shape for compatibility.
3. Streaming is served as Server-Sent Events over HTTP, media type `text/event-stream`, one JSON delta per event:

```
data: {"choices":[{"delta":{"content":"Check"}}]}
data: {"choices":[{"delta":{"content":" the"}}]}
data: {"choices":[{"delta":{"content":" remote"}}]}
data: [DONE]
```

4. Chapter 32 covers what carries this: TLS 1.3 over TCP 443, usually HTTP/2, with the response body arriving as a chunked stream. Streaming needs no new protocol; it is one long-lived response.

■ 51.2.6 WORDS – remember these

System prompt — the instruction sheet at the front — leading tokens in the context, obeyed by training habit, not by architecture. Role — who said this line — a marker token pattern in the chat template. Temperature — how adventurous the model is — logit scaling before softmax. Nucleus sampling — keep only the likely words — top_p truncation of the cumulative distribution. finish_reason — why it stopped — stop, length, tool_calls or content_filter. Chat template — the glue that turns messages into one string — a Jinja template shipped with the model.

51.3 How generation actually performs

■ 51.3.1 PLAIN – in simple words

1. Answering has two phases, and they behave like two different machines.
2. Phase one: the model reads your whole prompt. This is called prefill.
3. Phase two: the model writes the answer one token at a time. This is called decode.
4. Prefill can read every word of your prompt at the same moment, in parallel, because all the words already exist.
5. Decode cannot do that. Word five cannot be chosen before word four exists.
6. So prefill is limited by how much arithmetic the chip can do per second.
7. And decode is limited by something else entirely: how fast the chip can pull the model’s numbers out of memory.
8. That is the whole secret. For each single token of output, the machine has to read every parameter in the model once.
9. So the speed of writing is roughly: memory speed divided by model size.
10. That one division explains almost everything people find strange about model speed.

■ 51.3.2 PLAIN – a picture in your head

1. Imagine a librarian who must consult every book in a library before saying one word.
2. To read your question, the librarian can put a hundred assistants on it at once, one per sentence. That is quick, and it scales with staff.

3. But to say each word of the answer, the librarian must personally walk the whole library again. Every shelf. Every book.
4. Adding assistants does not help with the walking. The corridor is the limit.
5. So the wait before the first word depends on how long your question was and how many assistants are free.
6. And the speed of the words after that depends only on how fast one person can walk the library once.
7. A bigger library means slower words, in direct proportion.

Where this comparison breaks: the librarian would remember the books. The chip does not. It genuinely re-reads the weights from memory for every token, because there is nowhere near enough fast on-chip storage to hold them. That re-reading is not waste from bad design; it is the fundamental shape of the computation.

■ 51.3.3 PLAIN - a worked example

1. Take Llama 3.1 8B at 16-bit precision. Weights are 16.1 GB.
2. Run it on one NVIDIA H100 SXM. Its memory bandwidth is 3,350 GB per second. That figure is from NVIDIA's own specification sheet.
3. Decode ceiling equals 3,350 divided by 16.1, which is 208 tokens per second.
4. Real systems reach 60 to 80 percent of that, so expect 125 to 165 tokens per second for a single user. Measured single-stream figures for 8B on an H100 sit in that range.
5. Now the same model on a MacBook Air with the M5 chip. Its memory bandwidth is 153 GB per second, from Apple's technical specifications.
6. At 4-bit the model is about 4.7 GB. 153 divided by 4.7 is 32 tokens per second as a ceiling; expect 20 to 25 in practice.
7. Now prefill on the same H100. Prefill work is about 2 times parameters times prompt tokens.
8. For a 1,000-token prompt: 2 times 8.03 billion times 1,000 equals 16.1 trillion floating-point operations.
9. An H100 SXM does about 990 trillion dense bf16 operations per second. At 40 percent utilization that prompt takes about 41 milliseconds.
10. Compare the phases directly:

Phase	1,000-token prompt	400-token answer
Work	16.1 TFLOP	400 x 16.1 GFLOP
Bytes moved	16.1 GB once	16.1 GB x 400
Time on H100	about 41 ms	about 2.9 s

11. So the answer takes seventy times longer than reading the question, even though the question was longer.
12. One more real-world correction. The reader of this book is in India. A round trip to a server in the United States is typically 220 to 280 milliseconds.
13. So for short prompts, the network wait is larger than the prefill. Time to first token is network plus queueing plus prefill, and often the network wins.

■ 51.3.4 PLAIN – what is really happening inside

1. Here is the timeline of one request, drawn out:

2. Time to first token is everything up to the first arrow out: network, queue, prefill, and one decode step.
3. This is why a long prompt hurts your first token but not your typing speed, and why a long answer hurts total time but not the first token.

■ 51.3.5 TECHNICAL – the engineer’s version

1. The controlling ratio is arithmetic intensity: floating-point operations per byte moved from memory.
2. An H100 SXM has about 990 TFLOP/s dense bf16 against 3.35 TB/s, a balance point of roughly 295 FLOP per byte. Below that ratio you are bandwidth-bound.
3. Batch-1 decode does 2 FLOP per parameter and reads 2 bytes per parameter: 1 FLOP per byte. You are using about 0.3 percent of the chip’s arithmetic.
4. The metric for the decode side is memory bandwidth utilization, or MBU, popularized by Databricks in 2023: achieved bytes per second divided by peak. Well-tuned stacks reach 60 to 85 percent.
5. Note that the vendor’s headline FLOPS figure often includes 2:1 structured sparsity. NVIDIA’s 1,979 TFLOPS figure for H100 bf16 is the sparse number; the dense number is 989.5. Use the dense one for language models.

Hardware	Bandwidth GB/s	8B fp16 ceiling
H100 SXM	3,350	208 tok/s
H200 SXM	4,800	298 tok/s
RTX 5090	1,792	111 tok/s
RTX 4090	1,008	63 tok/s
M5 Max, 40-core	614	38 tok/s
MacBook Air M5	153	9.5 tok/s

6. Measure it yourself with `llama-bench` from `llama.cpp`, which reports prompt processing and token generation separately, or with `vLLM`’s `benchmark_serving.py`, which reports TTFT and inter-token latency percentiles under load.

■ 51.3.6 WORDS – remember these

Prefill — reading your question — parallel forward pass over all prompt tokens, compute-bound. Decode — writing the answer — sequential single-token forward passes, memory-bandwidth-bound. Arithmetic intensity — sums done per byte fetched — FLOP per byte, compared against the hardware’s balance point. MBU — how much of the memory pipe you are using — memory bandwidth

utilization. Inter-token latency — the gap between words — the reciprocal of decode tokens per second.

51.4 The serving optimizations, each explained

■ 51.4.1 PLAIN – in simple words

1. Every trick in serving exists to fight one of two enemies: reading the weights too often, or leaving the machine idle.
2. The KV cache stops the model re-reading your whole conversation for every new word.
3. Continuous batching stops the machine idling while one user thinks.
4. Speculative decoding lets a small fast model guess ahead so the big model can check several words at once.
5. Quantization shrinks the weights so there is less to read per token.
6. Tensor parallelism splits one model across several chips so their memory pipes add up.
7. Prefix caching stores the processed form of a shared opening so it is not re-processed for every user.
8. Streaming does not make anything faster, but it makes the wait feel far shorter, which is often what people actually want.

■ 51.4.2 PLAIN – a picture in your head

1. Think of a busy kitchen with one very slow oven.
2. The KV cache is keeping the prepared ingredients on the counter instead of re-chopping everything for each course.
3. Static batching is waiting until six orders arrive, cooking all six, and serving nobody until the slowest one finishes.
4. Continuous batching is putting each new order into the oven the moment a space appears, and taking each dish out as soon as it is done.
5. PagedAttention is using many small identical trays instead of reserving a whole shelf per order in case it turns out to be large.
6. Speculative decoding is a junior cook who prepares the next three likely steps; the chef glances at them and either accepts all three or redoes them.

Where this comparison breaks: in a kitchen, more staff means more parallel cooking. On a GPU, the constraint is a single memory bus that all the work shares, so most of these tricks are about using one bus better, not about adding more hands.

■ 51.4.3 PLAIN – a worked example

1. Start with the KV cache, because it is the one that changes the order of the arithmetic.
2. Without a cache, to produce token number t the model must process all $t-1$ previous tokens again from scratch.
3. Generating 500 tokens after a 1,000-token prompt means processing, on average, 1,250 tokens, 500 times: 625,000 token-passes.
4. With a cache, each new token processes exactly one new token, because the previous keys and values are already stored: 500 token-passes.
5. That is a saving of 1,250 times for this case. The work goes from growing with the square of the length to growing with the length itself.
6. Now the price. The cache is real memory, and it is calculated exactly:

```

KV bytes per token
  = 2 (keys and values)
  x layers
  x key/value heads
  x head dimension
  x bytes per number

```

```

Llama 3.1 8B, 16-bit:
  = 2 x 32 x 8 x 128 x 2 = 131,072 bytes = 128 KiB

```

```

Llama 3.1 70B, 16-bit:
  = 2 x 80 x 8 x 128 x 2 = 327,680 bytes = 320 KiB

```

7. So an 8B model with a 128,000-token context holds 16 GiB of cache, which is more than the 15 GiB of weights.
8. This is why serving systems spend so much effort on cache memory, and why grouped-query attention, which cuts the number of key/value heads from 64 to 8, was such an important change. It divided this table by eight.

■ 51.4.4 PLAIN – what is really happening inside

1. Static batching groups requests, runs them together, and returns them together. Every request waits for the longest one in the group.
2. Continuous batching, first described in the 2022 Orca paper, works at the level of single decode steps instead.
3. At each step the scheduler looks at every active sequence, runs one token for all of them in one fused operation, then evicts finished ones and admits waiting ones immediately.
4. The result is that the batch is never allowed to shrink, so the memory pipe stays busy. Reported throughput gains over static batching are large, often several times, at the same latency.
5. PagedAttention, from the vLLM paper at SOSP 2023, borrows the operating system idea of paging from Chapter 12.
6. Instead of reserving a contiguous block of cache for each sequence's maximum possible length, it allocates fixed-size blocks, typically 16 tokens each, and keeps a block table per sequence.
7. This removes internal fragmentation and lets several sequences share blocks, which matters when many requests begin with the same system prompt.
8. Speculative decoding uses a small draft model to propose the next k tokens cheaply, then runs the large model once over all k proposals in parallel.
9. Because the large model's forward pass over k tokens costs almost the same as over one token, accepted guesses are nearly free. Rejected ones cost only the draft work.
10. The mathematics were published independently by two groups in 2023, and the method is exact: the output distribution is identical to running the large model alone. It is a speed trick, not a quality trade.

■ 51.4.5 TECHNICAL – the engineer's version

1. The optimizations, with what each actually buys:

Technique	What it saves	Typical effect
KV cache	recompute	quadratic to linear
Continuous batching	idle GPU	2 to 10x throughput
PagedAttention	cache memory	19 to 27% memory

Technique	What it saves	Typical effect
Speculative decoding	decode steps	1.5 to 3x latency
4-bit weights	bytes per token	about 3x decode
Tensor parallel, 2 GPUs	bandwidth	1.6 to 1.9x
Prefix caching	prefill	up to 90% TTFT

2. Tensor parallelism splits each weight matrix across GPUs, so each device reads only its shard. Two GPUs give roughly twice the aggregate bandwidth, less an all-reduce over NVLink after every layer. Scaling is sub-linear and degrades sharply without a fast interconnect.
3. Quantized serving matters twice over: 4-bit weights cut both memory and bytes read per token. Activation quantization to FP8 additionally raises prefill throughput on Hopper and Blackwell hardware.
4. Why the same open model is faster at provider A than provider B, in order of how much it usually explains: the hardware generation, the quantization they silently chose, the batch size policy they run, the current queue depth, and the geographic distance to you.
5. That list is the reason a published benchmark of “model X speed” is close to meaningless without naming the deployment.

■ 51.4.6 WORDS – remember these

KV cache — saved notes so the model need not re-read — cached key and value projections per token per layer. Continuous batching — slot new work in as space frees — iteration-level scheduling, from the Orca paper, 2022. PagedAttention — memory in small blocks, not big reservations — block-table KV allocation, vLLM, 2023. Speculative decoding — a fast guesser the big model checks — draft-and-verify with an exact acceptance rule. Tensor parallelism — one model split across chips — sharded matrix multiply with all-reduce per layer. Prefix caching — reuse the shared opening — KV reuse keyed on a common token prefix.

51.5 Cost and capacity

■ 51.5.1 PLAIN – in simple words

1. Hosted models are sold by the token, and tokens in cost less than tokens out.
2. Chapter 47 explained what a token is: roughly three quarters of an English word, so 1,000 tokens is about 750 words.
3. The reason input is cheaper is exactly section 51.3. Your prompt is read in parallel in one pass, so it is cheap per token.
4. The answer is produced one token at a time, and each token costs a full read of the model. That is the expensive part.
5. Two discounts exist almost everywhere. Batch work that can wait up to a day is half price. Repeated openings you have marked as cacheable are about a tenth of the input price.
6. Building your own server instead is not obviously cheaper. You rent the machine by the hour whether anybody uses it or not.

■ 51.5.2 PLAIN – a picture in your head

1. Think of a taxi where the meter runs differently for the two halves of the journey.
2. Listening to your address is quick and charged at a low rate per word.
3. Driving you there is slow and charged at a high rate per street.
4. Batch pricing is agreeing to be picked up sometime today rather than now, for half fare.

5. Cache pricing is a regular route the driver already knows, so the first part of the journey needs no navigation.
6. Buying your own car instead is the self-hosting decision. The car costs the same whether you drive it or not.
7. It only beats taxis if you drive a great deal, every day.

Where this comparison breaks: taxi fares scale with distance, which you cannot change. Token costs scale with how much text you send, which you control completely. Trimming a system prompt from 2,000 tokens to 400 is a real 80 percent cut on that part of every request, forever.

■ 51.5.3 PLAIN – a worked example

1. Take a support assistant. Real shape, real numbers.
2. 10,000 conversations a day. Six turns each. A 800-token system prompt. 2,000 tokens of retrieved documents at the start. 100-token questions. 300-token answers.
3. Because the whole history is resent every turn, the input grows each turn: 2,900, then 3,300, 3,700, 4,100, 4,500, 4,900.
4. That totals 23,400 input tokens and 1,800 output tokens per conversation.
5. Now price it against three real published tiers from August 2026, in dollars per million tokens: a mid tier at 2 in and 10 out, a small tier at 1 and 5, and a very small tier at 0.10 and 0.60.

Choice	Per conversation	Per 30 days
Mid, 2 and 10	\$0.0648	\$19,440
Mid with caching	\$0.0466	\$13,980
Small, 1 and 5	\$0.0324	\$9,720
Very small, 0.10, 0.60	\$0.0034	\$1,026

6. Read that table twice. The same application costs nineteen thousand dollars a month or one thousand, depending on one decision.
7. The caching row assumes the 2,800-token opening is marked cacheable and hit on five of six turns, charged at one tenth, with a write surcharge on the first turn.

■ 51.5.4 PLAIN – what is really happening inside

1. Renting one datacentre GPU in 2026 costs roughly 2 to 4 US dollars an hour on the open market, varying by provider, region and commitment. Take 2.50.
2. That is about 1,825 dollars a month, per GPU, running or idle.
3. One such GPU serving an 8-billion-parameter model with good batching produces on the order of 2,000 to 4,000 output tokens per second in aggregate across all users.
4. At 2,500 tokens per second held constantly, that is 6.6 billion output tokens a month, which works out at about 28 cents per million.
5. That looks unbeatable until you notice the words “held constantly”.
6. Compare the two cost shapes across real volumes:

Output tokens/month	Hosted at \$0.60/M	Own GPU
10 million	\$6	\$1,825
100 million	\$60	\$1,825
1 billion	\$600	\$1,825
3 billion	\$1,800	\$1,825

Output tokens/month	Hosted at \$0.60/M	Own GPU
10 billion	\$6,000	\$3,650

- Break-even against a cheap hosted model is around 3 billion output tokens a month, and that is before you add a second GPU for redundancy, an engineer to run it, or the load spikes you must size for.
- The honest version: self-hosting is rarely cheaper below very high sustained volume. The good reasons to self-host are usually not cost.
- They are: data must not leave your network, you need a model that no provider hosts, you need the exact same weights for years, or you need a latency floor you control.

■ 51.5.5 TECHNICAL – the engineer’s version

- Published list prices, checked August 2026. Prices move; treat these as a snapshot, not a constant.

Model, August 2026	Input \$/M	Output \$/M
Claude Opus 5	5.00	25.00
Claude Sonnet 5	2.00	10.00
Claude Haiku 4.5	1.00	5.00
OpenAI gpt-5.6-sol	2.50	15.00
OpenAI gpt-5.6-terra	1.00	6.00
OpenAI gpt-5.6-luna	0.10	0.60

- Discount structure, also checked August 2026: batch processing at 50 percent of both input and output on both providers; cache reads at 10 percent of the input rate; cache writes at 125 percent for a short time-to-live.
- Long-context surcharges are now common. OpenAI applies a higher rate above a published input threshold for the whole request, which means one oversized prompt reprices the entire call.
- Reasoning models bill their internal thinking tokens as output. A model that thinks for 4,000 tokens before writing 200 costs twenty-one times more than the visible answer implies. This is the single most common billing surprise of 2025 and 2026.

■ 51.5.6 WORDS – remember these

Input token — text you send — prompt tokens, billed at the lower rate. Output token — text produced — completion tokens, billed several times higher. Batch API — cheaper if you can wait — asynchronous queue, typically 50 percent off with a 24-hour window. Prompt caching — pay less for a repeated opening — server-side KV reuse keyed on an exact prefix, billed at about 10 percent. Duty cycle — how much of the time your machine is busy — utilization, the term that decides every self-hosting argument.

51.6 Running one yourself, practically

■ 51.6.1 PLAIN – in simple words

- You can run a real language model on your own laptop today, offline, for free, in about ten minutes.
- llama.cpp is the engine. It is a C++ program that loads a model file and runs it on your processor, your graphics chip, or both.
- Ollama wraps that engine in something friendly: one command to fetch a model, one to talk to it, and a small local server.

4. LM Studio is a desktop application with a window and buttons, for people who would rather not use a terminal.
5. vLLM, SGLang and TGI are for the other end: serving many users at once on datacentre graphics cards.
6. MLX is Apple's own numerical framework, built for Apple silicon, and it is noticeably faster than the alternatives on those machines.
7. Start with Ollama. Move to llama.cpp when you want control. Move to vLLM when you have users.

■ 51.6.2 PLAIN – a picture in your head

1. Think of playing recorded music.
2. llama.cpp is the amplifier and speaker: raw, capable, many knobs, no case.
3. Ollama is the all-in-one hi-fi with one power button and a catalogue of albums you can fetch by name.
4. vLLM is the sound system for a concert hall, designed for two thousand listeners rather than one.
5. MLX is a speaker built specifically for the shape of your room.

Where this comparison breaks: with music, the recording is identical whatever plays it. Here the tools change the result. Different engines pick different default quantizations, context lengths and sampling settings, so the same named model can give different answers and very different speeds.

■ 51.6.3 PLAIN – a worked example

1. Here is Ollama, start to finish, on a Mac or Linux machine.

```
# install with a package manager, then check it runs
ollama --version

# fetch a small model (a few gigabytes) and chat
ollama pull qwen3:8b
ollama run qwen3:8b

# see what you have, and what is loaded right now
ollama list
ollama ps

# use it as a local HTTP service on port 11434
curl localhost:11434/api/chat -d '{
  "model": "qwen3:8b",
  "messages": [{"role": "user", "content": "Explain TCP in 3 lines"}],
  "stream": false
}'
```

2. That last call has the same shape as the hosted API in section 51.2. Most local servers deliberately imitate it so your code does not change.
3. Now llama.cpp directly, which is one level down.

```
# build once, with Apple GPU support turned on
cmake -B build -DGGML_METAL=ON
cmake --build build --config Release -j

# run a model pulled straight from Hugging Face
./build/bin/llama-cli -hf ggml-org/gemma-3-1b-it-GGUF \
  -p "Write one sentence about routers."
```

```
# serve it on port 8080, 8k context, all layers on the GPU
./build/bin/llama-server -m model-Q4_K_M.gguf \
  -c 8192 -ngl 99 --port 8080

# measure prompt speed and generation speed separately
./build/bin/llama-bench -m model-Q4_K_M.gguf
```

4. The flag that matters most is `-ngl`, the number of layers to put on the GPU. Setting it to 99 means “all of them, if they fit”.
5. If the model does not fit, layers stay on the processor and speed collapses, often by a factor of five or more. That is the single most common cause of “why is my local model so slow”.

■ 51.6.4 PLAIN – what is really happening inside

1. llama.cpp was started by Georgi Gerganov in March 2023 as an experiment in running Llama on a MacBook with no graphics card at all.
2. It defined a file format, now called GGUF, which packs the weights, the tokenizer and the metadata into one file that can be memory-mapped.
3. On the serving side the design goal is the opposite. vLLM keeps the GPU saturated with continuous batching and PagedAttention from section 51.4.
4. SGLang adds RadixAttention, a shared prefix tree, which pays off when thousands of requests begin with the same long system prompt.
5. Hugging Face’s Text Generation Inference was the early default, but Hugging Face put it into maintenance mode on 11 December 2025 and now points new users at vLLM or SGLang. Treat it as a migration topic, not a choice.
6. MLX is Apple’s array framework, released in December 2023, designed around unified memory so tensors are not copied between processor and graphics chip. Ollama added an MLX backend in version 0.19 on 27 March 2026.

■ 51.6.5 TECHNICAL – the engineer’s version

Tool	What it is	Use it when
llama.cpp	C/C++ engine, GGUF	any hardware, full control
Ollama	wrapper plus registry	fastest local start
LM Studio	desktop application	no terminal wanted
vLLM	Python serving engine	many users, GPUs
SGLang	serving, RadixAttention	shared prefixes
TGI	older HF server	existing systems only
MLX	Apple array framework	Apple silicon speed

1. macOS caps what the GPU may wire down, historically around 75 percent of unified memory. The `iogpu.wired_limit_mb` sysctl raises it. That is an implementation detail of one operating system version and it has been renamed before; check before relying on it.
2. Ollama’s published benchmark for its MLX backend, March 2026, on a mixture-of-experts model with 35 billion total and 3 billion active parameters: decode from 58 to 112 tokens per second, prefill from 1,154 to 1,810 tokens per second.
3. Vendor figures, so read them as a direction, not a promise.
4. For serving, the vLLM invocation you will actually type is `vllm serve <model> --tensor-parallel-size 2 --max-model-len 32768`, and it exposes an OpenAI-compatible endpoint plus a Prometheus `/metrics` path.

5. Watch three numbers in production: running batch size, waiting queue length, and KV cache utilization. When cache utilization hits 100 percent the scheduler starts preempting sequences and latency becomes erratic.

■ 51.6.6 WORDS – remember these

GGUF — the one-file local model format — successor to GGML, memory-mappable, carries weights, tokenizer and metadata. Offload — putting model layers on the graphics chip — `-ngl` or `n_gpu_layers`; partial offload is the usual cause of slow local models. Ollama — the friendly local runner — a daemon plus registry over llama.cpp. vLLM — the standard GPU serving engine — PagedAttention, continuous batching, OpenAI-compatible server. MLX — Apple’s numerical framework — unified-memory array library for Apple silicon, released December 2023.

51.7 What hardware you actually need

■ 51.7.1 PLAIN – in simple words

1. Two numbers decide everything: how much memory you have, and how fast that memory is.
2. Memory decides whether the model runs at all. Bandwidth decides how fast it talks.
3. The memory rule from Chapter 47: parameters times bytes per parameter, plus a bit for the conversation and the software.
4. At 4 bits per parameter, a rough working rule is that the model needs about 0.6 GB per billion parameters, plus 2 to 3 GB of headroom.
5. So an 8-billion model at 4 bits wants about 7 GB free, and a 32-billion model wants about 22 GB free.
6. If it does not fit, it does not simply run slower. Part of it spills to the processor or to disk and the speed falls off a cliff.
7. Apple silicon is unusually good here, because the processor and graphics chip share one pool of memory. A laptop with 32 GB can load models that need a 3,000 dollar graphics card on a PC.
8. But Apple laptops have much narrower memory pipes than datacentre cards, so they load big models and then run them slowly.

■ 51.7.2 PLAIN – a picture in your head

1. Think of memory as the size of your desk and bandwidth as how fast you can turn pages.
2. A PC graphics card is a small desk with an extremely fast hand.
3. An Apple laptop is a large desk with a moderate hand.
4. A datacentre card is a large desk with an extraordinarily fast hand, in somebody else’s building, rented by the hour.
5. If the book does not fit on the desk, you keep fetching pages from the floor, and everything stops.

Where this comparison breaks: a person can skim. The model reads every page for every word. There is no skimming, so the “fast hand” is used at full stretch on every single token.

■ 51.7.3 PLAIN – a worked example

1. Here are real machines, with real figures from the manufacturers, and what each can hold.

Machine	Usable memory	Bandwidth
MacBook Air M1/M2, 8 GB	about 5 GB	about 100 GB/s
MacBook Air M5, 16 GB	about 11 GB	153 GB/s

Machine	Usable memory	Bandwidth
MacBook Air M5, 24 GB	about 18 GB	153 GB/s
MacBook Pro M5 Max, 128 GB	about 110 GB	614 GB/s
Desktop, RTX 4090	24 GB	1,008 GB/s
Desktop, RTX 5090	32 GB	1,792 GB/s
Server, H100 SXM	80 GB	3,350 GB/s

- Now the speeds. These are the bandwidth ceiling from section 51.3 with a realistic 70 percent efficiency applied, for 4-bit models.

Model at 4-bit	Air M5 16 GB	M5 Max	RTX 5090
4B, 2.5 GB	43 tok/s	170 tok/s	500 tok/s
8B, 4.7 GB	23 tok/s	91 tok/s	267 tok/s
14B, 8.5 GB	12 tok/s	51 tok/s	148 tok/s
32B, 19 GB	will not fit	23 tok/s	66 tok/s
70B, 40 GB	will not fit	11 tok/s	will not fit

- Being specific, as promised. On an 8 GB MacBook Air: models up to about 4 billion parameters at 4 bits run fine. An 8B at 4 bits technically loads and then swaps to disk, giving a few tokens per second and a hot machine. Anything larger will not run at all.
- On a 16 GB Air: 8B is comfortable, 14B works, 32B does not fit.
- On a 24 GB Air: 32B at 4 bits fits with a short context and delivers about 8 tokens per second, which is slower than reading speed and unpleasant.
- A useful threshold: below about 10 tokens per second, most people stop using a model interactively. Above 25 it feels fine for chat.

■ 51.7.4 PLAIN – what is really happening inside

- Why unified memory helps so much: on a normal PC, the graphics card has its own memory, and anything not in it must cross the PCI Express bus, which moves about 64 GB per second on a sixteen-lane fourth-generation link.
- That is twenty to fifty times slower than the card's own memory, so a model that half fits runs at roughly the speed of the slow path.
- On Apple silicon there is one pool. There is no crossing, so a 70-billion model at 4 bits genuinely runs on a laptop, which no 3,000 dollar consumer graphics card can do.
- Where Apple silicon is still limited, in two places.
- First, bandwidth. Even the fastest laptop chip at 614 GB per second is under a fifth of an H100. Big models load and then crawl.
- Second, prompt processing. Prefill is compute-bound, and Apple's graphics cores have far less matrix throughput than a datacentre card. Pasting in a long document can take many seconds before the first word appears, even though generation afterwards looks reasonable.
- This asymmetry surprises people constantly. The machine feels fine in chat and terrible the moment you paste a file into it.

■ 51.7.5 TECHNICAL – the engineer's version

- Sizing formula for a local deployment, in bytes:

```
total = params x bytes_per_param
      + kv_bytes_per_token x context_length x concurrency
```

- + activations (0.5 to 1 GiB)
- + runtime overhead (0.5 to 2 GiB)

2. Mixture-of-experts models decouple the two limits: capacity is set by total parameters, speed by active parameters. A 26-billion-total, 4-billion-active model needs about 16 GB at 4 bits but decodes like a 4B model.
3. Community measurements in 2026 report roughly 150 tokens per second for such a model on an RTX 4090 or 5090 and roughly 80 on an M5 Max.
4. Apple's published bandwidths, August 2026: M5 in the MacBook Air, 153 GB/s; M5 Pro up to 307 GB/s with up to 64 GB; M5 Max 460 GB/s in the 32-core configuration and 614 GB/s in the 40-core, up to 128 GB.
5. NVIDIA's published bandwidths: RTX 4090 1,008 GB/s over 24 GB GDDR6X; RTX 5090 1,792 GB/s over 32 GB GDDR7; H100 SXM 3,350 GB/s over 80 GB HBM3; H200 4,800 GB/s over 141 GB HBM3e; B200 about 8,000 GB/s.
6. Observe the reality rather than the ceiling with llama-bench, which prints prompt-processing tokens per second and generation tokens per second as two separate rows. They will differ by one or two orders of magnitude, exactly as section 51.3 predicts.

■ 51.7.6 WORDS – remember these

Unified memory — one pool shared by processor and graphics — Apple silicon's architecture; capacity advantage, bandwidth disadvantage. VRAM — the graphics card's own memory — dedicated GDDR or HBM, fast but small on consumer cards. Offload spill — part of the model living on the slow side — layers left on the CPU or paged to disk; the usual cause of a tenfold slowdown. Prompt processing speed — how fast it reads what you paste — prefill tokens per second, compute-bound, weakest on laptops. Active parameters — the part of a sparse model actually used — the figure that sets decode speed in a mixture-of-experts model.

51.8 Getting weights and reading a model card

■ 51.8.1 PLAIN – in simple words

1. Hugging Face is the place where models live. It is a website and a set of tools, and it works much like a code-hosting site.
2. Each model has a repository with an owner and a name, files inside it, and a page of documentation called a model card.
3. As of 2026 the site hosts more than two million public models. Most are variations, fine-tunes and re-uploads of a much smaller number of originals.
4. You download either the original weights, which are large files in a format for research frameworks, or a converted single-file version for local tools.
5. The model card is the part people skip and should not. A good one tells you what the model was built from, what it may legally be used for, and where it fails.
6. A bad one tells you only that the model is excellent.
7. Then you choose a quantization level, which is the trade from Chapter 47: fewer bits per number means less memory and more speed, and a little less accuracy.

■ 51.8.2 PLAIN – a picture in your head

1. Think of buying a second-hand car from an online listing.
2. The files are the car. The model card is the seller's description.
3. A good listing states the year, the mileage, the service history, what is worn, and what the car is not suitable for.
4. A bad listing says "runs great, must sell" and shows one photograph taken from a flattering angle.
5. The licence is the logbook. Without it you may not legally use the car for the purpose you had in mind, however well it runs.

Where this comparison breaks: a car's condition can be inspected by a mechanic in an hour. A model's real behaviour on your task can only be found by running your own evaluation on your own data, which is why Chapter 50's material on evaluation matters more than any card.

■ 51.8.3 PLAIN – a worked example

1. A typical repository contains these files. Knowing what each is stops a lot of confusion.

config.json	architecture: layers, heads, sizes
model-00001-of-00004.safetensors	weight shard 1 of 4
model.safetensors.index.json	which tensor is in which shard
tokenizer.json	the vocabulary and merge rules
tokenizer_config.json	special tokens, chat template
generation_config.json	default temperature, stop tokens
README.md	the model card
LICENSE	the terms you are agreeing to

2. To download, use the official command-line tool, which is hf in current versions and was named huggingface-cli before 2025:

```
hf download meta-llama/Llama-3.1-8B-Instruct \
  --local-dir ./llama-3.1-8b

# or fetch only one quantized file for local use
hf download bartowski/Meta-Llama-3.1-8B-Instruct-GGUF \
  Meta-Llama-3.1-8B-Instruct-Q4_K_M.gguf --local-dir .
```

3. Prefer files ending in .safetensors over .bin. The older .bin format is Python pickle, which can execute code when loaded. Safetensors, introduced in 2022, is a plain data format that cannot.
4. Now the quantization decision. These are real measured figures from llama.cpp's own tables for an 8-billion model, showing file size and the increase in perplexity, which is the confusion measure from Chapter 50. Lower is better.

Level	File size	Extra perplexity
F16	14.00 GB	baseline
Q8_0	7.96 GB	+0.0026
Q6_K	6.14 GB	+0.0217
Q5_K_M	5.33 GB	+0.0569
Q4_K_M	4.58 GB	+0.1754
Q3_K_M	3.74 GB	+0.6569
Q2_K	2.96 GB	+3.5199

5. Read the last row. Two-bit quantization on a small model does not degrade it slightly; it breaks it.
6. The decision, as a table:

Situation	Choose	Reason
It fits at 8-bit	Q8_0	effectively lossless
Normal case	Q4_K_M	the standard default
Just short of fitting	IQ4_XS	smaller, small loss
Far short	smaller model at Q4	better than Q2

■ 51.8.4 PLAIN – what is really happening inside

1. What a good model card contains, in the order you should read it.
2. The base model and how this one relates to it: is it an original pre-trained model, an instruction-tuned version, or somebody's fine-tune of a fine-tune.
3. A description of the training data. Not the data itself, usually, but its sources, size, languages and cut-off date.
4. The licence, stated plainly, including whether commercial use is allowed and whether outputs may be used to train other models.
5. Intended use and out-of-scope use. Real cards say what the model is not for.
6. Limitations and known biases, in specifics rather than boilerplate.
7. Evaluation results with the benchmark names, the exact settings, and ideally the harness used, so the numbers can be reproduced.
8. What a bad card omits, in order of how much it should worry you: the licence, the training data description, the evaluation settings, and any statement of weakness at all.
9. A card that reports only wins on benchmarks, with no method and no limitations section, is marketing. Treat the numbers as unverified.
10. The idea is not new or informal. Model cards were proposed in a 2019 paper by Margaret Mitchell and colleagues, and datasheets for datasets in a 2018 paper by Timnit Gebru and colleagues. Both are conventions, widely adopted and nowhere enforced.

■ 51.8.5 TECHNICAL – the engineer's version

1. Licences differ far more than people assume, and "open" is not one thing. Apache 2.0 and MIT are permissive. Llama's community licence adds an acceptable-use policy and a threshold on monthly active users. Some research-only licences forbid commercial use entirely.
2. "Open weights" means you can download the parameters. It does not mean open source: the training data and training code are usually not released. Say open-weights when that is what you mean.
3. Gated repositories require accepting terms with your account before the files resolve, so automated pipelines need a token with the acceptance already recorded.

■ 51.8.6 WORDS – remember these

Model card — the honest description page — a structured README covering data, licence, intended use, limitations and evaluations. Safetensors — a weight file that cannot run code — a simple tensor container format, preferred over pickle-based .bin. Open weights — you can download the numbers — distinct from open source, which would include data and training code. Perplexity — how confused the model is by real text — exponentiated average negative log-likelihood; used here to price quantization damage. Gated repository — you must accept terms first — access controlled by account agreement on the hub.

51.9 Building something small from scratch, honestly

■ 51.9.1 PLAIN – in simple words

1. You can train your own language model on a laptop. It is a genuinely good afternoon's work, and it will teach you more than ten articles.
2. Realistically, on a laptop, you are training something between one and fifty million parameters on a few tens of millions of characters of text.
3. That is between one thousandth and one ten-thousandth of the size of the models you use every day.
4. What it will do: produce text with the correct shape. Sentences that look like sentences. Correct punctuation. Local coherence for a line or two.
5. If you train it on Shakespeare, it produces convincing Shakespeare-shaped nonsense with character names and stage directions in the right places.
6. What it will not do: know any facts, follow an instruction, answer a question, hold a conversation, or reason.
7. Those abilities appear only with vastly more data and a separate instruction-tuning stage afterwards.
8. Do it exactly once, as an education. Then never ship it, because a downloadable open model is thousands of times better and free.

■ 51.9.2 PLAIN – a picture in your head

1. Think of a child copying the appearance of adult handwriting before they can spell.
2. The loops are right. The spacing is right. The line has the rhythm of writing. From across the room it looks like a letter.
3. Your tiny model is at exactly that stage, and getting there takes an hour.
4. Learning to spell is the next thousand hours, and learning to write something worth reading is the thousand after that.

Where this comparison breaks: the child is learning towards meaning the whole time. The model has no such trajectory. Scale does not turn imitation into understanding by itself; it turns imitation into much better imitation, which turns out to be enough for a surprising number of tasks, and this distinction is exactly where thoughtful people still disagree.

■ 51.9.3 PLAIN – a worked example

1. Concrete plan, with real numbers.
2. Data: the collected works of Shakespeare, about 1.1 million characters, which is a standard toy dataset.
3. Model: a transformer with 6 layers, 6 attention heads, 384 hidden dimensions, character-level vocabulary. That is roughly 10 million parameters.
4. Training: a few thousand steps. On an Apple silicon laptop this takes on the order of 10 to 30 minutes. On a rented graphics card, a couple of minutes.
5. Result: text like this in shape, though the words will be invented.

DUKE VINCENTIO:
Well, your wit is in the care of side and that.

Second Lord:
They would be ruled after this chamber, and
my fair nues begun out of the fact, to be conveyed,
Whose noble souls I'll have the heart of the wars.

6. Every convention is right. Speaker names, colons, line breaks, capitalized verse. No sentence means anything.
7. Now the honest scaling. To get factual knowledge you need billions of tokens, not one million characters.
8. The compute-optimal ratio from the 2022 Chinchilla paper is roughly 20 training tokens per parameter. A useful 1-billion-parameter model implies about 20 billion tokens, which is not a laptop job.

■ 51.9.4 PLAIN – what is really happening inside

1. The canonical implementations to read, by name, so you can find them.
2. minGPT, by Andrej Karpathy, 2020: a few hundred lines, written to be read rather than run fast.
3. nanoGPT, by the same author, January 2023: the practical version, which reproduces GPT-2 at 124 million parameters.
4. The video “Let’s build GPT: from scratch, in code, spelled out”, 2023, which builds the whole thing live in about two hours.
5. llm.c, 2024: the same training in plain C and CUDA, with no framework at all, useful for seeing where the time actually goes.
6. nanochat, October 2025: the full pipeline including tokenizer, pre-training, fine-tuning, evaluation and a chat interface, in one repository.
7. The nanochat numbers are the useful ones for calibration. Its own documentation reports training a model of GPT-2 capability for about 48 dollars, roughly two to four hours on a node of eight H100 cards, against the roughly 43,000 dollars that training GPT-2 cost in 2019.
8. That fall of nearly a thousand times in six years is one of the clearest single facts about this field, and it is about hardware, software and recipes together, not about any one breakthrough.

■ 51.9.5 TECHNICAL – the engineer’s version

1. What a laptop-scale run looks like against the real thing:

Property	Laptop toy	Small open model
Parameters	10 million	8 billion
Training tokens	1 million chars	15 trillion
Hardware	1 laptop chip	thousands of GPUs
Wall-clock	20 minutes	weeks
Can follow orders	no	yes

2. The alternative, and usually the right one: fine-tune an existing open model instead of training one.
3. Full fine-tuning of an 8B model needs the 165 GiB from section 51.1, so it is a multi-GPU job.
4. Parameter-efficient methods avoid that. LoRA, from a 2021 Microsoft paper, freezes the model and trains small low-rank matrices alongside it, typically 0.1 to 1 percent of the parameters.
5. QLoRA, 2023, adds 4-bit quantization of the frozen base, which brought fine-tuning a 7B model onto a single 24 GB card, and a 70B model onto a single 80 GB card.
6. When fine-tuning is the right answer: you need a fixed output format, a house style, a domain vocabulary, or you want to make a small cheap model imitate a large expensive one on one narrow task.
7. When it is the wrong answer: you want the model to know new facts. Facts change, fine-tuning bakes them in, and the model will still state the old ones confidently. Use retrieval, which section 51.11 covers.

8. The practical threshold: below roughly 1,000 good examples, prompt engineering and few-shot examples usually beat fine-tuning. Above roughly 10,000, fine-tuning usually wins.
9. Evaluate before and after on a held-out set you wrote yourself. Fine-tuning frequently improves the target task and quietly degrades everything else, a phenomenon called catastrophic forgetting.

■ 51.9.6 WORDS – remember these

Pre-training — the long expensive stage — next-token prediction over a very large corpus, producing a base model. Base model — a text continuer, not an assistant — the pre-trained model before instruction tuning. Chinchilla ratio — how much text per parameter — about 20 training tokens per parameter for compute-optimal training, from the 2022 paper. LoRA — training a small patch instead of the whole model — low-rank adapter matrices added to frozen weights. Catastrophic forgetting — getting better at one thing and worse at everything else — degradation of unrelated capabilities after narrow fine-tuning.

51.10 Prompting as an engineering practice, not a trick

■ 51.10.1 PLAIN – in simple words

1. A prompt is just the text you send. There is no magic word.
2. What works is the same thing that works when briefing a competent new colleague who cannot ask you questions.
3. Be specific about the task, the audience, the length and the format.
4. Show an example of what you want, because one example beats a paragraph of description.
5. Say what the output must look like, exactly, especially if a program will read it.
6. For multi-step problems, let the model work through the steps rather than demanding the answer immediately.
7. Break big tasks into several calls instead of one enormous one.
8. And now the honest part: the same request phrased two ways can give noticeably different quality. That is a real weakness of the technology, not a skill you lack.

■ 51.10.2 PLAIN – a picture in your head

1. Think of writing a work order for a contractor who will do exactly what the paper says and will never phone you back.
2. “Fix the bathroom” gets you something. Possibly not the thing you wanted.
3. “Replace the tap with this model, keep the existing pipework, finish by Friday, leave the old tap in the box” gets you the thing you wanted.
4. Adding a photograph of a finished job you liked works better still.
5. The contractor is skilled. The failure was in the brief.

Where this comparison breaks: a real contractor who received an ambiguous brief would either ask or use judgement informed by having seen your house. The model has no judgement about your situation and cannot ask, so it fills gaps with the statistically ordinary choice, which may be nothing like your case.

■ 51.10.3 PLAIN – a worked example

1. Five real improvements. In each pair, the second version is not longer for the sake of it; each addition removes one specific ambiguity.

1 BEFORE: Summarize this.

AFTER: Summarize the text below in 5 bullet points for a

non-technical manager. Each bullet under 20 words.
Do not mention anything not in the text.

2 BEFORE: Write a regex for emails.

AFTER: Write a Python regex matching the addresses in the list below and rejecting the ones after "BAD:". Return only the pattern, no explanation.

3 BEFORE: Is this contract clause risky?

AFTER: Read the clause. List each obligation it places on the buyer, then rate each Low/Medium/High risk with one reason. If the clause is ambiguous, say so.

4 BEFORE: Extract the data.

AFTER: Return JSON only, matching exactly this shape:
{"invoice_no": string, "total": number,
"currency": string, "date": "YYYY-MM-DD"}
Use null for any field not present in the text.

5 BEFORE: What is 17% of 4,382 plus the VAT?

AFTER: Work step by step. State each arithmetic step on its own line, then give the final number. Use the calculator tool for each multiplication.

2. Improvement 2 supplies examples of both classes, which is what few-shot prompting means.
3. Improvement 4 pins the exact schema, which is the difference between code that parses and code that crashes at 3 a.m.
4. Improvement 5 does two things: asks for steps rather than a single leap, and moves the arithmetic to a tool, for reasons section 51.15 explains.

■ 51.10.4 PLAIN - what is really happening inside

1. Why examples work: the model is completing a pattern. Two worked examples define the pattern far more sharply than a description of it.
2. Zero-shot means no examples, just an instruction. Few-shot means two to five worked examples in the prompt. Few-shot costs tokens on every call and is usually worth it for format compliance.
3. Why step-by-step working helps: each token the model writes becomes input for the next token. Written reasoning is literally extra computation, and it gives the model somewhere to put intermediate results, since it has no scratchpad of its own.
4. This was formalized as chain-of-thought prompting in 2022, and the effect is large on multi-step arithmetic and logic.
5. When it does not help: simple lookups, classification, and formatting tasks, where it adds cost and latency for nothing.
6. There is also a 2026 research finding worth knowing: more reasoning is not monotonically better. Accuracy against reasoning length often follows an inverted U, and past a point extra thinking flips correct answers to wrong ones. That result is active research, not settled.
7. Recent reasoning models do this internally and are trained for it, so instructing them to “think step by step” can be redundant or harmful. Read the provider’s guidance for the specific model.

■ 51.10.5 TECHNICAL – the engineer’s version

1. Treat prompts as versioned artifacts. They belong in the repository, with a test suite, not pasted into a dashboard.
2. Prompt sensitivity is measurable and is a genuine limitation. Reported effects in the literature include changes in accuracy from reordering few-shot examples, from formatting choices such as separators, and from the position of the question relative to a long document.
3. The position effect has a name: models attend most reliably to the beginning and end of a long context and least reliably to the middle, described as “lost in the middle” in a 2023 paper.
4. Put the question after the documents, and put the most important document last.
5. Techniques with reasonable evidence: few-shot examples, explicit output schemas, decomposition into separate calls, self-consistency by sampling several answers and taking the majority, and constrained decoding when the output must parse.
6. Techniques that are mostly folklore: politeness, offering tips, threatening, role-play preambles such as “you are a world-class expert”, and long lists of adjectives. Some show small effects in some studies and vanish in others.
7. The honest summary: prompt engineering is real but shallow. Its ceiling is low compared with fixing your retrieval, your data or your task decomposition.

■ 51.10.6 WORDS – remember these

Zero-shot — no examples given — instruction-only prompting. Few-shot — a handful of worked examples — in-context learning from demonstrations in the prompt. Chain of thought — asking it to show working — eliciting intermediate reasoning tokens before the answer. Self-consistency — ask several times and take the majority — sampling multiple reasoning paths and voting. Prompt sensitivity — small wording changes, different quality — measured variance in output quality under semantically equivalent rephrasing.

51.11 RAG: giving a model your documents

■ 51.11.1 PLAIN – in simple words

1. A model knows only what was in its training data, which stopped at some date, and which never included your company’s files.
2. You cannot fix that by asking nicely. The information is genuinely not inside the weights.
3. But you can put the relevant text into the question. The model reads its context, so text you paste in is text it can use.
4. Doing that automatically is called retrieval-augmented generation, or RAG.
5. The pipeline is: cut the documents into pieces, turn each piece into a vector of numbers, store them, turn the question into a vector too, find the closest pieces, paste them into the prompt, and generate.
6. The vector is the embedding from Chapter 47: a list of numbers where similar meanings sit close together.
7. Every part of that pipeline can fail, and when the answer is wrong it is usually retrieval that failed, not the model.

■ 51.11.2 PLAIN – a picture in your head

1. Think of an exam where the candidate may bring notes, but only one page.
2. Someone else chooses which page, from a filing cabinet, in one second, based on the question.
3. If they bring the right page, the candidate looks brilliant.

4. If they bring a page about the right topic but the wrong year, the candidate confidently gives last year's answer.
5. If they bring six pages of near-misses, the candidate gets distracted and the good page gets lost among them.
6. The candidate's ability is not what varies between these cases. The filing clerk's is.

Where this comparison breaks: a real candidate would say "these notes do not cover this question". A model usually will not. It will answer from the notes if it can, and from habit if it cannot, and both answers look equally confident.

■ 51.11.3 PLAIN – a worked example

1. The pipeline, drawn out:

2. Real sizes for a small system: 500 documents, average 8 pages each, cut into chunks of about 500 tokens with 50 tokens of overlap.
3. That gives roughly 30,000 chunks. Embedded at 1,536 dimensions in 4-byte floats, the vectors occupy $30,000 \times 1,536 \times 4$ bytes, which is 184 MB.
4. Embedding cost, at a published rate of about 0.02 dollars per million tokens for a small embedding model: 15 million tokens costs 30 cents. Embedding is cheap; that is not where the money goes.
5. At query time you embed one question, find the 5 nearest chunks, and paste about 2,500 tokens into the prompt.
6. That 2,500 tokens is charged on every single question, which is why section 51.5's cost table had retrieved context in it.

■ 51.11.4 PLAIN – what is really happening inside

1. Chunking first, because it decides more than any other choice.
2. Chunk too small and each piece loses the context that made it meaningful. A sentence saying "this does not apply in India" is useless alone.
3. Chunk too large and the embedding becomes an average of several topics, which is close to nothing in particular, so it matches nothing well.
4. Strategies, in increasing order of effort: fixed size with overlap; splitting on structure such as headings and paragraphs; splitting on semantic shifts; and adding a short summary of the parent document to every chunk so it carries its own context.
5. Overlap exists so that a fact sitting on a boundary appears whole in at least one chunk. Ten percent is a common default.
6. Then embedding. An embedding model is a separate, smaller model that maps text to a fixed-length vector. Both the documents and the query must use the same one, and changing it means re-embedding everything.

7. Then storage and search. With 30,000 chunks you could compare the query to every vector, which is exact and fast enough. With 30 million you cannot.
8. So vector databases use approximate nearest neighbour search, and the dominant method is called HNSW.
9. Here is HNSW in plain words. Build a graph where each vector is a point joined to a few of its neighbours. Then build a second, sparser graph above it containing a random subset, and a third above that, and so on.
10. To search, start at the top layer, walk greedily to the closest point you can reach, then drop a layer and repeat from there.
11. The top layers move you across the whole space in a few hops. The bottom layer does the fine work. It is an express train, then a local train, then walking.
12. It is approximate: it can miss the true nearest neighbour. You trade recall against speed with a parameter, usually called `ef_search`.

■ 51.11.5 TECHNICAL – the engineer’s version

1. RAG was named in a 2020 paper by Patrick Lewis and colleagues at Facebook AI Research. HNSW is from a 2016 paper by Yury Malkov and Dmitry Yashunin. FAISS, the library that made billion-scale search routine, came from Facebook AI Research in 2017.
2. Vector store choices in 2026, honestly ranked by how often they are the right answer: pgvector inside an existing Postgres for anything up to tens of millions of vectors; Qdrant, Milvus or Weaviate when you need dedicated scale or filtering; Pinecone when you want it fully managed; Chroma or FAISS for prototypes and local work.
3. Pure vector search fails on exact tokens: part numbers, error codes, proper nouns and negations. Keyword search fails on paraphrase. Hybrid search runs both and fuses the results.
4. The standard fusion method is reciprocal rank fusion, from a 2009 paper by Cormack, Clarke and Buettcher: score each document by the sum of one over (a constant plus its rank) in each list.
5. It needs no score calibration, which is why it is used.
6. Re-ranking is a second, more expensive model that scores query-document pairs jointly, called a cross-encoder. Retrieve 50 candidates cheaply, re-rank to the best 5, pass those on. This is usually the single highest return improvement in a RAG system.
7. Evaluate retrieval separately from generation, always. Retrieval metrics: recall at k, mean reciprocal rank, normalized discounted cumulative gain. Generation metrics: groundedness, meaning every claim is supported by a retrieved chunk, and answer relevance.
8. The three honest failure modes:

Failure	Symptom	Usual fix
Retrieval miss	confident wrong answer	hybrid search, chunking
Crowded context	vague, hedged answer	fewer chunks, re-rank
Ignored context	contradicts the source	cite-and-quote prompt

9. The third one deserves a note. Models do sometimes override retrieved text with training-time knowledge, especially when the retrieved text is surprising. Requiring the model to quote the supporting sentence before answering reduces it measurably and makes the failure visible when it happens.

■ 51.11.6 WORDS – remember these

RAG — fetch the right text and paste it in — retrieval-augmented generation, named in a 2020 paper. Chunk — one searchable piece of a document — a token-bounded span, usually with overlap, that is embedded as a unit. Embedding model — turns text into a vector of meaning — a bi-encoder producing a fixed-length dense representation. HNSW — express train, local train, then walking — hierarchical navigable small world graph for approximate nearest neighbour search. Hybrid search — keywords and meaning together — dense plus sparse retrieval fused, commonly by reciprocal rank fusion. Re-ranker — a second opinion on the shortlist — a cross-encoder scoring query and document jointly.

51.12 Tool use and function calling

■ 51.12.1 PLAIN – in simple words

1. A model produces text. Only text. It cannot press a button or call a web service.
2. It writes down a request, in a structured form you specified, saying which function it wants and with what arguments.
3. Your program reads that request, decides whether to run it, runs it, and puts the result back into the conversation as a new message.
4. The model then continues, now with the answer in front of it.
5. That is the whole mechanism. The model never executes anything. Your code does.
6. Which means every tool you offer is a door in your system that a piece of text can ask to open. That is a security boundary, and it must be treated like one.

■ 51.12.2 PLAIN – a picture in your head

1. Think of a consultant behind a glass wall with no phone and no keyboard.
2. They can write notes and slide them under the glass.
3. A note might say: look up order 4471 and tell me the status.
4. You read it, decide whether that is a reasonable thing to ask, look it up, and slide the answer back.
5. At no point did the consultant touch your systems. They asked. You acted.
6. If you slide back whatever any note asks for, without checking, the glass wall is decorative.

Where this comparison breaks: a human consultant has intentions of their own. A model has none, but it can be steered by any text that reaches its context, including text inside the very documents it is reading for you. So the note under the glass may have been dictated by a stranger.

■ 51.12.3 PLAIN – a worked example

1. A complete exchange, in four steps. First you declare the tool.

```
"tools": [{
  "type": "function",
  "function": {
    "name": "get_order_status",
    "description": "Look up the status of one order.",
    "parameters": {
      "type": "object",
      "properties": {
        "order_id": {"type": "string",
                      "description": "Order number"}
      }
    },
    "required": ["order_id"]
  }
}]
```

```

    }
  }
}

```

- Second, the user asks “where is order 4471”, and the model replies with a request rather than an answer:

```

"message": {
  "role": "assistant",
  "content": null,
  "tool_calls": [{
    "id": "call_a1",
    "type": "function",
    "function": {
      "name": "get_order_status",
      "arguments": "{\"order_id\": \"4471\"}"
    }
  ]
},
"finish_reason": "tool_calls"

```

- Third, your code validates the arguments, runs the real lookup, and sends the whole conversation back with one extra message:

```

{"role": "tool",
 "tool_call_id": "call_a1",
 "content": "{\"status\": \"shipped\",
            \"eta\": \"2026-08-15\"}"}

```

- Fourth, the model produces the final answer: “Order 4471 shipped and should arrive on 15 August 2026.”

■ 51.12.4 PLAIN – what is really happening inside

- The tool declarations are inserted into the model’s context as text, usually as a schema in the system section. They cost tokens on every call.
- The model was trained to emit a particular token pattern when it wants a tool. The serving layer detects that pattern and returns it as structured JSON instead of prose.
- Many providers use constrained decoding here, so the arguments are guaranteed to match the schema. Others do not, and you must handle malformed JSON.
- The model chooses the tool by matching your description text against the user’s request. So the description is a prompt, and vague descriptions cause wrong tool choices.
- Now the security part, stated plainly. The model decides which tool to call based on text in its context. Some of that text came from your user. Some may have come from a document, a web page, or an email.
- Therefore any text the model can read can attempt to trigger any tool the model can call. There is no separation between instructions and data.
- So: validate every argument in your own code as if it came from an anonymous internet user, because effectively it did. Enforce permissions on the caller, not on the model.
- Never pass model output into a shell, a SQL string or a file path without the same checks you would use on a web form.
- Prefer narrow tools over general ones. `get_order_status(order_id)` is safe to expose. `run_sql(query)` is not, however convenient it looks.

■ 51.12.5 TECHNICAL – the engineer’s version

1. History: OpenAI shipped function calling in June 2023. The research precursor was Toolformer, published in February 2023. Anthropic released the Model Context Protocol in November 2024 to standardize how tools are described and discovered; OpenAI adopted it in March 2025, and its specification is dated by release, with 2026-07-28 current in August 2026.
2. Cost note: every tool round trip re-sends the entire conversation. A five-tool-call task sends the context six times. This is the main reason agent workloads are expensive, and the main reason prompt caching matters.
3. Threat model, in the vocabulary that has settled: the dangerous combination is private data access, exposure to untrusted content, and an ability to communicate outward. Simon Willison named this the “lethal trifecta” in June 2025. Remove any one of the three and exfiltration becomes much harder.
4. Practical controls: allowlist tools per session, require human confirmation for writes, run tools with least privilege, log every call with arguments, and put outbound network egress behind a proxy you control.

■ 51.12.6 WORDS – remember these

Function calling — the model asks, you do it — structured tool-request output matching a declared JSON schema. Tool result — the answer handed back — a message with role “tool” carrying the execution output into the context. Constrained decoding — only valid output can be produced — logit masking against a grammar or schema. MCP — a common plug for tools — Model Context Protocol, from Anthropic, November 2024, adopted broadly in 2025 and 2026. Lethal trifecta — the dangerous combination — private data, untrusted content and outbound communication in one agent.

51.13 Agents: what the word actually means

■ 51.13.1 PLAIN – in simple words

1. An agent is a loop, not a product and not a personality.
2. The loop is: the model decides what to do next, calls a tool, sees the result, and decides again, until it says it is finished or you stop it.
3. A single API call is one question and one answer. An agent is many calls in a row, where the model chooses what the next call contains.
4. RAG is different again: retrieval happens once, before the model runs, and the model does not choose it.
5. So the ladder is: one call, then one call with tools, then a loop with tools, which is an agent.
6. The problem is arithmetic. Steps multiply. If each step is 95 percent reliable, twenty steps together are 36 percent reliable.
7. That is not a detail to be tuned away. It is the central engineering fact about agents.

■ 51.13.2 PLAIN – a picture in your head

1. Think of a relay race where each runner hands over a written message rather than a baton.
2. Each runner is fast and mostly accurate, but occasionally mishears a word.
3. Over forty, it arrives as something else entirely, and nobody along the way noticed anything wrong.
4. Now add this: every runner is completely confident that what they passed on was correct.
5. The fix is not faster runners. It is checkpoints where the written message is compared against the original.

Where this comparison breaks: a garbled message is obviously garbled at the end. An agent's wrong result usually looks exactly like a right one, because the same fluency that makes the output readable makes the error invisible.

■ 51.13.3 PLAIN – a worked example

1. The compounding arithmetic, spelled out. This is just multiplication.

Per-step success	10 steps	30 steps
90%	34.9%	4.2%
95%	59.9%	21.5%
99%	90.4%	74.0%
99.9%	99.0%	97.0%

2. Read the 95 percent row. A step that fails once in twenty sounds excellent and produces a task that fails four times in five at thirty steps.
3. Now read the 99.9 percent row. To run thirty steps reliably you need per-step reliability that no language model currently offers unaided.
4. So the practical designs all do the same thing: reduce the number of steps, or make each step verifiable so failures are caught rather than compounded.
5. A verifiable step is one where something other than the model can check the result. Code that compiles. Tests that pass. A schema that validates. A number that reconciles.
6. This is exactly why coding agents work better than most other kinds. The compiler and the test suite are an independent judge on every step.

■ 51.13.4 PLAIN – what is really happening inside

1. The common patterns, named, so you recognize them in documentation.
2. ReAct, from a 2022 paper, interleaves reasoning and acting: think, act, observe, repeat. It is the default shape of most agent frameworks.

```
Thought: I need the order status.
Action: get_order_status("4471")
Observation: {"status": "shipped", "eta": "2026-08-15"}
Thought: I now have what I need.
Answer: It shipped and arrives on 15 August.
```

3. Plan-and-execute makes a full plan first, then carries out the steps. It is cheaper and more predictable, and worse at recovering when reality differs from the plan.
4. Reflection adds a criticism step: the model reviews its own output against the goal and revises. It helps when there is an objective standard to check against, and mostly produces confident agreement when there is not.
5. Multi-agent designs give different roles to different model calls, such as a planner, a coder and a reviewer, with messages between them.
6. The honest position on multi-agent systems as of 2026: they demonstrate well, they are expensive, and independent evidence that they beat one well-prompted model with good tools on ordinary tasks is thin. Some published analyses argue that errors compound faster across agents, not slower.
7. What actually makes agents work in production, in order of importance: narrow scope, verifiable steps, a hard step limit, a budget limit, retries with different phrasing, and a human checkpoint before anything irreversible.

■ 51.13.5 TECHNICAL – the engineer’s version

1. Separate what is established from what is sold.
2. Established: tool-calling loops work well for bounded tasks with checkable outputs; coding assistants that run tests are genuinely useful; retrieval plus a small number of tool calls is a solid production pattern.
3. Active research: long-horizon planning, self-correction without an external verifier, reliable multi-agent coordination, and memory that survives across sessions in a useful way.
4. Marketing claim: that an agent can be given a business objective and left alone. No published evidence supports this for open-ended tasks, and the compounding arithmetic above argues against it directly.
5. Engineering controls that belong in any agent you deploy:

Control	What it prevents
Max steps and max tokens	runaway loops and bills
Tool allowlist per task	unexpected capability
Idempotency keys	duplicate side effects
Human approval on writes	irreversible mistakes
Full trace logging	undebuggable failures

■ 51.13.6 WORDS – remember these

Agent — a loop where the model chooses the next action — iterative plan-act-observe with tools and a stopping condition. ReAct — think, act, observe, repeat — the interleaved reasoning and acting pattern from a 2022 paper. Reflection — the model criticizing its own draft — a self-review step, useful mainly with an external standard to check against. Compounding error — small failures multiplying — end-to-end success equals per-step reliability raised to the number of steps. Human in the loop — a person approves the risky bit — a mandatory confirmation gate before irreversible actions.

51.14 Memory, and why a model with none appears to have some

■ 51.14.1 PLAIN – in simple words

1. A language model has no memory between calls. None at all.
2. The only state it has is the text currently in its context window.
3. When a chat application seems to remember yesterday, an ordinary database remembered it and pasted it back in.
4. Every turn of a conversation resends the whole conversation so far.
5. That has a cost consequence people miss: turn twenty is not the same price as turn one, because turn twenty carries nineteen turns of history.
6. Everything sold as “memory” is an application feature: store some text, retrieve the relevant bits later, put them in the prompt.
7. So memory is just retrieval, from section 51.11, pointed at your own past conversations instead of your documents.

■ 51.14.2 PLAIN – a picture in your head

1. Imagine a brilliant advisor with complete amnesia every night.
2. Each morning you hand them a folder containing everything relevant from before, and they work perfectly.

3. They are not remembering. You are.
4. If your folder is wrong, they are confidently wrong, and they have no way to notice, because the folder is their entire world.

Where this comparison breaks: the advisor would know they had amnesia. The model has no sense of a gap. Text it was never given simply does not exist for it, and it will fill the space with something plausible rather than reporting the absence.

■ 51.14.3 PLAIN – a worked example

1. A ten-turn conversation with 500 tokens per turn, no caching:

Turn	Input tokens	Cumulative input
1	500	500
5	2,500	7,500
10	5,000	27,500

2. Ten turns of 500 tokens each is 5,000 tokens of conversation, but you paid for 27,500 input tokens, which is five and a half times more.
3. The growth is quadratic in the number of turns. Doubling the turns quadruples the input bill.
4. Three fixes, all standard: cache the stable prefix, summarize old turns into a short note, or drop old turns entirely past a window.

■ 51.14.4 PLAIN – what is really happening inside

1. The common designs, and what each is really doing.
2. Full history: send everything. Simple, exact, and quadratic in cost. Fine for short sessions.
3. Sliding window: keep the last N turns. Cheap and predictable; loses anything older, silently.
4. Running summary: after every few turns, ask the model to compress the older part into a paragraph, and send the summary plus recent turns. Cheap, and lossy in ways you cannot predict.
5. Retrieved memory: store every turn in a vector database and retrieve the few most relevant to the current message. Scales, and inherits every failure mode from section 51.11.
6. Structured facts: extract specific fields, such as the user's name, preferences and account, into an ordinary database, and inject them as text. This is the most reliable and the least fashionable.
7. The limits are the same in every case: whatever is not retrieved does not exist, and nothing about this is the model remembering.

■ 51.14.5 TECHNICAL – the engineer's version

1. Context is a hard bound, not a soft one. Exceeding it produces an error or silent truncation, and truncation usually removes the oldest tokens, which is where your system prompt might be.
2. Put the system prompt where truncation cannot reach it, and validate token counts before sending, using the model's own tokenizer.
3. Structured extraction beats free-text memory for anything you will filter or act on. "The user's plan is enterprise" belongs in a column, not in prose inside a vector store.

■ 51.14.6 WORDS – remember these

Context window — everything the model can see right now — the maximum token sequence, its only state. Conversation history — the transcript resent every turn — the messages array, billed in full on each call. Summarization memory — squash the old part — periodic lossy compression of

earlier turns into a short note. Structured memory — facts in a proper database — extracted fields injected as text, the most reliable design.

51.15 The limits, stated plainly

■ 51.15.1 PLAIN – in simple words

1. Hallucination is when a model states something false with the same confidence it states something true.
2. It is not a bug that was left in. It follows from what the model is.
3. The model was trained to produce likely continuations of text. A confident, fluent, plausible answer is a likely continuation whether or not it is true.
4. There is also no internal flag for “I do not know”. The model always produces a next token, and the machinery for producing a true one and a false one is identical.
5. Asking it to be accurate does not help, because it is not choosing to be inaccurate.
6. What helps is putting truth in front of it, or letting a tool check.
7. And this is the important sentence: confident wrongness is the default failure mode. Errors do not arrive marked as errors.

■ 51.15.2 PLAIN – a picture in your head

1. Think of an extremely well-read person answering at a dinner party, at speed, who considers not answering to be a failure.
2. Ninety percent of the time they are right and it is delightful.
3. Ten percent of the time they produce the same tone, the same fluency, the same specific detail, and it is invented.
4. You cannot tell the two apart from the outside, and neither can they.
5. Now imagine the party is a legal filing, a medical note or a payment.

Where this comparison breaks: the dinner guest could stop and say “I am not sure”. The model can be trained to say that more often, and modern ones do, but it is still producing the phrase because such phrases followed such contexts in training, not because it inspected its own uncertainty and found it high.

■ 51.15.3 PLAIN – a worked example

1. What actually reduces hallucination, and what does not:

Intervention	Effect
Retrieval with quoted source	large reduction
Tool for the checkable part	removes that class
Constrained output schema	removes format errors
Second pass verification	moderate reduction
Saying “be accurate”	negligible
Saying “do not hallucinate”	negligible

2. A concrete pair. Ask for a citation for a claim and you may get a real- looking reference that does not exist, with plausible authors, journal and year.
3. Give the model five real abstracts and require it to quote from one, and the invented citation disappears, because the correct behaviour is now the easy continuation.

4. Now three things the model cannot know, whatever you do.
5. Anything after its training cut-off. It will still answer, using the world as it was.
6. Anything private: your files, your database, this morning's ticket. Unless you put it in the context, it is not there.
7. Its own weights and internals. A model's account of why it answered is a plausible story generated after the fact, not a readout. This is established: self-reported reasoning does not reliably match the computation.

■ 51.15.4 PLAIN - what is really happening inside

1. Why counting and arithmetic fail, connecting to Chapter 47.
2. The model never sees letters. It sees tokens, which are chunks of several characters, and the chunks were chosen by compression statistics.
3. So "strawberry" may arrive as two or three tokens, and the letter r is not individually visible in any of them. Counting them is like counting bricks in a photograph of a wall taken from a mile away.
4. Long arithmetic fails for a second, separate reason: the model does a fixed amount of computation per token and has no scratchpad.
5. Multiplying two six-digit numbers requires carrying intermediate results through many steps. With no working memory, the only place to put them is the output itself.
6. That is exactly why writing out the steps helps, and why handing the sum to a calculator tool helps far more.
7. Now prompt injection, which is the unsolved one. The model has a single channel. Instructions and data arrive as the same tokens.
8. So text inside a document, a web page, an email or a code comment can address the model directly, and the model has no reliable way to tell that this text was not from you.
9. The term was coined by Simon Willison in September 2022. As of August 2026 it remains unsolved in the general case, and security guidance from national agencies now assumes it rather than promising a fix.
10. Jailbreaking is a related but different thing: the user of a model trying to get past its own trained refusals. Injection is a third party attacking your application through content it processes.
11. Sycophancy is the tendency to agree with the user, to soften a correct answer under pushback, and to praise a bad idea. It comes from training on human preference, and humans prefer agreement.

■ 51.15.5 TECHNICAL - the engineer's version

1. Hallucination is best understood as a calibration problem. A well-calibrated model would assign confidence matching its accuracy and abstain below a threshold.
2. A 2025 paper from OpenAI, "Why Language Models Hallucinate", argues the incentive is structural: both pre-training objectives and benchmark scoring reward a guess over an admission of ignorance, exactly as a multiple-choice exam with no penalty for wrong answers does.
3. That implies the fix is partly in evaluation design: score abstention as better than a wrong answer, and models trained against that scoring abstain more. This is active work, not a solved problem.
4. Uncertainty signals you can actually use: token log-probabilities where the provider exposes them, agreement across several samples at nonzero temperature, and agreement between two different models. All are weak but better than nothing.
5. Prompt injection defenses that reduce risk without solving it: strict separation of trusted and untrusted content with explicit markers, least-privilege tools, breaking the lethal trifecta by removing outbound communication or private data access from the same agent, output filtering, and human confirmation on consequential actions.

6. Defenses that do not work: instructing the model to ignore instructions in documents, and detecting injections with another language model, which is itself injectable.
7. What all of this means if you are building:

Rule	Because
Never auto-execute output	injection is unsolved
Verify facts with a source	fluency is not accuracy
Design for wrong answers	they are unmarked
Log inputs and outputs	you will need the trace
Keep a human on writes	reversal is expensive

■ 51.15.6 WORDS - remember these

Hallucination — confident invention — generation of unsupported content, a calibration failure rather than a discrete bug. Calibration — confidence matching accuracy — the property a model would need to know when to abstain. Prompt injection — instructions smuggled in through data — an architectural consequence of one shared channel; unsolved as of August 2026. Jailbreak — getting past the model's own rules — user-side circumvention of trained refusals, distinct from injection. Sycophancy — agreeing because you pushed — preference-trained bias toward agreement and flattery. Knowledge cut-off — the date the world stopped for it — the end of the training data, after which nothing is known.

51.16 The gaps you did not ask about but need

■ 51.16.1 PLAIN - in simple words

1. Six things you will meet in week one that nobody puts in the introduction.
2. Multimodality: how a picture becomes something a text model can read.
3. Reasoning models: models trained to think at length before answering, and billed for the thinking.
4. Long context: how a model that started with 2,000 tokens now takes a million, and why that is less useful than it sounds.
5. Cards: a model card describes one model; a system card describes a whole deployed product including its safety testing.
6. The safety vocabulary: alignment, red-teaming, refusal, guardrails, evals.
7. Distillation: making a small model imitate a big one.

■ 51.16.2 PLAIN - a picture in your head

1. For images, think of a photograph cut into a grid of small squares.
2. Each square is described as a list of numbers, in the same kind of language the model already uses for words.
3. The squares are then laid in a row alongside the text tokens, and the model reads the whole row as one sequence.

Where this comparison breaks: the translation is learned, not defined, and it is lossy in ways nobody chose. Fine print, precise counts and exact spatial relations survive badly, which is why models misread charts and miscount objects far more often than their fluent descriptions suggest.

■ 51.16.3 PLAIN – a worked example

1. Rough token costs of non-text inputs, which is what you will be billed on:

Input	Becomes roughly
1024 x 1024 image	750 to 1,600 tokens
One page of a PDF	1,000 to 2,000 tokens
One minute of speech	150 words, plus overhead

2. So ten screenshots can cost more than a long document, and a reasoning model may bill 4,000 hidden thinking tokens behind a 200-token answer.

■ 51.16.4 PLAIN – what is really happening inside

1. Images: a vision encoder cuts the picture into patches, embeds each patch, and a small projection layer maps those embeddings into the same space as token embeddings. The transformer then treats them as ordinary positions.
2. Audio: either a spectrogram is patched the same way, or a separate codec turns sound into discrete tokens from a learned audio vocabulary.
3. Reasoning models: trained with reinforcement learning to produce long internal chains of thought before answering. Established fact: this raises accuracy substantially on mathematics, competitive programming and multi-step logic.
4. Active research: how far it generalizes, and the 2026 finding that past a point extra thinking reduces accuracy.
5. Long context is achieved by changing how positions are encoded, most commonly by scaling rotary position embeddings, plus attention variants that avoid materializing a full attention matrix.
6. The honest note: a large advertised context is a capacity, not a competence. Retrieval quality inside a long context degrades with distance from the ends, and simple needle-finding benchmarks overstate real performance on tasks needing several facts combined.
7. Distillation, from a 2015 paper by Hinton and colleagues: train a small student model on the outputs of a large teacher. Most small fast models available today were made this way.

■ 51.16.5 TECHNICAL – the engineer’s version

1. Alignment, defined concretely rather than as a slogan: the engineering work of making a model’s outputs conform to a written specification of intended behaviour, implemented through preference training and rule-based methods, and measured by evaluations. It is a practice with artifacts, not an aspiration.
2. Red-teaming: adversarial testing by humans or automated attackers, aimed at producing the failures the model is meant not to produce. Findings feed back into training and into guardrails.
3. Refusal: the trained behaviour of declining a request. Both over-refusal and under-refusal are measured, and the trade between them is a product decision, not a technical constant.
4. Guardrails: checks outside the model, on input and output, such as classifiers, regular expressions, schema validation and allowlists. They are the only part of the safety stack that is deterministic.
5. Evals: automated test suites over fixed inputs with scoring, covering both capability and safety. Chapter 50 covered how to build them; the essential discipline is that a private eval set you wrote beats any public leaderboard.

6. System card: a document about a deployed system rather than a bare model, covering intended use, safety evaluations, red-team results, known failure modes and mitigations. The convention was established by the GPT-4 system card in March 2023 and is now normal for frontier releases.
7. Where the field appears to be heading, explicitly labelled speculation and not fact: more inference-time compute rather than only larger models; sparse mixture-of-experts as the default architecture; agentic use as the main product surface; standardized tool protocols; and small models on devices for the majority of routine work.
8. Any of these could be wrong within a year, and this paragraph should be read with its date attached.

■ 51.16.6 WORDS – remember these

Multimodal — text plus images or audio — inputs encoded into the same embedding space and consumed as one sequence. Reasoning model — thinks before it answers — trained to emit long internal chains of thought, billed as output tokens. System card — the document about the product — deployment-level description of intended use, evaluations and mitigations. Alignment — making behaviour match the specification — preference training and rules, measured by evaluations. Guardrail — a check outside the model — deterministic filtering or validation on inputs and outputs. Distillation — a small model taught by a big one — student trained on teacher outputs, from a 2015 paper.

51.17 A practical decision guide

■ 51.17.1 PLAIN – in simple words

1. Most projects reach for the most complicated option first. Work the other way.
2. Ask whether the task needs a language model at all. Regular expressions, database queries and existing libraries are cheaper, faster and exact.
3. If it does, start with one API call and a good prompt.
4. Add retrieval when the answer depends on documents the model has not seen.
5. Add tools when the answer depends on live data or on an action.
6. Add a loop, making it an agent, only when the number of steps genuinely cannot be known in advance.
7. Fine-tune when the format or style must be fixed, or when you want a small model to do one narrow job cheaply.
8. Self-host when policy, volume or control demands it, not because it sounds cheaper.

■ 51.17.2 PLAIN – a picture in your head

1. Think of choosing transport for a journey.
2. A taxi is a hosted API: instant, no maintenance, pay per trip.
3. Bringing a map is retrieval.
4. Hiring a driver who chooses the route as they go is an agent.
5. Buying a fleet is self-hosting, and it only pays if you drive constantly.

Where this comparison breaks: transport choices are reversible in an afternoon. Architecture choices lock in data formats, evaluation sets and vendor contracts, so the cost of starting too complicated is higher than the comparison suggests.

■ 51.17.3 PLAIN – a worked example

```

Does it need judgement about language?
no -> write ordinary code. Stop.
yes -> Is the needed knowledge in the model already?
      yes -> one API call with a good prompt
      no -> Is it in documents you hold?
            yes -> RAG
            no -> Is it live or an action?
                  yes -> tools
                  no -> reconsider the task

Is the number of steps known in advance?
yes -> a fixed chain of calls
no -> an agent loop, with step and cost limits

Is the output format or style unstable?
yes and you have 1,000+ examples -> fine-tune
yes and you do not -> few-shot examples

Must data stay inside your network, or is volume
above roughly 3 billion output tokens a month?
yes -> self-host
no -> hosted API

```

■ 51.17.4 PLAIN – what is really happening inside

1. The same guidance as a table, with the cost and latency notes that decide arguments.

Task	Approach	Note
Classify text	small hosted model	cheap, fast, few-shot
Extract fields	model plus schema	constrained decoding
Answer from your docs	RAG	retrieval is the risk
Answer about live data	tools	validate arguments
Summarize a document	one call	watch input cost
Fixed house style	fine-tune	needs 1,000+ examples
Multi-step research	agent	cap steps and budget
Regulated private data	self-host	cost is not the reason
Bulk offline work	batch API	half price, slower

2. Latency notes worth having in mind. A short hosted call is roughly 0.5 to 3 seconds. Adding retrieval adds 50 to 300 milliseconds.
3. Each tool round trip adds a full model call. A reasoning model can take 10 to 60 seconds. An agent is measured in minutes.
4. Cost notes. A simple call is fractions of a cent. RAG multiplies input tokens. An agent multiplies whole calls. Reasoning multiplies output tokens. The multipliers stack.

■ 51.17.5 TECHNICAL – the engineer's version

1. Build the evaluation set before choosing an approach. Thirty to two hundred real examples with known good answers, held privately, decides every question in this section empirically rather than by argument.
2. Choose the cheapest model that passes your evaluation, then move up only if it fails. Most production traffic does not need a frontier model.
3. Design for model substitution from the first day: keep prompts in one place, keep an adapter layer, and re-run the evaluation set when you change models, because a provider changing an undated model name is a real event.

4. Route by difficulty. A small model handles the common case and escalates on low confidence or explicit triggers. This routinely cuts costs by an order of magnitude while leaving quality on hard cases intact.
5. Instrument tokens per request, cost per task, cache hit rate, p50 and p99 latency, and end-to-end task success. The last one is the only one your users experience.

■ 51.17.6 WORDS – remember these

Model routing — send easy work to the cheap model — confidence or rule-based dispatch across a tier of models, with escalation. Escalation — try harder when the cheap answer looks weak — a second call to a stronger model triggered by a confidence signal. Eval set — your own private exam for the system — a fixed collection of real inputs with expected outputs, versioned with the code. Golden path — the case you optimize for — the dominant traffic pattern that should decide model and architecture choice.

51.98 Common wrong ideas

1. Wrong: it looked that up when I asked. Right: unless a retrieval or search tool ran, nothing was looked up. The answer came from frozen weights.
2. Wrong: it remembers me. Right: it has no memory between calls. An application stored your text and pasted it back into the context.
3. Wrong: hallucination will be fixed in the next version. Right: it is a property of predicting likely text without verification. Versions reduce the rate; retrieval, tools and checking reduce it much more.
4. Wrong: the system prompt is secure and hidden. Right: it is ordinary tokens at the front of the context, obeyed by training habit, and it can be overridden or revealed by clever input.
5. Wrong: an agent can be trusted to finish the job. Right: per-step errors compound, so a 95 percent reliable step is 21 percent reliable over thirty steps. Cap steps, verify each one, keep a human on writes.
6. Wrong: self-hosting is cheaper. Right: you rent the machine whether you use it or not. Break-even against cheap hosted models is around billions of output tokens a month.
7. Wrong: a bigger context window means it uses all of it well. Right: capacity is not competence. Attention to the middle of a long context is measurably weaker than to the ends.
8. Wrong: more parameters always means faster answers if the hardware is good. Right: decode speed is memory bandwidth divided by model bytes. A bigger model is slower on the same machine, in direct proportion.
9. Wrong: prompt engineering is the main skill. Right: it is real but shallow. Retrieval quality, task decomposition, evaluation and tool design matter more.
10. Wrong: the model runs my code when it calls a function. Right: it emits a structured request; your program decides whether to run it. Every tool is a security boundary you own.

51.99 Chapter summary in 20 lines

1. Inference is the frozen model answering; training is what produced it, and it needs roughly ten times the memory.
2. An API call is ordinary HTTPS carrying a list of messages plus sampling settings, and the whole conversation is resent every time.
3. The system prompt is only leading tokens. Its authority is a training habit, not a protection.
4. Generation has two phases: prefill, which is parallel and compute-bound, and decode, which is sequential and bandwidth-bound.
5. Decode speed is approximately memory bandwidth divided by model bytes, which explains almost every speed question people ask.
6. Time to first token is network plus queue plus prefill; tokens per second afterwards is a different limit entirely.
7. The KV cache turns quadratic recomputation into linear work and costs 128 KiB per token for an 8B model at 16-bit.
8. Continuous batching, PagedAttention, speculative decoding, quantization, tensor parallelism and prefix caching are the serving toolkit.
9. The same model runs at different speeds at different providers because of hardware, quantization, batching policy, load and distance.
10. Output tokens cost five to six times input tokens because decode is sequential and prefill is parallel.
11. Self-hosting is rarely cheaper below very high sustained volume; the good reasons are privacy, control and stability.
12. llama.cpp is the engine, Ollama and LM Studio the friendly wrappers, vLLM and SGLang the serving engines, MLX the Apple silicon path.
13. Memory decides whether a model runs; bandwidth decides how fast. Apple's unified memory wins on capacity and loses on bandwidth and prefill.
14. Read the model card for base model, data, licence, limitations and evaluations, and default to Q4_K_M unless you have a reason.
15. Training a tiny model on a laptop teaches shape without knowledge; do it once as education, then fine-tune or use an open model instead.
16. RAG is chunk, embed, store, retrieve, inject, generate; chunking and retrieval quality dominate the outcome.
17. Tool calling means the model emits a request and your code executes it, so every tool is a security boundary.
18. An agent is a loop, and per-step errors compound multiplicatively, so narrow scope, verifiable steps and human checkpoints are what make it work.
19. Hallucination is intrinsic to predicting likely text without verification; retrieval, tools and constrained output reduce it, exhortation does not.
20. Prompt injection remains unsolved as of August 2026 because instructions and data share one channel, so build as though confident wrong output will happen, because it will.

PART I

The Reference Desk

The numbers, commands, decision trees, timeline and
glossary you will come back to.

The Engineer's Reference

52.0 How to use this chapter

1. Every other chapter in this book teaches. This one does not teach. It answers.
2. It is the chapter you open when you are already in the middle of something and you need one number, one flag, or one next step.
3. Nothing here is new. Every fact appeared earlier in the book, in context, with the explanation attached. Here it is stripped down to the lookup.
4. The chapter is arranged so you can find things without reading. The section numbers below are the map.
5. Sections 52.1 to 52.3 are numbers: latency, powers of two, units, bases, character codes. Use these when you are estimating.
6. Section 52.4 is the networking reference: layers, addresses, ports, status codes, record types, states. Use this when you are reading a capture or a log.
7. Section 52.5 is the networking command cheat sheet. Every command has two extra columns that most cheat sheets leave out: what a pass **proves**, and what a pass does **not** prove. That distinction is the whole diagnostic method of this book.
8. Section 52.6 is a decision tree for “I cannot reach a site”. It is written as a branching procedure. Follow the numbers.
9. Sections 52.7 and 52.8 are the same two things for git: a full command cheat sheet, then a decision tree for a failed git operation.
10. Sections 52.9 to 52.16 are the rest of the desk reference: shell, file magic numbers, complexity, cloud, security, AI, regular expressions, editors.
11. Section 52.17 is what to do when none of the above worked.
12. Two conventions run through the chapter. First, macOS syntax is given first, because that is what the reader of this book is using, with the Linux difference noted on the next line. Second, anything that is a convention rather than a standard is labelled as such.
13. Anything marked “approximate” is an order of magnitude, not a measurement. Order of magnitude is usually what you need. A number that is right to within a factor of two will stop you making the wrong decision.
14. One warning before you start. A reference table tells you what a thing is. It does not tell you whether the thing is your problem. Keep the habit of asking what an observation rules out, not just what it looks like.

52.1 Numbers every engineer should know

■ 52.1.1 Why this section exists

1. Most engineering decisions are decided by a factor of a thousand, not by a factor of two.
2. If you know that memory is roughly one hundred times slower than cache, and a network hop across the planet is roughly a million times slower than memory, you will make the right architectural call without measuring.
3. The list below descends from fastest to slowest. Learn the shape, not the digits.
4. The original list of this kind is credited to Jeff Dean of Google, who presented “Numbers Everyone Should Know” in a 2009 keynote. Peter Norvig published a similar table earlier, in his 2001 essay “Teach Yourself Programming in Ten Years”.
5. The figures below are updated for typical 2025 to 2026 hardware. They are approximate.

■ 52.1.2 The latency ladder, real figures

Operation	Typical time	Note
1 CPU cycle at 3 GHz	0.33 ns	one tick
L1 cache reference	1 ns	4 to 5 cycles
Branch mispredict	3 to 5 ns	pipeline refill
L2 cache reference	4 ns	about 14 cycles
L3 cache reference	15 to 40 ns	shared, slower
Mutex lock and unlock	17 ns	uncontended
Main memory reference	80 to 100 ns	DDR4 or DDR5
Read 1 MB from RAM	50 us	one core, 20 GB/s
NVMe SSD 4 KiB read	20 to 100 us	random
Read 1 MB from NVMe	150 to 300 us	sequential
Same-rack round trip	0.1 ms	switch to switch
Same-datacentre round trip	0.5 ms	500 us
HDD seek, 7200 rpm	8 ms	seek plus rotate
Read 1 MB from HDD	5 ms	sequential
Same-city round trip	5 to 10 ms	metro fibre
Same-continent round trip	20 to 50 ms	
Mumbai to Frankfurt	110 to 130 ms	approximate
Mumbai to Virginia	190 to 220 ms	approximate
Cross-continent worst case	250 to 300 ms	
Geostationary satellite	480 to 600 ms	35,786 km up
Low-earth-orbit satellite	25 to 60 ms	about 550 km up

1. The single most useful line in that table is the second-from-last group: light in glass fibre travels at about 200,000 kilometres per second, which is roughly two thirds of the speed of light in vacuum.
2. That gives a rule you can do in your head: about **1 millisecond of round trip per 100 kilometres of fibre**.
3. Check it. Mumbai to London is about 7,200 km in a straight line and about 10,000 km of real cable route. Ten thousand divided by one hundred is 100 milliseconds. Measured round trips on that path are 110 to 130 ms.
4. This rule is physics. No amount of money buys past it. It is why content delivery networks exist: you cannot make the light faster, so you move the copy closer.

■ 52.1.3 The latency ladder, scaled to human time

1. Multiply every figure by one billion. One nanosecond becomes one second.
2. Now the ladder becomes something a person can feel.

Operation	Real	Human scale
L1 cache reference	1 ns	1 second
L2 cache reference	4 ns	4 seconds
L3 cache reference	15 ns	15 seconds
Main memory reference	100 ns	1 minute 40 seconds
NVMe SSD read, fast	20 us	5.6 hours
NVMe SSD read, typical	100 us	1.2 days
Same-datacentre round trip	0.5 ms	5.8 days
Read 1 MB from HDD	5 ms	2 months
HDD seek	8 ms	3 months
Mumbai to Frankfurt	120 ms	3.8 years
Mumbai to Virginia	200 ms	6.3 years
Cross-continent worst case	300 ms	9.5 years
Machine reboot	30 s	950 years
The reader's curl timeout	15 s	475 years

3. Read the last two lines again. When the reader's curl waited fifteen seconds and gave up, the processor had, in its own sense of time, waited several human centuries for an answer that never came.
4. That is why a timeout is such strong evidence. Nothing on a working network takes that long. Silence for fifteen seconds is not slowness. It is absence.

■ 52.1.4 Powers of two, 2⁰ to 2⁶⁴

1. Every size in computing is a power of two or a multiple of one.
2. Learn 2¹⁰ = 1024, 2²⁰ = about one million, 2³⁰ = about one billion. The rest follows.

Power	Value	As a byte size
2 ⁰	1	-
2 ¹	2	-
2 ²	4	-
2 ³	8	one byte in bits
2 ⁴	16	one hex digit range
2 ⁵	32	-
2 ⁶	64	-
2 ⁷	128	ASCII range
2 ⁸	256	one byte of values
2 ⁹	512	classic disk sector
2 ¹⁰	1024	1 KiB
2 ¹¹	2048	2 KiB
2 ¹²	4096	4 KiB, one page
2 ¹³	8192	8 KiB
2 ¹⁴	16384	16 KiB
2 ¹⁵	32768	32 KiB, int16 max+1
2 ¹⁶	65536	64 KiB, port count

Power	Value	As a byte size
2 ¹⁷	131072	128 KiB
2 ¹⁸	262144	256 KiB
2 ¹⁹	524288	512 KiB
2 ²⁰	1048576	1 MiB
2 ²¹	2097152	2 MiB
2 ²²	4194304	4 MiB
2 ²³	8388608	8 MiB
2 ²⁴	16777216	16 MiB, colours
2 ²⁵	33554432	32 MiB
2 ²⁶	67108864	64 MiB
2 ²⁷	134217728	128 MiB
2 ²⁸	268435456	256 MiB
2 ²⁹	536870912	512 MiB
2 ³⁰	1073741824	1 GiB
2 ³¹	2147483648	2 GiB, int32 max+1
2 ³²	4294967296	4 GiB, IPv4 space
2 ³³	8589934592	8 GiB
2 ³⁴	17179869184	16 GiB
2 ³⁵	34359738368	32 GiB
2 ³⁶	68719476736	64 GiB
2 ³⁷	137438953472	128 GiB
2 ³⁸	274877906944	256 GiB
2 ³⁹	549755813888	512 GiB
2 ⁴⁰	1099511627776	1 TiB
2 ⁴¹	2199023255552	2 TiB
2 ⁴²	4398046511104	4 TiB
2 ⁴³	8796093022208	8 TiB
2 ⁴⁴	17592186044416	16 TiB
2 ⁴⁵	35184372088832	32 TiB
2 ⁴⁶	70368744177664	64 TiB
2 ⁴⁷	140737488355328	128 TiB, x86 user VA
2 ⁴⁸	281474976710656	256 TiB, MAC space
2 ⁴⁹	562949953421312	512 TiB
2 ⁵⁰	1125899906842624	1 PiB
2 ⁵¹	2251799813685248	2 PiB
2 ⁵²	4503599627370496	4 PiB, double mantissa
2 ⁵³	9007199254740992	8 PiB, exact int limit
2 ⁵⁴	18014398509481984	16 PiB
2 ⁵⁵	36028797018963968	32 PiB
2 ⁵⁶	72057594037927936	64 PiB
2 ⁵⁷	144115188075855872	128 PiB
2 ⁵⁸	288230376151711744	256 PiB
2 ⁵⁹	576460752303423488	512 PiB
2 ⁶⁰	1152921504606846976	1 EiB
2 ⁶¹	2305843009213693952	2 EiB
2 ⁶²	4611686018427387904	4 EiB
2 ⁶³	9223372036854775808	8 EiB, int64 max+1
2 ⁶⁴	18446744073709551616	16 EiB, address space

3. Three lines in that table cause more real bugs than the rest combined.
4. 2^{31} minus 1 is 2147483647, the largest signed 32-bit integer. This is the Year 2038 problem: a 32-bit Unix timestamp counting seconds from 1 January 1970 overflows at 03:14:07 UTC on 19 January 2038.
5. 2^{53} is 9007199254740992. A double-precision floating point number, the only number type JavaScript had until BigInt was standardized in ES2020, can represent every integer up to 2^{53} exactly and not one above it. Git commit hashes and large database IDs sent as JSON numbers are silently corrupted here.
6. 2^{32} is 4294967296, the total number of IPv4 addresses. That is fewer than the number of humans alive. This is why NAT exists.

■ 52.1.5 Decimal versus binary prefixes

1. There are two systems and they disagree by a growing amount.
2. Decimal prefixes are powers of a thousand. Binary prefixes are powers of 1024. The binary ones were standardized by the International Electrotechnical Commission in IEC 60027-2, amendment 2, in January 1999, and now live in ISO/IEC 80000-13:2008.

Decimal	Value	Binary	Gap
kB	10^3	KiB = 2^{10}	2.4%
MB	10^6	MiB = 2^{20}	4.9%
GB	10^9	GiB = 2^{30}	7.4%
TB	10^{12}	TiB = 2^{40}	10.0%
PB	10^{15}	PiB = 2^{50}	12.6%
EB	10^{18}	EiB = 2^{60}	15.3%
ZB	10^{21}	ZiB = 2^{70}	18.1%
YB	10^{24}	YiB = 2^{80}	20.9%

3. Who uses which, in practice, is a convention and not a standard.
4. Disk and SSD makers use decimal. A “1 TB” drive holds 10^{12} bytes.
5. Operating systems differ. Windows reports that same drive as 931 GB, because it divides by 2^{30} but writes the label “GB”. macOS since version 10.6, released in 2009, uses decimal, so it agrees with the box and says 1 TB. Linux tools vary; `df -h` uses 1024 by default, `df -H` uses 1000.
6. RAM is always binary. A “16 GB” memory module is 16 GiB, because memory is addressed by binary address lines and cannot be anything else.
7. Network speeds are always decimal, and always in bits. “1 Gbit/s” is 1,000,000,000 bits per second.
8. In November 2022 the 27th General Conference on Weights and Measures added four new SI prefixes: ronna for 10^{27} , quetta for 10^{30} , ronto for 10^{-27} and quecto for 10^{-30} . There are no matching binary prefixes.

■ 52.1.6 Common bandwidth figures

Link	Rate	Year introduced
10BASE-T Ethernet	10 Mbit/s	1990
100BASE-TX	100 Mbit/s	1995
1000BASE-T	1 Gbit/s	1999
10GBASE-T	10 Gbit/s	2006
400G Ethernet	400 Gbit/s	2017

Link	Rate	Year introduced
800G Ethernet	800 Gbit/s	2024
Wi-Fi 802.11b	11 Mbit/s	1999
Wi-Fi 802.11g	54 Mbit/s	2003
Wi-Fi 4, 802.11n	up to 600 Mbit/s	2009
Wi-Fi 5, 802.11ac	up to 6.9 Gbit/s	2013
Wi-Fi 6, 802.11ax	up to 9.6 Gbit/s	2021
Wi-Fi 7, 802.11be	up to 46 Gbit/s	2024
USB 2.0	480 Mbit/s	2000
USB 3.0	5 Gbit/s	2008
USB4	40 Gbit/s	2019
USB4 version 2	80 Gbit/s	2022
Thunderbolt 3 and 4	40 Gbit/s	2015, 2020
Thunderbolt 5	80 to 120 Gbit/s	2023
SATA III	6 Gbit/s	2009
PCIe 3.0 x16	15.75 GB/s	2010
PCIe 4.0 x16	31.5 GB/s	2017
PCIe 5.0 x16	63 GB/s	2019
DDR4-3200, one channel	25.6 GB/s	2014
DDR5-6400, one channel	51.2 GB/s	2020
HBM3 per stack	819 GB/s	2022
HBM3E per stack	about 1.2 TB/s	2024

1. Note the unit change halfway down. Network and bus speeds are quoted in bits per second. Memory and PCIe totals are usually quoted in bytes per second. Mixing them up gives you an eight-fold error.

■ 52.1.7 Typical throughput of real systems

1. These are order-of-magnitude figures for a single well-configured node in 2025 to 2026. Your numbers will differ. The shape will not.

System	Typical throughput	Note
Redis, single core	100k ops/s	simple GET and SET
Redis, pipelined	1M ops/s	batched requests
PostgreSQL, simple reads	10k to 50k queries/s	indexed, cached
nginx, static file	50k to 500k req/s	small files
Kafka, one broker	100 MB/s and up	sequential writes
HDD, 7200 rpm	100 to 200 IOPS	random 4 KiB
SATA SSD	up to 90k IOPS	random 4 KiB
NVMe SSD	up to 1M IOPS	random 4 KiB
gzip compress	30 to 100 MB/s	one core
zstd compress, level 3	300 to 500 MB/s	one core
SHA-256 with hardware	1 to 2 GB/s	one core
AES-256-GCM with AES-NI	2 to 10 GB/s	one core
JSON parse	100 to 500 MB/s	one core

2. One more figure that catches people out. A single TCP connection is limited by its window divided by the round-trip time. With a 64 KiB window and a 100 ms round trip, that is 64 KiB divided by 0.1 seconds, which is about 655 kB/s, which is about 5.2 Mbit/s.

3. That is the bandwidth-delay product limit. It is why a single download from a distant server can crawl on a gigabit line, and why parallel connections or a larger window fix it. Modern systems scale the window automatically, up to 1 GiB, using the window scale option of RFC 7323.

52.2 Units and conversions

■ 52.2.1 Bit and byte

1. A **bit** is one binary digit. It is either 0 or 1.
2. A **byte** is eight bits. This has been near-universal since the IBM System/360 in 1964. Older machines used 6, 7, 9 and 36-bit units.
3. The correct formal word for exactly eight bits is **octet**. Networking standards use it, because “byte” once meant other sizes. RFC documents say octet.
4. Lowercase b means bit. Uppercase B means byte. This is a convention, but a very strongly held one.
5. A **nibble** is four bits, which is exactly one hexadecimal digit.
6. A **word** has no fixed size. It means the natural unit of the processor: 16 bits on an 8086, 32 on an i386, 64 on modern x86-64 and ARM64.

■ 52.2.2 The full prefix table

Prefix	Symbol	Factor
quetta	Q	10^{30}
ronna	R	10^{27}
yotta	Y	10^{24}
zetta	Z	10^{21}
exa	E	10^{18}
peta	P	10^{15}
tera	T	10^{12}
giga	G	10^9
mega	M	10^6
kilo	k	10^3
milli	m	10^{-3}
micro	u	10^{-6}
nano	n	10^{-9}
pico	p	10^{-12}
femto	f	10^{-15}
atto	a	10^{-18}
zepto	z	10^{-21}
yocto	y	10^{-24}
ronto	r	10^{-27}
quecto	q	10^{-30}

1. Note that kilo is lowercase k in SI. Uppercase K is not an SI prefix; it is the symbol for kelvin. Everyone writes KB anyway. That is a convention that contradicts the standard.
2. The micro symbol is properly the Greek letter mu. In plain text everyone writes u. This book writes us for microseconds.

■ 52.2.3 MB/s versus Mb/s

1. To convert bits per second to bytes per second, divide by 8.
2. To convert bytes per second to bits per second, multiply by 8.
3. Some people add ten per cent for framing overhead when talking about Ethernet. That is a rough allowance, not a standard.

Line rate	Theoretical max	Realistic
10 Mbit/s	1.25 MB/s	1.1 MB/s
100 Mbit/s	12.5 MB/s	11 MB/s
1 Gbit/s	125 MB/s	110 to 118 MB/s
2.5 Gbit/s	312.5 MB/s	290 MB/s
10 Gbit/s	1.25 GB/s	1.15 GB/s
40 Gbit/s	5 GB/s	4.6 GB/s
100 Gbit/s	12.5 GB/s	11.5 GB/s

4. Worked example. Your broadband plan says 300 Mbit/s. Divide by 8 to get 37.5 MB/s. A 4 GB file, at best, takes 4000 divided by 37.5, which is about 107 seconds. If your download manager shows 5 MB/s, you are getting about 40 Mbit/s, which is roughly one seventh of the plan.

■ 52.2.4 Hertz to time period

1. Frequency and period are reciprocals. Period equals one divided by frequency.

Frequency	Period	Where you see it
1 Hz	1 s	a clock tick
50 Hz	20 ms	mains power, India
60 Hz	16.67 ms	mains power, USA
60 Hz refresh	16.67 ms	standard display
120 Hz refresh	8.33 ms	fast display
1 kHz	1 ms	audio low end
44.1 kHz	22.7 us	CD sample rate
1 MHz	1 us	early CPUs
1 GHz	1 ns	modern CPU order
3 GHz	0.333 ns	one CPU cycle
2.4 GHz	0.417 ns	Wi-Fi band centre
5 GHz	0.2 ns	Wi-Fi band centre

2. Wavelength equals the speed of light divided by frequency. At 2.4 GHz that is 300,000,000 divided by 2,400,000,000, which is 12.5 centimetres. That is why a 2.4 GHz antenna is a few centimetres long.

■ 52.2.5 dBm to milliwatts

1. dBm is power measured in decibels relative to one milliwatt. It is a logarithmic scale, so it turns multiplication into addition.
2. The formula is: power in dBm equals 10 times the base-10 logarithm of the power in milliwatts.
3. Two shortcuts do almost all the work. Adding 3 dB doubles the power. Adding 10 dB multiplies it by ten.

dBm	Power	Meaning for Wi-Fi
+30 dBm	1000 mW = 1 W	legal max in some bands
+20 dBm	100 mW	typical router transmit
0 dBm	1 mW	reference point
-30 dBm	0.001 mW	excellent signal
-50 dBm	very small	very good
-60 dBm	very small	good
-67 dBm	very small	minimum for video
-70 dBm	very small	usable, weak
-80 dBm	very small	unreliable
-90 dBm	very small	unusable, near noise

- Signal strength in Wi-Fi is always a negative dBm number, because received power is always far below one milliwatt. Closer to zero is stronger. Minus 50 is much better than minus 80.
- A drop of 3 dBm means you are receiving half the power. A drop of 10 dBm means one tenth.

■ 52.2.6 Temperature

- To convert Celsius to Fahrenheit: multiply by 9, divide by 5, add 32.
- To convert Fahrenheit to Celsius: subtract 32, multiply by 5, divide by 9.
- To convert Celsius to Kelvin: add 273.15.

Celsius	Fahrenheit	What it is
-273.15	-459.67	absolute zero
0	32	water freezes
20	68	comfortable room
27	80.6	warm room, India
35	95	hot ambient
40	104	idle CPU, normal
70	158	CPU under load
90	194	CPU throttling starts
100	212	water boils, CPU limit
105	221	typical shutdown point

- Silicon does not fail at 90 degrees Celsius. It slows itself down on purpose, which is called thermal throttling, to avoid getting hotter. A laptop that suddenly gets slow after ten minutes of heavy work is almost always throttling.

■ 52.2.7 Storage sizes and what fits

Size	What fits
1 byte	one ASCII character
100 bytes	a short sentence
1 KiB	half a page of text
10 KiB	a small web page's HTML
100 KiB	a compressed photo, low
1 MiB	a typical JPEG photo
5 MiB	a 4-minute MP3 at 160 kbit/s
50 MiB	a phone photo burst

Size	What fits
700 MiB	one CD-ROM
1 GiB	250 songs, or 1 hour SD video
4.7 GB	one single-layer DVD
8 GiB	a small language model, 4-bit
25 GB	one Blu-ray layer
50 GB	a large modern game
256 GB	a typical phone
1 TB	250,000 photos
4 TB	a big desktop drive
20 TB	one large hard disk, 2026
1 PB	a mid-size company's archive
1 EB	global scale, a few of these

- Two facts to keep the scale honest. The English Wikipedia text dump, without images and without history, is roughly 25 GB uncompressed and about 22 GB compressed as of 2025. The complete works of Shakespeare in plain text are about 5.5 MB.

52.3 Number bases and encoding

■ 52.3.1 Binary, decimal, hexadecimal and octal, 0 to 32

- Hexadecimal is base 16. It uses 0 to 9 then A to F.
- One hex digit is exactly four bits. Two hex digits are exactly one byte. That is the entire reason hex exists in computing.
- Octal is base 8, three bits per digit. It survives in Unix file permissions and in C escape sequences.

Dec	Binary	Hex	Octal
0	000000	00	0
1	000001	01	1
2	000010	02	2
3	000011	03	3
4	000100	04	4
5	000101	05	5
6	000110	06	6
7	000111	07	7
8	001000	08	10
9	001001	09	11
10	001010	0A	12
11	001011	0B	13
12	001100	0C	14
13	001101	0D	15
14	001110	0E	16
15	001111	0F	17
16	010000	10	20
17	010001	11	21
18	010010	12	22
19	010011	13	23
20	010100	14	24

Dec	Binary	Hex	Octal
21	010101	15	25
22	010110	16	26
23	010111	17	27
24	011000	18	30
25	011001	19	31
26	011010	1A	32
27	011011	1B	33
28	011100	1C	34
29	011101	1D	35
30	011110	1E	36
31	011111	1F	37
32	100000	20	40

■ 52.3.2 The powers of two in hexadecimal

1. In hex, every power of two is a 1, 2, 4 or 8 followed by zeros. This makes sizes instantly recognizable in a hex dump.

Power	Decimal	Hex
2 ⁸	256	0x100
2 ¹⁰	1024	0x400
2 ¹²	4096	0x1000
2 ¹⁶	65536	0x10000
2 ²⁰	1048576	0x100000
2 ²⁴	16777216	0x1000000
2 ³⁰	1073741824	0x40000000
2 ³¹	2147483648	0x80000000
2 ³²	4294967296	0x100000000
2 ⁴⁰	1 TiB	0x10000000000
2 ⁴⁸	256 TiB	0x1000000000000
2 ⁶⁴	16 EiB	0x10000000000000000

2. When you see 0xFFFFFFFF in a log, that is 4294967295, which is the largest unsigned 32-bit value, which usually means “all bits set” or “not found”.
3. When you see 0xDEADBEEF or 0xCAFEFABE, that is a human-chosen marker value, put there so it stands out in memory. 0xCAFEFABE is also the real first four bytes of a Java class file, chosen by James Gosling's team in 1991 for exactly that reason.

■ 52.3.3 The printable ASCII table

1. ASCII was standardized in 1963 by the American Standards Association and revised in 1967 and 1986. It defines 128 codes, 0 to 127.
2. Codes 0 to 31 and 127 are control codes. Codes 32 to 126 are printable.

Dec	Hx	Ch	Dec	Hx	Ch	Dec	Hx	Ch	Dec	Hx	Ch
32	20	SP	56	38	8	80	50	P	104	68	h
33	21	!	57	39	9	81	51	Q	105	69	i
34	22	"	58	3A	:	82	52	R	106	6A	j
35	23	#	59	3B	;	83	53	S	107	6B	k
36	24	\$	60	3C	<	84	54	T	108	6C	l

37	25	%	61	3D	=	85	55	U	109	6D	m
38	26	&	62	3E	>	86	56	V	110	6E	n
39	27	'	63	3F	?	87	57	W	111	6F	o
40	28	(	64	40	@	88	58	X	112	70	p
41	29	)	65	41	A	89	59	Y	113	71	q
42	2A	*	66	42	B	90	5A	Z	114	72	r
43	2B	+	67	43	C	91	5B	[	115	73	s
44	2C	,	68	44	D	92	5C	\	116	74	t
45	2D	-	69	45	E	93	5D	]	117	75	u
46	2E	.	70	46	F	94	5E	^	118	76	v
47	2F	/	71	47	G	95	5F	_	119	77	w
48	30	0	72	48	H	96	60	`	120	78	x
49	31	1	73	49	I	97	61	a	121	79	y
50	32	2	74	4A	J	98	62	b	122	7A	z
51	33	3	75	4B	K	99	63	c	123	7B	{
52	34	4	76	4C	L	100	64	d	124	7C	
53	35	5	77	4D	M	101	65	e	125	7D	}
54	36	6	78	4E	N	102	66	f	126	7E	~
55	37	7	79	4F	O	103	67	g			

3. Four relationships in that table are worth memorizing, because they let you do character arithmetic in your head.
4. The digit 0 is 48, which is hex 0x30. So the numeric value of a digit character is the character minus 48.
5. Uppercase A is 65, hex 0x41. Lowercase a is 97, hex 0x61.
6. The gap between an uppercase letter and its lowercase form is exactly 32, which is a single bit: bit 5, value 0x20. Flipping that one bit changes case. That is not an accident; the 1963 committee arranged it deliberately.
7. Space is 32, hex 0x20. Delete is 127, hex 0x7F.

■ 52.3.4 Control codes and escape sequences

Escape	Dec	Hex	Meaning
\0	0	00	null, string end in C
\a	7	07	bell, terminal beep
\b	8	08	backspace
\t	9	09	horizontal tab
\n	10	0A	line feed, newline
\v	11	0B	vertical tab
\f	12	0C	form feed, new page
\r	13	0D	carriage return
\e	27	1B	escape, starts ANSI
\\	92	5C	a literal backslash
\"	34	22	a literal double quote
\'	39	27	a literal single quote
\x41	65	41	hex escape, gives A
\101	65	41	octal escape, gives A
\u00E9	233	E9	Unicode escape, e-acute

1. The line ending difference is the single most common cause of a file looking corrupted when moved between systems.
2. Unix and macOS since version 10 end a line with LF alone, which is 0x0A.

3. Windows ends a line with CR then LF, which is 0x0D 0x0A.
4. Classic Mac OS, up to version 9 in 2001, used CR alone, 0x0D.
5. In a hex dump, 0D 0A at the end of each line means the file came from Windows. In git, the setting `core.autocrlf` controls whether git converts between the two.

■ 52.3.5 UTF-8 byte-length rules

1. UTF-8 was designed by Ken Thompson and Rob Pike in September 1992, famously sketched on a placemat in a diner in New Jersey. It is defined today by RFC 3629, from 2003.
2. It encodes every Unicode code point in one to four bytes, and it is backward compatible with ASCII: any ASCII file is already valid UTF-8.

Code point range	Bytes	First byte pattern
U+0000 to U+007F	1	0xxxxxxx
U+0080 to U+07FF	2	110xxxxx
U+0800 to U+FFFF	3	1110xxxx
U+10000 to U+10FFFF	4	11110xxx

3. Every byte after the first in a multi-byte sequence has the pattern 10xxxxxx. That is the self-synchronizing property: from any byte you can find the start of the character by scanning backwards past bytes beginning with 10.
4. A byte beginning with 0 is a lone ASCII character. A byte beginning with 11 starts a multi-byte character. A byte beginning with 10 is a continuation.
5. Practical consequences you will meet.
6. English text costs about 1 byte per character. Latin letters with accents, Greek, Cyrillic, Hebrew and Arabic cost 2. Devanagari, Chinese, Japanese and Korean cost 3. Emoji and rarer historic scripts cost 4.
7. So the same sentence stored in Hindi takes roughly three times the bytes of the English version, before you even count that Hindi may need more characters.
8. `len()` in Python 3 counts code points, not bytes. `strlen()` in C counts bytes. `.length` in JavaScript counts UTF-16 code units, so an emoji outside the basic plane counts as 2.
9. A byte order mark, U+FEFF, encoded as the bytes EF BB BF, sometimes appears at the start of a UTF-8 file written by Windows tools. It is legal but discouraged, and it breaks shell scripts, because the shell sees those three bytes before the `#!` line.

52.4 The networking reference

■ 52.4.1 OSI and TCP/IP side by side

1. The OSI model has seven layers. It was published as ISO/IEC 7498-1, with the first version in 1984.
2. The TCP/IP model has four layers. It was written down in RFC 1122 in October 1989, by which time the protocols had already been running for years.
3. OSI is the vocabulary everyone uses. TCP/IP is the thing that actually runs. Both statements are true at the same time.

OSI	Name	TCP/IP	Examples
7	Application	Application	HTTP, DNS, SSH
6	Presentation	Application	TLS, JPEG, UTF-8

OSI	Name	TCP/IP	Examples
5	Session	Application	RPC, TLS sessions
4	Transport	Transport	TCP, UDP, QUIC
3	Network	Internet	IP, ICMP, IPsec
2	Data link	Link	Ethernet, Wi-Fi, ARP
1	Physical	Link	copper, fibre, radio

4. Three honest notes about that table.
5. TLS does not fit cleanly. It sits above TCP and below HTTP, which is layer 6-ish, but it has its own handshake and session resumption, which is layer 5-ish. People argue about this. Nobody wins.
6. ARP is called layer 2 by most people and layer 2.5 by pedants, because it carries layer 3 addresses inside layer 2 frames.
7. QUIC, standardized in RFC 9000 in May 2021, runs on top of UDP but does transport work: streams, ordering, congestion control, encryption. In OSI terms it is layer 4 built on top of layer 4.
8. Where the reader's own failure sat: DNS worked, so layer 7 name lookup was fine. The TCP handshake never completed, so the failure was at layer 4 or below, on the path.

■ 52.4.2 The RFC 1918 private ranges

1. RFC 1918, published February 1996, reserves three blocks that anyone may use inside a private network and that no router on the public internet will forward.

Block	Range	Addresses
10.0.0.0/8	10.0.0.0 to 10.255.255.255	16,777,216
172.16.0.0/12	172.16.0.0 to 172.31.255.255	1,048,576
192.168.0.0/16	192.168.0.0 to 192.168.255.255	65,536

2. The middle block is the one people get wrong. 172.16.0.0/12 covers 172.16.x.x through 172.31.x.x, not 172.16 through 172.16.
3. That is exactly why the reader's traceroute looked odd. Hops showing 172.31.0.17, 172.26.22.235, 172.26.14.75 and 172.16.18.33 are all private addresses inside the same /12, used by the reader's ISP for its own core network.
4. Seeing private addresses in a traceroute is normal and proves nothing about a fault. It tells you the ISP numbers its own core privately, which is ordinary practice, especially with carrier-grade NAT.

■ 52.4.3 Reserved IPv4 ranges with their RFCs

Block	Purpose	RFC
0.0.0.0/8	"This network"	RFC 791
0.0.0.0/32	This host, this network	RFC 1122
10.0.0.0/8	Private use	RFC 1918
100.64.0.0/10	Shared, carrier NAT	RFC 6598
127.0.0.0/8	Loopback	RFC 1122
169.254.0.0/16	Link local, no DHCP	RFC 3927
172.16.0.0/12	Private use	RFC 1918
192.0.0.0/24	IETF assignments	RFC 6890
192.0.0.0/29	DS-Lite	RFC 6333

Block	Purpose	RFC
192.0.2.0/24	Docs, TEST-NET-1	RFC 5737
192.31.196.0/24	AS112 redirection	RFC 7535
192.52.193.0/24	AMT relay	RFC 7450
192.88.99.0/24	Old 6to4, deprecated	RFC 7526
192.168.0.0/16	Private use	RFC 1918
192.175.48.0/24	AS112 delegation	RFC 7534
198.18.0.0/15	Benchmarking only	RFC 2544
198.51.100.0/24	Docs, TEST-NET-2	RFC 5737
203.0.113.0/24	Docs, TEST-NET-3	RFC 5737
224.0.0.0/4	Multicast	RFC 5771
240.0.0.0/4	Reserved, future use	RFC 1112
255.255.255.255/32	Limited broadcast	RFC 919

1. The full list lives in the IANA IPv4 Special-Purpose Address Registry. The rows above are the ones you meet.
2. 169.254.x.x on your own machine means DHCP failed. The machine gave itself a link-local address because no server answered. If you see it, fix DHCP before you look at anything else.
3. 100.64.0.0/10 is the range your ISP uses when it puts many customers behind one public address. If your router's outside address is in this range, you are behind carrier-grade NAT and you cannot accept inbound connections.
4. Use 192.0.2.0/24, 198.51.100.0/24 and 203.0.113.0/24 in documentation and examples. They exist for that. Never invent an example address that belongs to somebody.

■ 52.4.4 CIDR from /8 to /32

1. The prefix length is how many leading bits are the network part. The rest is the host part.
2. Total addresses is 2 to the power of (32 minus the prefix). Usable hosts is that minus two, because the all-zeros address is the network itself and the all-ones address is the broadcast.

Prefix	Netmask	Total	Usable hosts
/8	255.0.0.0	16,777,216	16,777,214
/9	255.128.0.0	8,388,608	8,388,606
/10	255.192.0.0	4,194,304	4,194,302
/11	255.224.0.0	2,097,152	2,097,150
/12	255.240.0.0	1,048,576	1,048,574
/13	255.248.0.0	524,288	524,286
/14	255.252.0.0	262,144	262,142
/15	255.254.0.0	131,072	131,070
/16	255.255.0.0	65,536	65,534
/17	255.255.128.0	32,768	32,766
/18	255.255.192.0	16,384	16,382
/19	255.255.224.0	8,192	8,190
/20	255.255.240.0	4,096	4,094
/21	255.255.248.0	2,048	2,046
/22	255.255.252.0	1,024	1,022
/23	255.255.254.0	512	510
/24	255.255.255.0	256	254
/25	255.255.255.128	128	126

Prefix	Netmask	Total	Usable hosts
/26	255.255.255.192	64	62
/27	255.255.255.224	32	30
/28	255.255.255.240	16	14
/29	255.255.255.248	8	6
/30	255.255.255.252	4	2
/31	255.255.255.254	2	2
/32	255.255.255.255	1	1

- Two special cases. A /31 has no network or broadcast address; RFC 3021, from December 2000, allows both addresses to be hosts, which is how router-to-router links are numbered. A /32 is one single address, used for loopbacks and for host routes.
- Classless Inter-Domain Routing replaced the old class A, B and C scheme. It was defined in RFC 1518 and RFC 1519 in September 1993, and was a direct response to the routing table growing faster than router memory.

■ 52.4.5 The ports worth memorizing

- Port numbers are 16 bits, so 0 to 65535. RFC 6335 splits them into three ranges: 0 to 1023 system, 1024 to 49151 user or registered, and 49152 to 65535 dynamic or ephemeral.
- On Linux the outgoing ephemeral range is usually 32768 to 60999. On macOS it is 49152 to 65535. Both are settings, not standards.

Port	Service	Note
20, 21	FTP data, control	plaintext, obsolete
22	SSH, SFTP, scp	git over SSH
23	Telnet	plaintext, do not use
25	SMTP relay	often blocked at home
53	DNS	UDP and TCP
67, 68	DHCP server, client	UDP
69	TFTP	UDP, no auth
80	HTTP	plaintext
110	POP3	plaintext
123	NTP	UDP
143	IMAP	plaintext
161, 162	SNMP, SNMP trap	UDP
179	BGP	over TCP
389	LDAP	plaintext
443	HTTPS, and HTTP/3	TCP and UDP
445	SMB file sharing	never expose
465	SMTP over TLS	submission
514	syslog	UDP
587	SMTP submission	with STARTTLS
636	LDAPS	over TLS
993	IMAPS	over TLS
995	POP3S	over TLS
1080	SOCKS proxy	
1194	OpenVPN	UDP usually
1433	Microsoft SQL Server	

Port	Service	Note
1521	Oracle database	
3306	MySQL, MariaDB	
3389	RDP, remote desktop	never expose
5432	PostgreSQL	
5672	AMQP, RabbitMQ	
5900	VNC	
6379	Redis	no auth by default
6443	Kubernetes API server	
8080, 8000	HTTP alternate	dev convention
8443	HTTPS alternate	dev convention
9042	Cassandra	
9090	Prometheus	
9200	Elasticsearch	
11211	Memcached	
27017	MongoDB	
51820	WireGuard	UDP

- Note the two rows that mattered in the reader's session. Git over SSH uses port 22. Git over HTTPS uses port 443. In the reader's session one transport worked while the other did not, which is only possible because they are different ports to different endpoints.

■ 52.4.6 ICMP types worth knowing

Type	Name	When you see it
0	Echo Reply	a successful ping
3	Destination Unreachable	see the code below
5	Redirect	router says use another
8	Echo Request	the ping you sent
11	Time Exceeded	every traceroute hop
12	Parameter Problem	malformed header

- Type 3 carries a code that says exactly what was unreachable.

Code	Meaning
0	Network unreachable
1	Host unreachable
2	Protocol unreachable
3	Port unreachable
4	Fragmentation needed, DF set
13	Administratively prohibited

- Code 4 is the one that causes mysterious hangs. It is how path MTU discovery works. If a firewall blocks it, large packets vanish and small ones get through, and a page loads its HTML but never its images.
- Code 13 is a firewall openly telling you it refused. That is a polite refusal, and it is evidence. Silence is not.

- Traceroute works entirely on type 11 code 0. Each probe goes out with a time-to-live one higher than the last, and each router that decrements it to zero sends back type 11.
- Under IPv6, ICMPv6 is defined by RFC 4443 and the numbers change. Echo Request is 128, Echo Reply is 129, Packet Too Big is 2. ICMPv6 is not optional: blocking it breaks IPv6 entirely, because Neighbor Discovery rides on types 133 to 137.
- The reader's trace showed * * * from hop 13 to hop 20. That means no type 11 replies came back from those hops. It does not mean the packets died there. Many routers rate-limit or refuse to generate ICMP.

■ 52.4.7 HTTP methods

- Safe** means the method is not supposed to change anything on the server.
- Idempotent** means doing it twice has the same effect as doing it once.
- Both properties are promises made by the specification, currently RFC 9110, published June 2022. A server can break them. A well-behaved one does not.

Method	Safe	Idempotent	Usual use
GET	yes	yes	fetch a resource
HEAD	yes	yes	headers only
OPTIONS	yes	yes	what is allowed
TRACE	yes	yes	echo the request
PUT	no	yes	replace at this URL
DELETE	no	yes	remove
POST	no	no	create or act
PATCH	no	no	partial update
CONNECT	no	no	tunnel, used by proxies

- The practical consequence: a client may retry a GET, HEAD, PUT or DELETE automatically after a network failure. It must not retry a POST automatically, because it cannot know whether the first one landed.
- That is exactly the reasoning behind the git failure in section 52.8. A disconnect while reading the response tells you nothing about whether the write was applied.

■ 52.4.8 HTTP status codes

- The first digit gives the family. One hundred series is informational, two hundred success, three hundred redirection, four hundred client error, five hundred server error.
- Codes marked with a star are ones you should know without looking up.

Code	Name	Star
100	Continue	
101	Switching Protocols	star
102	Processing	
103	Early Hints	
200	OK	star
201	Created	star
202	Accepted	
203	Non-Authoritative Info	
204	No Content	star

Code	Name	Star
205	Reset Content	
206	Partial Content	star
207	Multi-Status	
208	Already Reported	
226	IM Used	
300	Multiple Choices	
301	Moved Permanently	star
302	Found	star
303	See Other	star
304	Not Modified	star
305	Use Proxy, deprecated	
307	Temporary Redirect	star
308	Permanent Redirect	star
400	Bad Request	star
401	Unauthorized	star
402	Payment Required	
403	Forbidden	star
404	Not Found	star
405	Method Not Allowed	star
406	Not Acceptable	
407	Proxy Auth Required	
408	Request Timeout	
409	Conflict	star
410	Gone	
411	Length Required	
412	Precondition Failed	star
413	Content Too Large	
414	URI Too Long	
415	Unsupported Media Type	
416	Range Not Satisfiable	
417	Expectation Failed	
418	I am a teapot	
421	Misdirected Request	
422	Unprocessable Content	star
423	Locked	
424	Failed Dependency	
425	Too Early	
426	Upgrade Required	
428	Precondition Required	
429	Too Many Requests	star
431	Headers Too Large	
451	Legal Reasons	star
500	Internal Server Error	star
501	Not Implemented	
502	Bad Gateway	star
503	Service Unavailable	star
504	Gateway Timeout	star
505	Version Not Supported	
506	Variant Also Negotiates	

Code	Name	Star
507	Insufficient Storage	
508	Loop Detected	
510	Not Extended	
511	Network Auth Required	star

- Four distinctions that people get wrong every day.
- 401 versus 403. A 401 means “I do not know who you are; send credentials”. A 403 means “I know who you are and you may not”. The reader’s missing workflow scope produced a 403-class refusal, not a 401.
- 502 versus 503 versus 504. A 502 means the gateway got a broken answer from the thing behind it. A 503 means the service is deliberately unavailable, often overloaded or in maintenance. A 504 means the thing behind it never answered in time.
- 301 versus 308, and 302 versus 307. The older pair, 301 and 302, historically allowed clients to change a POST into a GET when following. The newer pair, 307 and 308, forbid changing the method. Use 308 and 307 when you care.
- 418 is real and is a joke. It comes from RFC 2324, the Hyper Text Coffee Pot Control Protocol, published on 1 April 1998. RFC 7168 extended it to teapots in 2014. It is not part of HTTP.
- 451 is named for the novel Fahrenheit 451 and was standardized in RFC 7725 in February 2016. It means content is blocked for legal reasons.

■ 52.4.9 Common DNS record types

Type	Number	What it holds
A	1	one IPv4 address
AAAA	28	one IPv6 address
CNAME	5	an alias to another name
MX	15	mail server plus priority
NS	2	authoritative name server
PTR	12	name for an address
SOA	6	zone parameters
TXT	16	free text, SPF, DKIM
SRV	33	host, port, priority
CAA	257	who may issue certificates
DS	43	DNSSEC delegation signer
DNSKEY	48	DNSSEC public key
RRSIG	46	DNSSEC signature
NSEC3	50	DNSSEC proof of absence
SVCB	64	service binding
HTTPS	65	HTTPS service binding
TLSA	52	certificate pinning, DANE
SSHFP	44	SSH host key fingerprint

- A CNAME cannot exist at the zone apex, that is at `example.com` itself, because the apex must also hold SOA and NS records and a CNAME forbids any other record at the same name. Providers work around this with a non-standard record they call ALIAS or ANAME. That is a vendor convention, not a standard.

2. SVCB and HTTPS records were standardized in RFC 9460 in November 2023. The HTTPS record can tell a browser to use HTTP/3, and can carry the encrypted client hello parameters, before any connection is made.
3. TTL is a number of seconds attached to every record. It is a request, not a guarantee. Resolvers may cache longer or shorter.

■ 52.4.10 TCP flags and states

1. The TCP header has a flags field. The current specification is RFC 9293, from August 2022, which replaced RFC 793 from 1981.

Flag	Name	Meaning
SYN	Synchronize	start a connection
ACK	Acknowledge	I received up to here
FIN	Finish	I have no more to send
RST	Reset	tear down now, refused
PSH	Push	deliver to the app now
URG	Urgent	urgent pointer valid
ECE	ECN Echo	congestion signalled
CWR	Congestion Window Reduced	I slowed down

2. The three-way handshake is SYN, then SYN plus ACK, then ACK. The four-way close is FIN, ACK, FIN, ACK.
3. An RST in reply to a SYN means “nothing is listening on that port”. That is a refusal, and it is information. It arrives in milliseconds.
4. No reply at all to a SYN means the packet was dropped somewhere and nobody told you. That is what the reader saw. It costs the full timeout.

State	Meaning
CLOSED	no connection
LISTEN	waiting for a SYN
SYN_SENT	sent SYN, waiting
SYN_RECEIVED	got SYN, sent SYN-ACK
ESTABLISHED	data can flow
FIN_WAIT_1	we sent FIN
FIN_WAIT_2	our FIN was acked
CLOSE_WAIT	they sent FIN, we have not
CLOSING	both sent FIN together
LAST_ACK	we sent our FIN last
TIME_WAIT	waiting out stray packets

5. Two states are diagnostic on their own.
6. Many sockets stuck in CLOSE_WAIT means your own application is not calling close. That is an application bug, not a network problem.
7. Many sockets in TIME_WAIT is normal on a busy client. The specification says wait twice the maximum segment lifetime, which by the letter of the standard is four minutes. Linux uses a fixed sixty seconds and does not let you change it without recompiling.
8. A connection that sits in SYN_SENT and never leaves it is the exact signature of the reader's fault: the SYN went out, nothing came back.

52.5 Networking command cheat sheet

■ 52.5.1 How to read this section

1. Every entry below gives the macOS form first, because that is the machine in the running example, then the Linux difference on the next line.
2. Then two lines that most cheat sheets omit.
3. **Proves** is the set of things that must be true for the command to have succeeded. If it passed, all of these are true.
4. **Does not prove** is the trap. These are things people assume a pass means and that it does not mean.
5. Getting this second line right is the difference between diagnosing a problem and guessing at it.

■ 52.5.2 The commands at a glance

Command	Layer it tests	Needs network
ifconfig or ip addr	your own interface	no
arp -a	local link, layer 2	local only
netstat -rn or ip route	your routing table	no
ping	ICMP reachability	yes
traceroute	path, hop by hop	yes
mtr	path plus loss over time	yes
dig, host, nslookup	DNS resolution	yes
scutil --dns	which resolver macOS uses	no
nc -vz	one TCP port	yes
telnet	one TCP port, old	yes
nmap	many ports at once	yes
curl -v	full request, TLS, HTTP	yes
wget	file download	yes
openssl s_client	TLS handshake only	yes
tcpdump	actual packets on the wire	no
lsof -i	which process holds a port	no
ss or netstat -an	socket states	no
whois	who owns a name or address	yes
networksetup	macOS network settings	no

■ 52.5.3 ping

1. macOS: ping -c 5 github.com
2. Linux: same, plus -w 5 sets a total deadline in seconds.
3. Useful flags, macOS: -c count, -i interval, -s size, -t timeout in seconds for the whole run, -D set the do-not-fragment bit.
4. Careful: on Linux -t means time-to-live, not timeout. Same letter, different meaning. Linux uses -M do for do-not-fragment.
5. Proves: your interface is up, your route exists, the target address is reachable by ICMP, and something at that address answers ICMP.
6. Does not prove: that any TCP port is open, that the web server is running, that DNS is correct, or that the service you want works. Ping tests ICMP and only ICMP.
7. A failed ping proves even less. Very many hosts and networks drop ICMP on purpose. Cloudflare, AWS load balancers and corporate firewalls commonly do. A ping that fails while curl succeeds is completely normal.

8. Path MTU test, macOS: `ping -D -s 1472 github.com`. If 1472 fails and 1400 works, something on the path has a smaller MTU. Add 28 bytes of headers to get the real figure: 1472 plus 28 is 1500.

■ 52.5.4 traceroute

1. macOS: `traceroute -n github.com`
2. Linux: `traceroute -n github.com`, and `tracepath` is a simpler alternative that needs no privileges.
3. Useful flags: `-n` no reverse lookups so it runs fast, `-m 30` maximum hops, `-q 1` one probe per hop, `-w 2` wait two seconds, `-I` use ICMP probes instead of UDP.
4. macOS default probes are UDP to high port numbers. Linux default is the same. Windows `tracert` uses ICMP by default. This matters, because firewalls filter the three differently.
5. TCP mode is the most useful on a modern network. Linux: `traceroute -T -p 443 github.com`. macOS: `traceroute -P TCP -p 443 github.com`.
6. Proves: which routers along the path are willing to answer, in order, up to the last one that replied.
7. Does not prove: that the path is symmetric, that the reply came back the same way it went, that a hop with no reply is broken, or that the last replying hop is where the trouble is.
8. The reader's trace stopped replying after hop 12, `ae106-0.rwa04.pnq20.ntwk.msn.net (104.44.20.42)`. That does not mean hop 12 dropped the traffic. It means hops beyond it did not send back ICMP time-exceeded messages, which is extremely common.
9. Hops showing more than one address, as hops 5, 6, 8, 9 and 11 did in the reader's trace, mean the traffic is being spread over parallel links. That is load balancing working correctly, not a fault.

■ 52.5.5 mtr

1. `mtr` combines `ping` and `traceroute` and keeps running, so it shows loss per hop over time.
2. macOS: not installed by default. Install with `brew install mtr`, then run with `sudo mtr github.com` because it needs raw sockets.
3. Linux: `mtr github.com`, often already installed.
4. Report mode, for pasting into a ticket: `mtr -rcw 100 github.com`. That means report, wide output, one hundred cycles.
5. TCP mode: `mtr -T -P 443 github.com`.
6. Proves: sustained loss or latency at and beyond a specific hop.
7. Does not prove: that loss shown at a middle hop is real. Routers deliberately rate-limit the ICMP replies they generate for themselves while forwarding everything else perfectly. Only loss that continues to the final hop and stays there is real loss.
8. That single rule saves more wasted hours than any other line in this chapter. Read the last row, not the middle rows.

■ 52.5.6 dig, host and nslookup

1. `dig` is the precise one. Use it.
2. macOS: `dig github.com`. On recent macOS versions Apple has removed the BIND lookup tools from the base install. If `dig` is missing, get it with `brew install bind`.
3. Linux: `dig github.com`, from the `dnsutils` or `bind-utils` package.

```
dig +short github.com           # just the answer
dig +short A github.com         # only IPv4
dig +short AAAA github.com      # only IPv6
dig @1.1.1.1 github.com         # ask a specific resolver
dig @8.8.8.8 github.com         # ask a different one
dig +trace github.com           # walk from the root down
dig -x 20.207.73.82            # reverse lookup
```

```
dig +noall +answer github.com      # answer section only
dig NS github.com                  # nameservers
dig MX github.com                  # mail servers
dig TXT github.com                 # text records
dig +tcp github.com                # force TCP not UDP
dig +dnssec github.com             # ask for signatures
```

4. Proves: that a resolver answered, what it answered, and how long the answer may be cached.
5. Does not prove: that the address is reachable, that it is the right address for you, or that your operating system will use it. `dig` talks to the resolver directly and bypasses the system cache.
6. That last point matters on macOS, which has its own resolver daemon. To see what the system will actually do, use `dscacheutil -q host -a name github.com`, and to see which resolvers are configured use `scutil --dns`.
7. `host github.com` gives a one-line answer. `nslookup github.com 1.1.1.1` works everywhere including Windows. Both are fine for a quick check and worse than `dig` for anything else.
8. In the reader's session, name resolution worked: `github.com` resolved to `20.207.73.82` through the Cloudflare resolver at `1.1.1.1`. That single fact eliminated DNS as the cause.

■ 52.5.7 curl

1. The single most useful network command on any machine.
2. macOS and Linux syntax are the same. macOS has shipped `curl` since 10.4.

```
curl -v https://github.com          # show the whole conversation
curl -I https://github.com          # headers only, HEAD request
curl -sS -o /dev/null -w '%{http_code}\n' https://github.com
curl -L https://example.com         # follow redirects
curl --max-time 10 https://github.com # give up after 10 seconds
curl --connect-timeout 3 https://x.io # give up connecting after 3
curl -4 https://github.com          # force IPv4
curl -6 https://github.com          # force IPv6
curl --resolve github.com:443:20.207.73.82 https://github.com
curl -H 'Accept: application/json' https://api.github.com
curl -X POST -d 'a=1' https://example.com/f
curl -k https://self-signed.example # skip cert check
curl --http1.1 https://github.com   # force HTTP/1.1
curl -x http://proxy:3128 https://x.io # go via a proxy
```

3. The timing breakdown is the hidden gem. It tells you which stage was slow.

```
curl -sS -o /dev/null -w \
'dns %{time_namelookup} conn %{time_connect} tls
%{time_appconnect} first %{time_starttransfer} total
%{time_total}\n' https://github.com
```

4. Proves, when it returns a status code: DNS resolved, TCP connected, TLS completed if the URL was HTTPS, the request was sent, and a server answered.
5. Does not prove: that the answer is correct, that the site works in a browser, or that the certificate is trusted if you passed `-k`.
6. A hang with no output after Trying `<address>:443...` proves the TCP handshake never completed. That is a layer 4 or below problem and nothing above it can be at fault yet.
7. That is exactly what the reader saw. `curl -v https://github.com` printed Trying `20.207.73.82:443...` and then produced nothing for fifteen seconds. No RST, no ICMP unreachable, no TLS error. Silence.

8. Silence is a specific finding. A server that is down sends RST. A firewall that refuses politely sends ICMP type 3 code 13. Nothing at all means a silent drop somewhere on the path.

■ 52.5.8 wget

1. macOS: not installed by default. `brew install wget`.
2. Linux: usually present.

```
wget https://example.com/file.tar.gz # save with its own name
wget -O out.bin https://example.com/f # save under a chosen name
wget -O - https://example.com        # print to standard output
wget --spider https://example.com    # exists? do not save
wget -c https://example.com/big.iso  # continue a partial download
wget -T 10 -t 3 https://example.com  # 10s timeout, 3 tries
```

3. Proves and does not prove: the same as curl.
4. Use wget for downloading files and mirroring. Use curl for inspecting a request. That split is a convention, not a rule.

■ 52.5.9 nc, the netcat tool

1. The cleanest way to test one TCP port and nothing else.
2. macOS: `nc -vz github.com 443`. Apple ships its own build of the OpenBSD version.
3. Linux: `nc -vz -w 3 github.com 443` with the OpenBSD build.

```
nc -vz github.com 443          # is port 443 open
nc -vz -w 3 github.com 22      # with a 3 second timeout
nc -vzu 1.1.1.1 53             # UDP, far less reliable
nc -l 8080                     # listen on 8080, a fake server
nc -vz github.com 20-25        # a small range
```

4. Proves, on success: the full TCP three-way handshake completed to that address on that port.
5. Does not prove: that the service behind the port speaks the protocol you expect, that TLS will succeed, or that your credentials are valid.
6. This is the correct tool for separating “the network is blocked” from “the application is refusing me”. If `nc -vz` succeeds and `curl` fails, the problem is above layer 4.
7. UDP testing with `-u` is close to useless on its own, because a silent UDP port and an open UDP port look identical. Only the application reply proves anything.

■ 52.5.10 telnet

1. Removed from macOS since High Sierra, version 10.13, in 2017. Install with `brew install telnet` or, better, use `nc` instead.
2. `telnet github.com 443` then type text. Historically used to speak HTTP by hand.
3. Proves: a TCP connection opened, and you can type raw bytes into it.
4. Does not prove: anything about encryption. Telnet is plaintext. Never use the telnet protocol itself, on port 23, for real work. It sends passwords in the clear. SSH replaced it in 1995.

■ 52.5.11 nmap

1. Not installed by default anywhere. `brew install nmap` on macOS, `apt install nmap` on Debian and Ubuntu.

```
nmap -Pn -p 443 github.com      # one port, skip host discovery
nmap -p 22,80,443 192.168.0.1   # a few ports
nmap -p- 192.168.0.1           # all 65535 ports, slow
nmap -sV -p 443 example.com     # try to identify the service
```

```
nmap -sn 192.168.0.0/24      # who is on my network
nmap --top-ports 100 192.168.0.1 # the common ones only
sudo nmap -sS -p 443 example.com # half-open scan, needs root
```

2. Proves: which of the scanned ports answered, and how.
3. Does not prove: that a filtered result means blocked by the target. It may be blocked anywhere along the path, including by your own network.
4. One legal and social rule, and it is not optional. Scan only machines you own or have written permission to scan. Port scanning other people's networks is, in many countries including India under the Information Technology Act 2000, potentially an offence, and at minimum it will get your connection blocked.

■ 52.5.12 netstat, ss and lsof

1. These look at your own machine, not the network. None of them need connectivity.
2. macOS: netstat -an -p tcp shows all TCP sockets. netstat -rn shows the routing table. netstat -i shows interface counters. netstat -s shows protocol statistics.
3. Linux: netstat is deprecated in favour of ss, from the iproute2 package.

```
ss -tulpn      # Linux: listening TCP+UDP, pids
ss -tn state established # Linux: established TCP only
ss -s          # Linux: summary counts
netstat -an -p tcp # macOS: all TCP sockets
netstat -rn     # both: routing table
lsof -i -P -n   # both: sockets with process names
lsof -nP -iTCP:443 # both: who is using port 443
lsof -nP -iTCP -sTCP:LISTEN # both: what is listening
```

4. Proves: exactly which local process holds which port, and what state each connection is in.
5. Does not prove: anything about the remote end. A socket shown as ESTABLISHED locally can be dead, if the peer vanished without sending FIN or RST. Only traffic proves liveness.
6. On macOS, lsof needs sudo to see other users' processes.

■ 52.5.13 arp

1. macOS and Linux: arp -a lists the address resolution cache, which maps IPv4 addresses to hardware addresses on your local network segment.
2. Linux modern form: ip neigh show.
3. sudo arp -d 192.168.0.1 deletes one entry, which forces a fresh lookup.
4. Proves: which machines your computer has recently talked to on the same local segment, and their MAC addresses.
5. Does not prove: anything beyond your own network. ARP does not cross a router. If the gateway is in the table with a MAC address, your link to the router is working.
6. arp -a showing 192.168.0.1 with a valid MAC address would have been the first thing to check in the reader's case, and it would have passed. The local network was fine.

■ 52.5.14 ifconfig, ip and route

1. macOS: ifconfig and ifconfig en0. Apple has not adopted the ip command.
2. Linux: ip addr show, or the short form ip -br a.

```
ifconfig -a      # macOS: every interface
ifconfig en0     # macOS: just Wi-Fi
ipconfig getifaddr en0 # macOS: just the IPv4 address
ipconfig getpacket en0 # macOS: the whole DHCP lease
```

```
netstat -rn                # macOS: routing table
route -n get default       # macOS: which route wins
ip -br a                  # Linux: brief addresses
ip link show               # Linux: layer 2 state
ip route show              # Linux: routing table
ip route get 20.207.73.82  # Linux: which route wins
```

3. On macOS, en0 is usually Wi-Fi on a laptop and Ethernet on a desktop. lo0 is loopback. utun0 and upwards are tunnel interfaces, created by VPNs, by iCloud Private Relay, and by some corporate agents.
4. The reader's machine showed several utun interfaces. That is worth noticing but does not prove a VPN was routing the traffic. Check with `route -n get default` and see which interface the default route uses.
5. Proves: your own addresses, your own routes, your own link state.
6. Does not prove: that the route leads anywhere.

■ 52.5.15 tcpdump

1. The ground truth. Everything else is an interpretation; this is the packets.
2. macOS: `sudo tcpdump -i en0 -n host 20.207.73.82`
3. Linux: same, with the interface usually named eth0, ens3 or wlan0.

```
sudo tcpdump -i en0 -n host 20.207.73.82
sudo tcpdump -i en0 -nn port 443
sudo tcpdump -i any -n icmp
sudo tcpdump -i en0 -n -c 20 tcp port 443
sudo tcpdump -i en0 -w capture.pcap          # save for Wireshark
sudo tcpdump -i en0 -n 'tcp[tcpflags] & tcp-syn != 0'
sudo tcpdump -i en0 -n -A port 80            # show payload as text
```

4. Flags that matter: -n no name lookups, -nn also no port names, -i any all interfaces on Linux, -c N stop after N packets, -s 0 full packet, -w file write a capture file, -A print payload as ASCII, -X print hex and ASCII.
5. Proves: exactly what left your machine and exactly what came back.
6. Does not prove: what happened in the middle. You see your end of the wire and nothing else.
7. In the reader's case, tcpdump would have shown repeated SYN packets going out to 20.207.73.82 on port 443, with retransmissions at roughly one, three and seven seconds, and nothing at all coming back. That is the signature of a silent drop, and it is different from every other failure.

■ 52.5.16 openssl s_client

1. Tests the TLS handshake by itself, with nothing above it.

```
openssl s_client -connect github.com:443 -servername github.com
openssl s_client -connect github.com:443 -showcerts
openssl s_client -connect github.com:443 -tls1_2
openssl s_client -connect github.com:443 -tls1_3
echo | openssl s_client -connect github.com:443 2>/dev/null \
| openssl x509 -noout -subject -issuer -dates
```

2. -servername sets Server Name Indication, which almost every modern host requires. Without it you may get the wrong certificate or a failure.
3. Proves: TCP connected, a TLS handshake completed, which version and cipher were agreed, and which certificate chain was presented.

4. Does not prove: that the certificate is trusted by your operating system. The `openssl` command uses its own trust store, which on macOS is usually not the system keychain. A certificate that `openssl` rejects may work fine in Safari, and the reverse.
5. Check expiry dates with the last command above. Certificate expiry is one of the most common causes of a site that worked yesterday and not today.
6. Since 2024 the industry has been shortening maximum certificate lifetimes. The CA/Browser Forum voted in April 2025 to reduce the maximum from 398 days down in stages, reaching 47 days by March 2029. Expiry checks are getting more important, not less.

■ 52.5.17 whois

1. `whois github.com` looks up who registered a domain name.
2. `whois 20.207.73.82` looks up who owns an address block.
3. Proves: what a registry says. Registry data is often stale, and since the European General Data Protection Regulation took effect in May 2018, most personal contact details in domain records are hidden.
4. Does not prove: who is operating the machine today.
5. In the reader's session, `whois` on `20.207.73.82` would show a Microsoft range. That is consistent with GitHub being owned by Microsoft, which acquired it in 2018 for 7.5 billion dollars in stock, and fronting traffic through Microsoft's network edge.
6. The traceroute agreed: from hop 7 onward the names all ended in `ntwk.msn.net`, which is Microsoft's backbone naming.

■ 52.5.18 macOS-only tools

1. `scutil --dns` shows every resolver the system will use, in order, with the search domains and the interface each is bound to. This is the truth about macOS DNS; `/etc/resolv.conf` on macOS is a compatibility file and can be misleading.
2. `scutil --nwi` shows network information: which interfaces are usable, and whether IPv4 and IPv6 are available on each.
3. `scutil --proxy` shows the proxy configuration.
4. `networksetup -listallnetworkservices` lists the named services such as Wi-Fi and Ethernet.
5. `networksetup -getinfo "Wi-Fi"` shows address, mask, router and MAC.
6. `networksetup -getdnsservers "Wi-Fi"` shows configured resolvers.
7. `sudo networksetup -setdnsservers "Wi-Fi" 1.1.1.1 8.8.8.8` sets them.
8. `sudo networksetup -setdnsservers "Wi-Fi"` Empty puts it back to DHCP.
9. `sudo dscacheutil -flushcache`; `sudo killall -HUP mDNSResponder` clears the DNS cache. Both halves are needed on modern macOS.
10. `networkQuality` runs Apple's built-in throughput and responsiveness test. It has shipped since macOS 12 Monterey, released in 2021.
11. `ipconfig getpacket en0` prints the entire DHCP lease including the offered DNS servers, which is how you tell what the router wanted you to use.
12. The reader was using `1.1.1.1`, Cloudflare's public resolver, rather than the router. `scutil --dns` is what proves that.

■ 52.5.19 Worked example: the reader's own five commands

1. Here is the exact sequence that settled the reader's case, with what each step eliminated.

```
Step 1 ping 192.168.0.1
      -> replies. Local network and router: fine.
```

```

Step 2  dig +short github.com
        -> 20.207.73.82.  DNS: fine.

Step 3  curl -v --max-time 15 https://github.com
        -> "Trying 20.207.73.82:443..." then nothing.
        -> TCP handshake never completed.

Step 4  traceroute -n github.com
        -> reaches Microsoft's Pune edge, then * * *.
        -> path exists at least that far.

Step 5  same URL on mobile data, same phone
        -> loads instantly.
        -> the server is up; the destination is fine.

```

2. What that combination proves: the failure is specific to the path between this home connection and that destination, at the transport layer, and it is a silent drop rather than a refusal.
3. What it does not prove: who is dropping the packets, or why. The evidence does not name a party, and you should not either.

52.6 Decision tree: I cannot reach a site

■ 52.6.1 The shape of the procedure

1. Work upward through the layers. Never start in the middle.
2. Each step either passes, which eliminates everything below it, or fails, which tells you exactly where to stop looking.
3. Do not skip a step because you are sure it is fine. The reader's case looked like a DNS problem and was not.

```

START: "I cannot reach a site"
    |
    1. Is any other site reachable?
       no -> your machine or link. Go to A.
       yes v
    2. Does the name resolve?
       no -> DNS. Go to B.
       yes v
    3. Does TCP connect on the port?
       no -> path or firewall. Go to C.
       yes v
    4. Does TLS complete?
       no -> certificate or version. Go to D.
       yes v
    5. Does HTTP return a status code?
       no -> the app is hung. Go to E.
       yes v
    6. Is the status what you expected?
       no -> application layer. Go to F.
       yes -> it works. The problem is elsewhere.
           Go to G.

```

■ 52.6.2 Step 1: is anything reachable at all

1. Run `ping -c 3 192.168.0.1`, using your own gateway address.
2. Find your gateway with `route -n get default` on macOS or `ip route show` on Linux.
3. If the gateway does not answer, stop. The problem is your machine, your cable, or your Wi-Fi. Check `ifconfig en0` for an address.
4. If your address begins 169.254., DHCP failed. Nothing else matters until that is fixed. Renew the lease or restart the interface.
5. If the gateway answers, run `ping -c 3 1.1.1.1`.
6. If a public address answers but names do not resolve, jump straight to step 2. That combination is the classic DNS-only failure.
7. If the gateway answers and 1.1.1.1 does not, the problem is between your router and the internet. Check the router's own status page and the physical line.
8. Branch A conclusion: local. Fix the interface, the lease, the cable or the router before going further.

■ 52.6.3 Step 2: does the name resolve

1. Run `dig +short github.com`.
2. If you get an address, DNS works. Note the address and move on.
3. If you get nothing, ask a different resolver: `dig @1.1.1.1 +short github.com` and `dig @8.8.8.8 +short github.com`.
4. If a public resolver answers and your configured one does not, your resolver is the problem. On macOS, check with `scutil --dns` and change it with `networksetup -setdnsservers`.
5. If no resolver answers for that one name but others resolve, the domain itself may be broken. Check with `dig +trace github.com`, which walks from the root servers down and shows where the chain stops.
6. If the answer looks wrong, for example a private address for a public site, suspect a captive portal, a filtering resolver, or a modified hosts file. Check `/etc/hosts` on macOS and Linux.
7. Clear the cache and try again: on macOS, `sudo dscacheutil -flushcache;` `sudo killall -HUP mDNSResponder`.
8. Branch B conclusion: DNS. Nothing above this layer can work until a name turns into an address.

■ 52.6.4 Step 3: does TCP connect

1. Run `nc -vz github.com 443`.
2. Success means the three-way handshake completed. Move to step 4.
3. Now read the failure carefully, because the three failure modes mean completely different things.
4. **Connection refused**, immediately. You received a TCP RST. Something is there and it said no. The host is up; the port is closed. Suspect a service that is not running, or the wrong port.
5. **No route to host** or **host unreachable**, quickly. You received an ICMP type 3. A router along the way openly told you it could not deliver. Suspect routing or a firewall that refuses politely.
6. **Timeout**, after many seconds, with no message at all. Nothing came back. This is a silent drop. It is the hardest case and it is the reader's case.
7. Confirm which of the three you have with `curl -v --max-time 15` and, if you can, with `sudo tcpdump -i en0 -n host <address> and port 443` in another window.
8. If it is a timeout, test whether it is that one destination or all destinations: try `nc -vz 1.1.1.1 443` and `nc -vz google.com 443`.
9. Test whether it is that one port: try `nc -vz github.com 22` and `nc -vz github.com 80`.
10. Test whether it is that one network path: use a different network. Mobile data on a phone, with tethering or with the same URL typed into the phone, is the cleanest test available to a home user.

11. If it works on a different network and not on yours, the destination is fine and the path is not.
12. Branch C conclusion: transport or path. See section 52.6.8 for what to do next, because this is where the reader ended up.

■ 52.6.5 Step 4: does TLS complete

1. Run `openssl s_client -connect github.com:443 -servername github.com`.
2. Success prints a certificate chain and a line saying which protocol version and cipher were negotiated.
3. `certificate verify failed` means the chain did not validate. Look at the reason code printed on the same line.
4. `certificate has expired` means exactly that. Check the dates with `openssl x509 -noout -dates`.
5. `unable to get local issuer certificate` usually means an intermediate certificate is missing from the server's chain, or your trust store is old.
6. `wrong version number or no protocols available` means a version mismatch. Old servers that only speak TLS 1.0 are refused by modern clients. Test with `-tls1_2` and `-tls1_3` explicitly.
7. A hostname mismatch means the certificate does not cover the name you asked for. Check the subject alternative names with `openssl x509 -noout -text` and look for the SAN extension.
8. If TLS fails only in your browser but succeeds with `openssl`, suspect a corporate inspection proxy that is re-signing traffic, or a VPN.
9. Branch D conclusion: TLS. The network is fine; the trust is not.

■ 52.6.6 Step 5 and 6: does HTTP answer, and correctly

1. Run `curl -sS -o /dev/null -w '%{http_code} %{time_total}\n'` against the URL.
2. No status code and a long time means the connection opened and the server never replied. That is an application hang, not a network fault. Branch E.
3. A 502, 503 or 504 means you reached a gateway and the thing behind it is broken or overloaded. That is the operator's problem, not yours. Branch F.
4. A 401 or 403 means you reached the right service and it refused you. Check your credentials, token, or scopes. Branch F.
5. A 404 means you reached the right service and asked for the wrong path.
6. A 429 means you are being rate limited. Read the `Retry-After` header.
7. A 200 with wrong content means caching, a stale CDN copy, or the wrong virtual host. Try `curl -H 'Cache-Control: no-cache'` and try the origin directly with `--resolve`.
8. Branch F conclusion: application layer. The whole network stack worked.

■ 52.6.7 Everything passes and it still fails

1. This happens, and it has a small number of causes. Work through them in this order.
2. It works from the command line but not in the browser. Suspect a browser extension, a proxy setting inside the browser, or a service worker holding a cached broken response. Test in a private window with extensions off.
3. It works over IPv4 and not IPv6, or the reverse. Force each with `curl -4` and `curl -6`. Broken IPv6 with working IPv4 is common and produces long pauses because the browser tries IPv6 first.
4. The reader's machine reported IPv6: (none), which removes this branch from the reader's own case entirely.
5. It works for small requests and fails for large ones. That is an MTU problem. Test with `ping -D -s 1472` and step the size down. If 1400 works and 1472 does not, something on the path has a smaller MTU and is not sending the ICMP message that would let path MTU discovery work.

6. It works sometimes. Run `mttr -rwc 200` and look at the loss on the final row only. Intermittent means loss, congestion, or a load-balanced path where one of several parallel links is broken.
7. That last case is worth naming: if a hop shows several addresses, as hops 5, 6, 8, 9 and 11 did in the reader's trace, then some flows take one link and some take another. A single bad link out of four gives you a fault that appears for one in four connections and looks random.
8. It works for other people on the same network. Compare `scutil --dns`, `route -n get default` and the proxy settings between the two machines.
9. It stopped working at a specific time. Ask what changed then: a certificate expiry, a DNS TTL running out, a scheduled firewall rule, a router reboot.
10. It works with a VPN on. That proves the destination and the server are fine and that the direct path is the problem, because the VPN carries your traffic through a different route. It does not prove who is blocking.

■ 52.6.8 Exactly what to report to an ISP

1. Support staff cannot act on "the internet is not working". They can act on a reproducible measurement. Give them these seven things, in this order.
2. Your own public address and the time, including the time zone. Get the address with `curl -4 ifconfig.me` when you have any working path, or from the router's status page.
3. The destination name and the exact address it resolves to on your machine. For the reader: `github.com` resolving to `20.207.73.82`.
4. The exact symptom, in protocol terms. Not "it is slow". Say: "TCP SYN to `20.207.73.82` port 443 receives no response of any kind, no RST and no ICMP unreachable, and times out after 15 seconds."
5. A full traceroute, pasted verbatim, with `-n` so it is fast and unambiguous. Include the hop where replies stop.
6. The control test that proves it is not the destination. For the reader: "The same URL loads instantly over mobile data on the same phone, at the same moment."
7. The control test that proves it is not everything. For example: "Other HTTPS sites work normally from the same machine at the same time."
8. An `mttr` report over at least 100 cycles, in report mode, so they can see loss over time rather than one snapshot.
9. What you have already ruled out, listed plainly: local network, DNS, the destination server, IPv6.
10. One sentence of what you want: "Please check whether traffic from my connection to `20.207.73.82` on port 443 is being dropped in your network."
11. Do not accuse anyone. The evidence supports a silent drop somewhere on that path. It does not identify who is doing it, and claiming otherwise makes the ticket easier to dismiss.
12. Keep a copy of every command output with timestamps. If the fault is intermittent, that record is the only thing that will get it taken seriously.

52.7 Git command cheat sheet

■ 52.7.1 How to read the two extra columns

1. **Net** says whether the command needs the network. If it says no, the command works with the cable unplugged. That is most of git.
2. **Risk** says whether the command can destroy work that is not recoverable from the reflog.
3. Low means safe. Medium means it rewrites history but the old commits stay reachable through git reflog for 90 days by default. High means it can delete uncommitted changes or untracked files, which nothing can recover.

■ 52.7.2 Setup and configuration

Command	What it does	Net	Risk
git init	make a new repository	no	low
git init --bare	make a server-side repo	no	low
git clone URL	copy a repo and history	yes	low
git clone --mirror	exact copy of all refs	yes	low
git clone --depth 1	shallow, latest commit	yes	low
git config --global x y	set a user-wide setting	no	low
git config --list	show every setting	no	low
git config --list --show-origin	and which file set it	no	low
git remote -v	list remotes and URLs	no	low
git remote add name URL	add a remote	no	low
git remote set-url name URL	change a remote URL	no	low
git help command	full documentation	no	low

1. The three settings worth doing on a new machine, once:

```
git config --global user.name "Your Name"
git config --global user.email "you@example.com"
git config --global init.defaultBranch main
git config --global pull.rebase false
git config --global core.editor "vim"
```

■ 52.7.3 Local work

Command	What it does	Net	Risk
git status	what changed, what is staged	no	low
git status -sb	the same, one line each	no	low
git add file	stage a file	no	low
git add -p	stage chosen hunks	no	low
git add -A	stage everything	no	low
git commit -m "msg"	record the staged snapshot	no	low
git commit --amend	replace the last commit	no	med
git diff	working tree vs index	no	low
git diff --staged	index vs last commit	no	low
git diff main..feature	between two branches	no	low
git rm file	delete and stage the delete	no	high
git mv old new	rename and stage it	no	low
git restore file	discard working changes	no	high
git restore --staged file	unstage, keep changes	no	low

Command	What it does	Net	Risk
git stash	park changes, clean tree	no	low
git stash pop	bring them back	no	low
git stash list	see what is parked	no	low
git clean -n	show what would be deleted	no	low
git clean -fd	delete untracked files	no	high

1. `git restore file` and `git clean -fd` are the two most dangerous commands in daily use. They delete things git has never seen. The reflog cannot help you. Always run `git clean -n` first.

■ 52.7.4 History and inspection

Command	What it does	Net	Risk
git log	full history	no	low
git log --oneline	one line per commit	no	low
git log --oneline --graph --all	the branch shape	no	low
git log -p	history with diffs	no	low
git log -S "text"	commits that changed text	no	low
git log --since="2 weeks"	by date	no	low
git show SHA	one commit in full	no	low
git blame file	who last touched each line	no	low
git shortlog -sn	commits per author	no	low
git describe --tags	nearest tag plus distance	no	low
git rev-list --count HEAD	how many commits	no	low
git bisect start	begin a binary search	no	low
git bisect good SHA	mark a known-good point	no	low
git bisect bad	mark the current as bad	no	low
git bisect reset	stop and go back	no	low
git reflog	every position HEAD held	no	low
git range-diff a...b	compare two versions of a series	no	low

1. `git reflog` is the undo button for almost everything. If a rebase or reset went wrong, find the old SHA in the reflog and `git reset --hard` to it. Entries expire after 90 days for reachable commits and 30 days for unreachable ones, by default.

■ 52.7.5 Branching

Command	What it does	Net	Risk
git branch	list local branches	no	low
git branch -a	include remote-tracking	no	low
git branch -vv	show tracking and ahead/behind	no	low
git switch name	move to a branch	no	low
git switch -c name	create and move to it	no	low
git switch -	back to the previous branch	no	low
git checkout name	the older form of switch	no	low
git branch -d name	delete a merged branch	no	low
git branch -D name	delete regardless	no	med
git merge feature	join a branch in	no	low
git merge --abort	undo a conflicted merge	no	low

Command	What it does	Net	Risk
git merge --no-ff	always make a merge commit	no	low
git rebase main	replay commits on a new base	no	med
git rebase -i HEAD~5	edit the last five commits	no	med
git rebase --abort	undo an in-progress rebase	no	low
git cherry-pick SHA	copy one commit here	no	low
git merge-base a b	the common ancestor	no	low
git tag -a v1.0 -m "msg"	make an annotated tag	no	low
git worktree add ../dir br	second checkout, same repo	no	low

1. The one fact about rebase that matters. Rebase does not move commits. It creates new commit objects with the same changes and new parents, so every rebased commit gets a new SHA.
2. That is exactly what the reader saw: a local branch rebased onto a moved main came out with a different SHA, because it was a different object.
3. Merge preserves history and adds a commit. Rebase rewrites history and adds none. Neither is correct in general; teams pick one by convention.

■ 52.7.6 Remotes and the network

Command	What it does	Net	Risk
git fetch	download objects and refs	yes	low
git fetch --all --prune	all remotes, drop dead refs	yes	low
git pull	fetch then merge	yes	low
git pull --rebase	fetch then rebase	yes	med
git push	send commits to a remote	yes	low
git push -u origin br	push and set upstream	yes	low
git push --force	overwrite the remote branch	yes	high
git push --force-with-lease	force, but refuse if it moved	yes	med
git push --tags	send tags too	yes	low
git ls-remote origin	list remote refs, live	yes	low
git remote show origin	remote details	yes	low
git remote update	fetch all remotes	yes	low
git remote prune origin	delete stale tracking refs	yes	low
git bundle create f.bundle --all	history in one file	no	low
git archive HEAD -o src.tar	export files, no history	no	low
git submodule update --init	fetch nested repos	yes	low

1. Only the rows marked yes need the network. Everything in 52.7.3, 52.7.4, 52.7.5 and 52.7.7 works offline, because the whole history is already in .git.

2. That is why the reader could keep committing to branches during a total outage and push them later. Commits are local writes to local files.
3. `git ls-remote origin` is the only way to learn the true current state of a remote. `git rev-parse origin/main` reads a cached value from your last fetch.
4. In the reader's session, `origin/main` showed `0a95cc8` during the outage. That was the remote-tracking ref, which is a note about the past, not a live fact.
5. Never use `--force` on a shared branch. Use `--force-with-lease`, which checks that the remote is still where you last saw it and refuses if somebody else pushed in the meantime.

■ 52.7.7 Undoing

Command	What it does	Net	Risk
<code>git restore --staged file</code>	unstage, keep the change	no	low
<code>git restore file</code>	throw away the change	no	high
<code>git reset --soft HEAD~1</code>	undo commit, keep staged	no	med
<code>git reset --mixed HEAD~1</code>	undo commit, keep in tree	no	med
<code>git reset --hard HEAD~1</code>	undo commit, delete changes	no	high
<code>git reset --hard origin/main</code>	make local match remote	no	high
<code>git revert SHA</code>	new commit that undoes one	no	low
<code>git commit --amend</code>	fix the last commit	no	med
<code>git reflog then reset --hard</code>	recover a lost position	no	med
<code>git checkout SHA -- file</code>	one file from a past commit	no	high
<code>git clean -fdx</code>	delete untracked and ignored	no	high

1. The rule that keeps you safe: `revert` is for history that other people have. `reset` is for history only you have.
2. `--soft` keeps everything staged. `--mixed`, the default, keeps changes in the working tree but unstaged. `--hard` deletes them.

■ 52.7.8 Plumbing, for looking inside

Command	What it does	Net	Risk
<code>git cat-file -t SHA</code>	the object's type	no	low
<code>git cat-file -p SHA</code>	the object's contents	no	low
<code>git cat-file -s SHA</code>	the object's size	no	low
<code>git hash-object -w file</code>	store a blob, print its SHA	no	low
<code>git rev-parse HEAD</code>	resolve a name to a SHA	no	low
<code>git rev-parse --short HEAD</code>	the short form	no	low
<code>git rev-parse --git-dir</code>	where <code>.git</code> actually is	no	low
<code>git ls-tree HEAD</code>	one tree object listed	no	low
<code>git ls-files -s</code>	the index, with SHAs	no	low

Command	What it does	Net	Risk
git write-tree	index becomes a tree object	no	low
git commit-tree tree -p par	build a commit by hand	no	low
git update-ref refs/heads/x SHA	point a ref somewhere	no	med
git symbolic-ref HEAD	what HEAD points at	no	low
git show-ref	every ref and its SHA	no	low
git for-each-ref	refs, formatted	no	low
git fsck --full	check every object	no	low
git gc	pack and prune	no	low
git count-objects -v	how many objects, how big	no	low
git verify-pack -v file.idx	inside a pack file	no	low
git check-ignore -v file	which rule ignores it	no	low

1. The four object types, seen with `git cat-file -t`: blob is file contents, tree is a directory listing, commit is a snapshot plus metadata, tag is an annotated tag.
2. Git stores content addressed by hash. Git 2.29, released October 2020, added experimental SHA-256 repositories; SHA-1 remains the default in 2026.

52.8 Decision tree: my git operation failed

■ 52.8.1 The five families

1. Every git failure belongs to one of five families. Naming the family is 90 per cent of the fix.

Family	Where it happens	Retry safe
Transport	before or during the bytes	usually
Authentication	who are you	after fixing
Permission or scope	you, but not allowed	after fixing
Server-side rejection	server said no, on purpose	after fixing
Local	never left your machine	yes

git command failed. Read the FIRST error line.

```

|
Does it mention a host, port, TLS,
timeout, disconnect, or reset?
yes -> TRANSPORT. See 52.8.3
no v
Does it say Authentication failed,
Permission denied (publickey),
or ask for a password repeatedly?
yes -> AUTHENTICATION. See 52.8.4
no v
Does it name a scope, a permission,
or say 403 / not authorized?
yes -> SCOPE. See 52.8.5
no v
Does it say rejected, non-fast-forward,
protected branch, hook declined, or
pre-receive?
yes -> SERVER REJECTION. See 52.8.6
no -> LOCAL. See 52.8.7

```

■ 52.8.2 First, always: did it actually happen

1. Before diagnosing anything, find out the current true state.
2. Run `git ls-remote origin`. That is a live query. It is the only reliable answer.
3. Compare with `git rev-parse HEAD` locally.
4. Do not trust `git rev-parse origin/main` or `git status` after a failure. Those read remote-tracking refs, which are a cached memory of your last successful fetch.
5. This step is not optional. Half of all git panic is caused by acting on a stale local belief about the remote.

■ 52.8.3 Transport failures

1. Symptoms: Could not resolve host, Failed to connect, Connection timed out, Connection reset by peer, `SSL_ERROR_SYSCALL`, RPC failed, early EOF, unexpected disconnect while reading sideband packet.
2. Diagnostics, in order:

```
git ls-remote origin          # does anything work at all
ssh -T git@github.com        # SSH transport, port 22
nc -vz github.com 22         # is port 22 even reachable
nc -vz github.com 443        # is port 443 reachable
curl -sS -o /dev/null -w '%{http_code}\n' \
    https://github.com
GIT_CURL_VERBOSE=1 git fetch  # verbose HTTPS
GIT_TRACE=1 GIT_TRACE_PACKET=1 git fetch
```

3. Retry: usually safe for fetch, clone and pull, because they only read.
4. Retry for push: safe only after you have re-queried with `git ls-remote` and know whether the previous attempt landed.
5. Common fixes. If port 22 is blocked but 443 is not, use SSH over 443 by putting this in `~/.ssh/config`:

```
Host github.com
  Hostname ssh.github.com
  Port 443
  User git
```

6. If large pushes fail but small ones work, raise the buffer: `git config --global http.postBuffer 524288000`. This is a workaround, not a fix, and it helps only with HTTP transport.
7. If HTTPS fails and SSH works, or the reverse, that is not a git problem at all. It is two different ports to two different endpoints, and one path is broken. The reader saw exactly this in the same session.

■ 52.8.4 Worked branch: sideband packet disconnect

1. The exact error, seen twice in the reader's session: `send-pack: unexpected disconnect while reading sideband packet`.
2. What it means, literally. Git pushed the pack of objects, then waited on the sideband channel for the server's progress and status messages, and the connection died while it was reading them.
3. Now the important part. The disconnect happened while reading the **response**. It says nothing about whether the **write** was applied.
4. Three outcomes are all consistent with that one message. The server never received the pack. The server received it and rejected it. The server received it, applied it, and the acknowledgement was lost on the way back.

5. This is the same problem as a POST over HTTP that times out. The request is not idempotent, so the client cannot safely assume anything.
6. The only correct next step is to ask the server what it now believes:

```
git ls-remote origin
git ls-remote origin refs/heads/main
git rev-parse HEAD
```

7. If the remote SHA equals your local SHA, the push landed. Do nothing.
8. If it does not, push again. A repeated push of the same commits is harmless, because git will only send objects the server lacks.
9. In the reader's case, both times the operation had **not** been applied. That was established by re-querying, not by reading the error.
10. Retry safety: safe to retry, but only after checking. Never force-push as a response to this error. Force is how a lost acknowledgement turns into lost commits.

■ 52.8.5 Authentication and scope failures

1. Authentication symptoms: Permission denied (publickey), Authentication failed, repeated password prompts, Invalid username or password.

```
ssh -vT git@github.com          # verbose SSH handshake
ssh-add -l                      # keys the agent holds
ssh-add ~/.ssh/id_ed25519       # load a key
git config --get remote.origin.url
git credential-osxkeychain erase # macOS, then type host lines
```
2. GitHub stopped accepting account passwords for git over HTTPS on 13 August 2021. If something is prompting you for a password, it wants a personal access token, not your password.
3. Scope symptoms are different and more specific. The push authenticates fine and is then refused with a named reason.
4. Worked branch, from the reader's session. A push was refused because the token lacked the workflow scope, and the push modified a file under `.github/workflows/`.
5. That is not a bug. It is a deliberate rule: a token that can push code should not be able to change what runs automatically in CI, because CI has its own secrets and its own privileges.
6. The diagnosis is the error text plus one question: does this push touch a workflow file? Check with `git diff --stat origin/main...HEAD` and look for `.github/workflows/`.
7. The fix is to add the workflow scope to the token, or to move the workflow change into a separate push made with a token that has it.
8. Retry safety: retrying with the same token will fail identically, every time. Nothing was applied, because the server refused before applying.
9. This is a clean example of the difference between 401 and 403 thinking. You were identified successfully. You were then found to lack a permission.
10. The general rule for tokens: check three things, in this order. Is it expired. Does it cover this repository. Does it have the scope this specific action needs.

■ 52.8.6 Server-side rejections

1. Symptoms: ! [rejected], non-fast-forward, Updates were rejected because the remote contains work that you do not have locally, protected branch, pre-receive hook declined, GH006.

2. A non-fast-forward rejection means somebody pushed since your last fetch. The server is protecting their work.

```
git fetch origin
git log --oneline HEAD..origin/main    # what they added
git log --oneline origin/main..HEAD    # what you added
git rebase origin/main                 # or: git merge origin/main
git push
```

3. A protected-branch rejection means the repository's rules forbid a direct push. Open a pull request instead. This is a setting, not an error.
4. A pre-receive hook declined means the server ran a script that said no. The reason is usually in the lines just after. Common causes are commit message format rules, file size limits, and secret scanning.
5. GitHub blocks any single file over 100 MiB, and warns above 50 MiB. That limit has been in place since 2015 and is a service policy, not a git limit. Use Git Large File Storage for big files.
6. Retry safety: retrying unchanged always fails again. Nothing was applied. Fix the cause first.

■ 52.8.7 Local failures

1. Symptoms: not a git repository, pathspec did not match any file, your local changes would be overwritten, You have unmerged paths, index.lock exists, detached HEAD.

```
git rev-parse --git-dir      # am I in a repo at all
git status                  # the honest current state
git diff --name-only --diff-filter=U # conflicted files
rm -f .git/index.lock       # only if no git is running
git fsck --full              # object integrity
git switch -                 # leave detached HEAD safely
```

2. index.lock exists almost always means a previous git process died or an editor's git integration is running. Check with `ps aux | grep git` before deleting the lock file.
3. detached HEAD is not an error. It means HEAD points at a commit rather than a branch. Commits made there are reachable only from the reflog, so create a branch before you go further: `git switch -c rescue`.
4. Retry safety: always safe. Nothing left your machine.
5. Finally, one distinction that matters and that the reader's session showed clearly. Git the tool and GitHub the service are different things. During the outage plain git kept working locally, and the GitHub web API did not. An error from gh or from the API is not a git error.

■ 52.8.8 Verifying CI properly

1. A green tick next to a branch name means "some run for something on this branch passed". It does not say which commit.
2. The strong check is by run identifier against the exact head SHA:

```
git rev-parse HEAD
gh run list --branch main --limit 5
gh run view <run-id> --json headSha,status,conclusion
```

3. Compare the headSha field with your local SHA character by character. If they differ, the tick is about a different commit.
4. Merge state, seen through the API, uses values such as CLEAN, BLOCKED and UNKNOWN. UNKNOWN usually means the server has not finished computing the merge yet; re-query rather than assuming a failure.

52.9 Shell and system cheat sheet

■ 52.9.1 Files and directories

Command	What it does
<code>pwd</code>	print the current directory
<code>cd -</code>	go back to the previous one
<code>ls -lah</code>	long, all, human sizes
<code>ls -lt</code>	newest first
<code>ls -ls</code>	biggest first
<code>mkdir -p a/b/c</code>	make the whole path
<code>cp -r src dst</code>	copy a directory
<code>cp -a src dst</code>	copy, keep all attributes
<code>mv old new</code>	move or rename
<code>rm -i file</code>	delete, asking first
<code>rm -rf dir</code>	delete a tree, no questions
<code>ln -s target link</code>	make a symbolic link
<code>touch file</code>	create empty, or update time
<code>stat file</code>	size, times, permissions
<code>file thing</code>	guess the format
<code>du -sh dir</code>	total size of a directory
<code>du -sh * \ sort -h</code>	biggest items first
<code>df -h</code>	free space per filesystem
<code>basename path</code>	last part of a path
<code>dirname path</code>	everything but the last part

■ 52.9.2 Looking inside files

Command	What it does
<code>cat file</code>	print the whole file
<code>less file</code>	page through it, q to quit
<code>head -n 20 file</code>	first 20 lines
<code>tail -n 20 file</code>	last 20 lines
<code>tail -f log</code>	follow as it grows
<code>wc -l file</code>	count lines
<code>sort file</code>	sort lines
<code>sort -u</code>	sort and remove duplicates
<code>uniq -c</code>	count runs, needs sort first
<code>cut -d, -f2 file</code>	second comma field
<code>tr 'a-z' 'A-Z'</code>	change characters
<code>sed 's/old/new/g'</code>	replace text
<code>awk '{print \$3}'</code>	print the third field
<code>grep -n pattern file</code>	matching lines, numbered
<code>grep -ri pattern dir</code>	recursive, ignore case
<code>grep -v pattern</code>	lines that do not match
<code>grep -c pattern</code>	just the count
<code>diff -u a b</code>	unified difference
<code>xxd file \ head</code>	hex dump
<code>jq '.field' file.json</code>	read JSON properly

■ 52.9.3 Finding things

```
find . -name '*.log'           # by name
find . -type f -size +100M    # files over 100 MB
find . -mtime -1             # changed in the last day
find . -name '*.tmp' -delete  # find and delete
find . -type f -exec grep -l x {} + # search inside
which python3                 # which one runs
type -a python3               # every match, and aliases
command -v python3            # portable form
locate filename               # from an index, if built
```

■ 52.9.4 Processes and resources

Command	What it does
ps aux	every process
ps aux grep name	find one
top	live view
htop	nicer live view, install it
kill PID	ask politely, signal 15
kill -9 PID	force, signal 9
pkill -f pattern	kill by command line
jobs	this shell's background jobs
bg and fg	move a job
nohup cmd &	keep running after logout
time cmd	how long it took
uptime	load averages
free -h	memory, Linux only
vm_stat	memory, macOS
sysctl -n hw.ncpu	core count, macOS
nproc	core count, Linux
uname -a	kernel and machine
sw_vers	macOS version
lsb_release -a	Linux distribution

1. Signal 15, SIGTERM, asks a program to shut down cleanly. Signal 9, SIGKILL, cannot be caught or ignored and gives the program no chance to save. Try 15 first, always.

■ 52.9.5 Archives, permissions and transfer

```
tar -czf out.tar.gz dir/      # create, gzip
tar -xzf in.tar.gz            # extract
tar -tzf in.tar.gz            # list without extracting
zip -r out.zip dir/           # create a zip
unzip in.zip                   # extract a zip
gzip file                      # replaces file with file.gz
gunzip file.gz                 # and back
chmod 644 file                 # rw for owner, r for others
chmod 755 script               # add execute for everyone
chmod +x script                # just add execute
chown user:group file          # change ownership
umask                           # default permission mask
rsync -avz src/ host:dst/      # copy, resume, compress
scp file host:/path            # simple copy over SSH
ssh -i key user@host           # connect with a key
```

1. Permission digits are octal. Read is 4, write is 2, execute is 1. Add them. The three digits are owner, group, others. So 755 is read-write-execute for the owner and read-execute for everyone else.

■ 52.9.6 Keyboard shortcuts in the shell

Keys	What it does
Ctrl-C	interrupt the running command
Ctrl-D	end of input, or log out
Ctrl-Z	suspend, resume with fg
Ctrl-L	clear the screen
Ctrl-A	jump to start of line
Ctrl-E	jump to end of line
Ctrl-U	delete to start of line
Ctrl-K	delete to end of line
Ctrl-W	delete the word before
Ctrl-Y	paste what you just deleted
Alt-B, Alt-F	back or forward one word
Ctrl-R	search command history
Ctrl-G	leave the history search
Up, Down	previous, next command
Tab	complete a name
Tab Tab	show all completions
!!	the previous command
!\$	last argument of it
sudo !!	rerun the last one as root

1. On macOS Terminal, Alt is the Option key, and you may need to enable “Use Option as Meta key” in the settings before Alt-B and Alt-F work.

■ 52.9.7 The shell expansion order

1. The shell rewrites your command line in a fixed order before running anything. Knowing the order explains almost every strange quoting bug.

1. brace expansion	{a,b}	->	a b
2. tilde expansion	~	->	/Users/you
3. parameter expansion	\$VAR	->	its value
4. arithmetic expansion	\$((2+2))	->	4
5. command substitution	\$(cmd)	->	its output
6. word splitting			on spaces, tabs, newlines
7. pathname expansion	*.txt	->	matching files
8. quote removal	"x"	->	x

2. The two consequences that bite people.
3. Word splitting happens **after** variable expansion. So an unquoted \$FILE holding my report.txt becomes two arguments. Quoting it stops that.
4. Pathname expansion happens after variable expansion too, so a variable containing * will expand to filenames unless you quote it.

■ 52.9.8 The safety rules

1. **Quote every variable.** Write "\$FILE", not \$FILE. Write "\$@", not \$@. This one habit prevents most shell bugs.
2. **Start scripts with strict mode.**

```
#!/usr/bin/env bash
set -euo pipefail
IFS=$'\n\t'
```

3. -e exits on the first failing command. -u treats an unset variable as an error. -o pipefail makes a pipeline fail if any stage fails, not just the last. Setting IFS stops word splitting on plain spaces.
4. **Never pipe an unknown URL into a shell.** curl ... | sh hands a remote server the ability to run anything as you. Download first, read it, then run it.
5. There is a further reason beyond trust: a server can serve different bytes to curl piped into a shell than to curl writing a file, because it can see the download stall as the shell executes. Reading the file you downloaded is the only real protection.
6. **Test destructive commands first.** Use git clean -n, rm -i, rsync --dry-run, and find ... -print before find ... -delete.
7. **Never run rm -rf with a variable that might be empty.** If \$DIR is unset, rm -rf "\$DIR"/ becomes rm -rf /. set -u prevents this.
8. **Use sudo for one command, not for a session.** A root shell left open is a mistake waiting for a typing error.
9. **Prefer absolute paths in scripts and cron jobs.** The working directory and the PATH in an automated context are not the ones you have interactively.

52.10 File format identification by magic number

1. A magic number is a fixed byte sequence at a known offset that identifies a file's format. The extension is a hint; the magic number is the fact.
2. Check with file thing for a guess, or xxd file | head -2 for the bytes.

Format	Hex bytes at start	Extension
PNG image	89 50 4E 47 0D 0A 1A 0A	.png
JPEG image	FF D8 FF	.jpg
GIF image	47 49 46 38	.gif
BMP image	42 4D	.bmp
TIFF, little-endian	49 49 2A 00	.tif
TIFF, big-endian	4D 4D 00 2A	.tif
WebP	52 49 46 46 then WEBP	.webp
ICO icon	00 00 01 00	.ico
PSD, Photoshop	38 42 50 53	.psd
PDF document	25 50 44 46 2D	.pdf
PostScript	25 21	.ps
RTF document	7B 5C 72 74 66	.rtf
ZIP, and docx, xlsx, jar	50 4B 03 04	.zip
GZIP	1F 8B	.gz
BZIP2	42 5A 68	.bz2
XZ	FD 37 7A 58 5A 00	.xz
Zstandard	28 B5 2F FD	.zst

Format	Hex bytes at start	Extension
7-Zip	37 7A BC AF 27 1C	.7z
RAR version 5	52 61 72 21 1A 07 01	.rar
TAR	75 73 74 61 72 at byte 257	.tar
Old Office, OLE2	D0 CF 11 E0 A1 B1 1A E1	.doc
MP3 with ID3 tag	49 44 33	.mp3
FLAC audio	66 4C 61 43	.flac
OGG container	4F 67 67 53	.ogg
WAV audio	52 49 46 46 then WAVE	.wav
MP4, HEIC, AVIF	66 74 79 70 at byte 4	.mp4
Matroska, WebM	1A 45 DF A3	.mkv
ELF executable	7F 45 4C 46	none
Mach-O 64-bit	CF FA ED FE	none
Windows PE, EXE	4D 5A	.exe
Java class file	CA FE BA BE	.class
WebAssembly	00 61 73 6D	.wasm
SQLite 3 database	53 51 4C 69 74 65 20 66	.sqlite
Git pack file	50 41 43 4B	.pack
Git index file	44 49 52 43	none
Debian package	21 3C 61 72 63 68 3E	.deb
RPM package	ED AB EE DB	.rpm
Shell script	23 21	.sh
PEM certificate	2D 2D 2D 2D 2D 42 45 47	.pem
ISO 9660 image	43 44 30 30 31 at 0x8001	.iso
WOFF web font	77 4F 46 46	.woff
OpenType font	4F 54 54 4F	.otf

- Two entries in that table are the same bytes, and this is a real trap. CA FE BA BE is both a Java class file and an old Mach-O universal binary header. The disambiguation is what follows.
- 50 4B 03 04 covers a very large family. Modern Office files, Java jar files, EPUB books, Android APK files and OpenDocument files are all zip archives with different contents inside.
- Two other useful facts. MZ at the start of a Windows executable stands for Mark Zbikowski, one of the original MS-DOS developers, and has been there since 1983. 7F 45 4C 46 is a non-printable byte followed by the letters ELF, deliberately chosen so text tools do not mangle it.

52.11 Complexity and performance reference

■ 52.11.1 Big-O and what fits in one second

- Big-O describes how the work grows as the input grows. It hides constant factors on purpose.
- The table assumes a rough budget of 100 million simple operations per second, which is a fair figure for interpreted-to-compiled code across the range. Compiled C can do ten times more; Python often ten times less.

Complexity	Name	Largest n in 1 s
O(1)	constant	any size
O(log n)	logarithmic	effectively unlimited
O(n)	linear	100,000,000
O(n log n)	linearithmic	about 4,500,000

Complexity	Name	Largest n in 1 s
$O(n^2)$	quadratic	about 10,000
$O(n^3)$	cubic	about 464
$O(2^n)$	exponential	about 26
$O(n!)$	factorial	about 11

3. The practical reading. If n is a million, you need $O(n)$ or $O(n \log n)$. If n is ten thousand, $O(n^2)$ is acceptable. If n is twenty, anything works.
4. Constants matter in real code. A cache-friendly $O(n^2)$ can beat a pointer-chasing $O(n \log n)$ for small n . Measure before optimizing.

■ 52.11.2 Data structure operation costs

Structure	Lookup	Insert or delete
Array, by index	$O(1)$	$O(n)$
Array, by value	$O(n)$	$O(n)$
Dynamic array, append	$O(1)$	$O(1)$ amortized
Linked list	$O(n)$	$O(1)$ at a known node
Hash table	$O(1)$ average	$O(1)$ average
Hash table, worst case	$O(n)$	$O(n)$
Balanced tree	$O(\log n)$	$O(\log n)$
Binary heap, minimum	$O(1)$	$O(\log n)$
Trie	$O(k)$, k is key length	$O(k)$
B-tree	$O(\log n)$	$O(\log n)$
Skip list	$O(\log n)$ expected	$O(\log n)$ expected
Bloom filter	$O(k)$ hashes	insert only

1. A hash table is $O(1)$ on average and $O(n)$ in the worst case, when every key lands in the same bucket. Modern languages randomize the hash seed at startup to stop attackers forcing that deliberately.
2. A B-tree is the shape used by databases and filesystems because its nodes are sized to a disk block, so one comparison level costs one read.
3. A Bloom filter can say “definitely not present” or “probably present”. It never gives a false negative and cannot delete.

■ 52.11.3 Sorting algorithms

Algorithm	Average	Worst	Note
Quicksort	$O(n \log n)$	$O(n^2)$	in place, unstable
Mergesort	$O(n \log n)$	$O(n \log n)$	needs $O(n)$ space, stable
Heapsort	$O(n \log n)$	$O(n \log n)$	in place, unstable
Timsort	$O(n \log n)$	$O(n \log n)$	stable, fast on runs
Introsort	$O(n \log n)$	$O(n \log n)$	quicksort with fallback
Insertion sort	$O(n^2)$	$O(n^2)$	$O(n)$ if nearly sorted
Selection sort	$O(n^2)$	$O(n^2)$	fewest swaps
Bubble sort	$O(n^2)$	$O(n^2)$	teaching only
Counting sort	$O(n + k)$	$O(n + k)$	small integer keys
Radix sort	$O(n k)$	$O(n k)$	not comparison based

1. **Stable** means two records with equal keys keep their original order. That matters when you sort by one column and then another.
2. Timsort was written by Tim Peters in 2002 for Python. Java adopted it for objects in Java 7, released 2011. It finds runs that are already sorted and merges them, which is why it is $O(n)$ on nearly sorted data.
3. Introsort, by David Musser in 1997, is what most C++ standard libraries use for `std::sort`. It runs quicksort and switches to heapsort if the recursion gets too deep, which removes the $O(n^2)$ worst case.
4. No comparison sort can beat $O(n \log n)$ in the worst case. That is a proved lower bound, not an engineering limit. Counting and radix sort beat it only because they do not compare.

■ 52.11.4 The cost of common operations

Operation	Rough cost
Integer add or subtract	under 1 ns
Integer multiply	1 to 3 ns
Integer divide	6 to 13 ns
Float add or multiply	1 to 2 ns
Float divide	4 to 5 ns
Square root	about 5 ns
Function call	1 to 2 ns
Virtual or indirect call	2 to 5 ns
Branch, predicted correctly	under 1 ns
Branch, mispredicted	3 to 5 ns
Uncontended mutex	about 17 ns
Contended atomic increment	50 to 100 ns
Hash a short string	20 to 50 ns
Small malloc and free	50 to 100 ns
A simple system call	100 to 500 ns
Thread context switch	1 to 5 us
Create a thread	10 to 30 us
Fork and exec a process	0.5 to 1 ms
One Python bytecode step	30 to 50 ns
One Python function call	about 100 ns

1. System calls got more expensive in 2018, when the Meltdown and Spectre mitigations forced page table isolation. Depending on the machine and the mitigation set, a simple system call can cost several times what it did before.
2. The gap between a Python operation and a C operation is roughly fifty to a hundred times. That is why numerical Python work is done inside NumPy, where the loop lives in C.

52.12 Cloud and infrastructure reference

■ 52.12.1 Service equivalence

Category	AWS	Azure	Google
Virtual machines	EC2	Virtual Machines	Compute Engine
Object storage	S3	Blob Storage	Cloud Storage
Block storage	EBS	Managed Disks	Persistent Disk

Category	AWS	Azure	Google
Shared file storage	EFS	Azure Files	Filestore
Archive storage	S3 Glacier	Archive Storage	Archive
Managed relational	RDS	Azure SQL Database	Cloud SQL
Scale-out relational	Aurora	SQL Hyperscale	Spanner
Managed NoSQL	DynamoDB	Cosmos DB	Firestore
Wide-column store	Keyspaces	Cosmos DB	Bigtable
Data warehouse	Redshift	Synapse, Fabric	BigQuery
In-memory cache	ElastiCache	Azure Cache	Memorystore
Serverless functions	Lambda	Functions	Cloud Run functions
Containers, managed	ECS, Fargate	Container Apps	Cloud Run
Kubernetes	EKS	AKS	GKE
Container registry	ECR	Container Registry	Artifact Registry
Load balancing	ELB, ALB, NLB	Load Balancer	Cloud Load Balancing
Content delivery	CloudFront	Front Door	Cloud CDN
DNS	Route 53	Azure DNS	Cloud DNS
Private network	VPC	Virtual Network	VPC
Identity	IAM	Entra ID	IAM
Secrets	Secrets Manager	Key Vault	Secret Manager
Message queue	SQS	Service Bus	Pub/Sub
Publish and subscribe	SNS	Event Grid	Pub/Sub
Event streaming	Kinesis	Event Hubs	Pub/Sub
Managed Kafka	MSK	Event Hubs	Managed Kafka
Workflow orchestration	Step Functions	Logic Apps	Workflows
Monitoring and logs	CloudWatch	Azure Monitor	Cloud Monitoring
Infrastructure as code	CloudFormation	Bicep, ARM	Deployment Manager
Machine learning	SageMaker	Azure ML	Vertex AI
Hosted large models	Bedrock	Azure AI Foundry	Vertex AI

- Names change. Microsoft renamed Azure Active Directory to Microsoft Entra ID in 2023, and has been folding Synapse into Microsoft Fabric since 2023. Google renamed Cloud Functions to Cloud Run functions in 2024.
- The equivalences are approximate. Spanner and Aurora are not the same thing; both solve “a relational database bigger than one machine” and solve it differently.

■ 52.12.2 The service model responsibility split

Model	You manage	Provider manages
On-premises	everything	nothing
IaaS	OS upward	hardware, network, power
PaaS	code and data	OS, runtime, scaling
Serverless	function and data	everything else
SaaS	your data and users	the whole application

- One rule survives every model: **you are always responsible for your own data and your own access control**. No provider takes that on.
- The shared responsibility model is the standard phrase. AWS states it as “security of the cloud” being theirs and “security in the cloud” being yours.

3. The most common real breach in cloud is not a provider failure. It is a storage bucket left open to the public, which is entirely on the customer side of the line.

■ 52.12.3 Instance families and what they are for

Family letter	Optimized for	Use it for
t	burstable, cheap	dev, small sites
m	balanced	general servers
c	CPU per unit cost	encoding, simulation
r	memory	caches, in-memory DBs
x, z	very large memory	SAP, huge datasets
i, d	local NVMe storage	databases, search
p	GPU for training	model training
g	GPU for inference	inference, graphics
inf, trn	custom AI silicon	inference, training

1. The letters above are the AWS convention. Azure uses series letters such as D for general purpose, F for compute, E and M for memory, and N for GPU. Google uses names such as N2, C3, M3 and A3.
2. A modern name such as m7g.2xlarge reads as: family m, generation 7, Graviton Arm processor, size 2xlarge. The suffix g for Arm is an AWS convention.
3. Size doubling is a convention too. Each step up in size usually doubles vCPU and memory and doubles the price, so cost per unit of work is roughly flat. That is why splitting across smaller instances rarely saves money by itself.

■ 52.12.4 Cost dimensions to check on any bill

1. Compute time, per hour or per second, per instance.
2. Storage, per gigabyte-month, separately for each class.
3. Data transfer out to the internet, per gigabyte. This is the item that surprises people. Ingress is usually free; egress is not.
4. Data transfer between availability zones and between regions, per gigabyte, in both directions.
5. Request counts. Object storage charges per PUT and per GET, and a workload with many tiny objects can cost more in requests than in storage.
6. Provisioned throughput and IOPS on disks and databases, whether or not you use them.
7. Load balancer hours plus a per-capacity-unit charge.
8. NAT gateway hours plus a per-gigabyte processing charge. This is a common source of unexplained cost in private networks.
9. Public IPv4 addresses. AWS began charging for every public IPv4 address on 1 February 2024, at 0.005 US dollars per hour, which is about 3.60 dollars a month each.
10. Snapshots and backups, which keep growing and which nobody deletes.
11. Log ingestion and log retention, charged separately.
12. Idle waste: unattached volumes, stopped instances still holding disks, old snapshots, forgotten test environments.
13. Support plan, usually a percentage of the total spend.
14. Commitment discounts. Reserved instances and savings plans trade flexibility for a lower rate. Spot instances are much cheaper and can be taken away with two minutes of notice.

52.13 Security reference

■ 52.13.1 Hash functions, as of 2026

Algorithm	Verdict	Note
MD5	broken	collisions since 2004
SHA-1	broken	collision proved 2017
SHA-256	use	the default choice
SHA-384, SHA-512	use	wider, often faster on 64-bit
SHA-3 family	use	different internal design
BLAKE2, BLAKE3	use	very fast, not FIPS
CRC32	not a hash	error detection only

1. MD5 was broken by Xiaoyun Wang and colleagues in 2004. SHA-1 was broken in practice on 23 February 2017, when Google and CWI Amsterdam published two different PDF files with the same SHA-1 digest, an attack they named SHAttered. A chosen-prefix collision followed in January 2020.
2. Neither is safe for signatures or integrity against an attacker. Both are still acceptable as non-security checksums, and git still uses SHA-1 with an added collision-detection check.

■ 52.13.2 Ciphers and key exchange, as of 2026

Purpose	Use	Avoid
Symmetric encryption	AES-256-GCM	DES, 3DES, RC4
Symmetric, no AES hardware	ChaCha20-Poly1305	AES in ECB mode
Mode of operation	GCM, or GCM-SIV	CBC without a MAC
Key exchange	X25519, ECDHE	static RSA, small DH
Signature	Ed25519, ECDSA P-256	DSA, RSA-1024
RSA, if you must	3072 bits or more	1024, 2048 for new keys
SSH host and user keys	Ed25519	DSA, RSA-1024

1. NIST disallowed three-key Triple DES for new encryption after 31 December 2023. RC4 was prohibited in TLS by RFC 7465 in February 2015.
2. Post-quantum standards arrived on 13 August 2024, when NIST published FIPS 203 for ML-KEM, derived from Kyber, FIPS 204 for ML-DSA, derived from Dilithium, and FIPS 205 for SLH-DSA, derived from SPHINCS+.
3. Deployment is hybrid: browsers and servers have been negotiating X25519 combined with ML-KEM-768 since 2024, so a future quantum computer cannot decrypt traffic captured today. This is established practice now, not a research claim.

■ 52.13.3 Password storage parameters

1. Never store a password. Store a slow, salted hash of it. These are the OWASP recommended minimums.

Algorithm	Parameters
Argon2id, preferred	m=19456 KiB, t=2, p=1
Argon2id, alternative	m=47104 KiB, t=1, p=1
Argon2id, alternative	m=12288 KiB, t=3, p=1

Algorithm	Parameters
scrypt	$N=2^{17}$, $r=8$, $p=1$
scrypt, alternative	$N=2^{16}$, $r=8$, $p=2$
bcrypt	work factor 10 or more
PBKDF2-HMAC-SHA256	600,000 iterations
PBKDF2-HMAC-SHA512	220,000 iterations

2. m is memory in kibibytes, t is the number of passes, p is parallelism. Memory cost is the point: it is what makes custom hardware attacks expensive.
3. bcrypt silently ignores everything past 72 bytes of input. Enforce a maximum length or pre-hash. The work factor is a power of two, so 12 is four times the work of 10.
4. Always use a random salt per password, at least 16 bytes. A pepper, a secret stored outside the database, is optional and adds real value.
5. Plain SHA-256 of a password is not acceptable, with or without a salt. It is far too fast: modern hardware computes billions per second.

■ 52.13.4 TLS configuration essentials

1. Enable TLS 1.3 and TLS 1.2. Disable everything older. TLS 1.0 and 1.1 were formally deprecated by RFC 8996 in March 2021.
2. TLS 1.3, standardized in RFC 8446 in August 2018, has only five cipher suites and all of them are safe. The three you will see are TLS_AES_128_GCM_SHA256, TLS_AES_256_GCM_SHA384 and TLS_CHACHA20_POLY1305_SHA256.
3. For TLS 1.2, allow only suites beginning ECDHE_ with GCM or CHACHA20. That gives forward secrecy and authenticated encryption.
4. Turn on OCSP stapling so clients do not have to contact the certificate authority themselves.
5. Send the HTTP Strict Transport Security header with a long lifetime: Strict-Transport-Security: max-age=31536000; includeSubDomains.
6. Disable TLS compression and client-initiated renegotiation. The CRIME attack of 2012 used compression to recover session cookies.
7. Publish a CAA DNS record naming which certificate authorities may issue for your domain.
8. Watch expiry. The CA/Browser Forum agreed in April 2025 to reduce the maximum certificate lifetime in stages, reaching 47 days by March 2029. Automated renewal stops being optional.

■ 52.13.5 The OWASP Top 10, 2025 release

Code	Category
A01	Broken Access Control
A02	Security Misconfiguration
A03	Software Supply Chain Failures
A04	Cryptographic Failures
A05	Injection
A06	Insecure Design
A07	Authentication Failures
A08	Software or Data Integrity Failures
A09	Security Logging and Alerting Failures
A10	Mishandling of Exceptional Conditions

1. This list replaced the 2021 edition. Two changes are worth knowing. Supply chain failures moved up to third place, reflecting attacks on dependencies and build systems rather than on the application itself. Mishandling of exceptional conditions is new at tenth: error handling that leaks information or fails open.
2. The list is an awareness document, ordered by a mix of measured incidence and survey. It is not a checklist you can pass.

■ 52.13.6 A personal security checklist

1. Use a password manager and a different password for every site. This one change removes the largest category of real-world account loss.
2. Turn on two-factor authentication everywhere it is offered. Prefer a passkey or a hardware security key, then a time-based code app, and use SMS only if nothing else is available. SMS codes can be stolen by taking over the phone number.
3. Turn on full disk encryption. On macOS that is FileVault, in System Settings under Privacy and Security.
4. Let the operating system and browser update themselves.
5. Use a non-administrator account for daily work where you can.
6. Back up on the 3-2-1 rule: three copies, on two kinds of media, one of them off-site. Test a restore at least once; an untested backup is a guess.
7. Lock the screen when you walk away.
8. Review which applications have access to your accounts. On GitHub, check authorized OAuth applications and personal access tokens, and delete the ones you do not recognize.
9. Give every token the smallest scope that works, and an expiry date. The reader's workflow scope refusal is the system working correctly.
10. Check your email addresses against public breach databases once a year.
11. Do not install browser extensions you do not need. An extension can read everything you see on every page.
12. Be suspicious of urgency. Almost every successful phishing message manufactures a deadline.

52.14 AI and machine learning reference

■ 52.14.1 The memory formula

1. For inference, the base memory is simple: **bytes = number of parameters times bytes per parameter**.

Precision	Bytes per parameter	Note
FP32	4	full precision
FP16 or BF16	2	standard for inference
FP8	1	newer hardware only
INT8	1	common quantization
INT4 or NF4	0.5	aggressive quantization

2. Add roughly 20 per cent on top for the runtime, activations and fragmentation.
3. Then add the key-value cache, which grows with the conversation: **KV bytes = 2 times layers times kv-heads times head-dim times sequence length times batch size times bytes per element**.
4. The leading 2 is because there is one key tensor and one value tensor.

- For training with the Adam optimizer in mixed precision, budget roughly 16 to 20 bytes per parameter: 4 for the master weights, 4 for momentum, 4 for variance, 2 for the working copy, 2 for gradients, plus activations.
- So a 7 billion parameter model needs about 14 GB to run at 16-bit and about 112 GB or more to train the same way. That gap is why fine-tuning methods such as LoRA exist.

■ 52.14.2 Model size against hardware

Parameters	4-bit	8-bit	16-bit
1 B	0.5 GB	1 GB	2 GB
3 B	1.5 GB	3 GB	6 GB
7 B	3.5 GB	7 GB	14 GB
8 B	4 GB	8 GB	16 GB
13 B	6.5 GB	13 GB	26 GB
32 B	16 GB	32 GB	64 GB
70 B	35 GB	70 GB	140 GB
405 B	203 GB	405 GB	810 GB

- Practical readings for 2026 hardware. A laptop with 16 GB of unified memory runs a 7B or 8B model comfortably at 4-bit. A 24 GB consumer GPU runs 13B at 8-bit or 32B at 4-bit. A 70B model at 16-bit needs two 80 GB accelerators. A 405B model needs a multi-node cluster.
- Quantization costs quality, and the cost is not linear. Going from 16-bit to 8-bit is usually almost free. Going to 4-bit is usually acceptable. Going below 4-bit degrades noticeably, though the frontier moves.

■ 52.14.3 Token cost rules of thumb

Rule	Figure
1 token, English	about 4 characters
1 token, English	about 0.75 words
1,000 words English	about 1,300 tokens
1 page of prose	about 500 tokens
Source code	about 3 chars per token
Hindi in Devanagari	3 to 6 times English
A 300-page book	about 170,000 tokens

- Non-Latin scripts cost more because the tokenizer was trained mostly on English text, so it has fewer merged pieces for them. This is a measured property of specific tokenizers, not a law.
- Cost scales with tokens in plus tokens out, and output tokens are usually priced several times higher than input tokens.
- Attention cost grows with the square of the sequence length in the classical transformer, so doubling the context roughly quadruples that part of the compute.

■ 52.14.4 Common hyperparameters

Name	What it controls
Learning rate	step size when updating weights
Batch size	examples per update

Name	What it controls
Epochs	passes over the whole dataset
Warmup steps	ramp-up before full learning rate
Weight decay	penalty that keeps weights small
Dropout	fraction of units randomly ignored
Gradient accumulation	fake a bigger batch on small memory
LoRA rank	size of the small trained adapter
Temperature	randomness when sampling output
Top-p, nucleus	keep tokens summing to probability p
Top-k	keep only the k most likely tokens
Repetition penalty	discourage repeating tokens
Context length	how many tokens the model can see
Max new tokens	how long the answer may be

1. Temperature 0 means always take the most likely token, which makes output nearly deterministic. Temperature 1 samples from the model's own distribution. Above about 1.2 the output usually becomes incoherent.
2. Learning rate is the hyperparameter that matters most. Too high and training diverges; too low and it never gets anywhere.

■ 52.14.5 How to read a model announcement

1. Separate the three kinds of claim before you read anything else.
2. **Established fact:** parameter count, context length, licence, price per million tokens, whether weights can be downloaded, release date.
3. **Active research:** benchmark scores, reasoning ability, agentic behaviour, long-context quality. These are measured, but the measurements are contested and move quickly.
4. **Marketing claim:** "state of the art", "PhD-level", "reasoning", "understands". These words have no agreed definition.
5. Then ask these ten questions.
6. Which exact benchmark, which version, and which prompting setup. A score with chain-of-thought and 64 samples is not comparable to a single-shot score.
7. Was the benchmark possibly in the training data. Contamination is common and usually undetectable from outside.
8. Is this a base model or an instruction-tuned model. They are not interchangeable.
9. What is the licence. "Open weights" means you can download the numbers. "Open source" properly means you also get the training data and code, which is rare.
10. What is the real context window, and is there an independent measurement of quality at the far end of it. Advertised context and usable context often differ.
11. What is the throughput in tokens per second, and at what batch size.
12. What is the price per million input tokens and per million output tokens.
13. Who ran the evaluation. First-party numbers should be treated as a claim until someone independent repeats them.
14. What is the cut-off date of the training data.
15. What is not mentioned. Announcements omit the benchmarks where the model did badly, and that omission is information.

52.15 Regular expressions

■ 52.15.1 The syntax table

Pattern	Means	Example match
.	any one character	a.c matches abc
^	start of string or line	^Hi
\$	end of string or line	end\$
*	zero or more of the last	ab* matches a
+	one or more of the last	ab+ matches ab
?	zero or one of the last	colou?r
{3}	exactly three	a{3} matches aaa
{2,4}	two to four	a{2,4}
{2,}	two or more	a{2,}
*?, +?	lazy, match as few as possible	<.+?>
[abc]	any one listed character	[aeiou]
[^abc]	any character not listed	[^0-9]
[a-z]	a range	[A-Za-z]
\d	a digit	same as [0-9]
\D	not a digit	
\w	word character	letters, digits, underscore
\W	not a word character	
\s	whitespace	space, tab, newline
\S	not whitespace	
\b	word boundary	\bcat\b
\B	not a word boundary	
\	either side	cat\ dog
()	group and capture	(ab)+
(?:)	group without capturing	(?:ab)+
(?<name>)	named capture group	
\1	what group 1 matched	(\w)\1 finds doubles
(?=)	followed by, lookahead	foo(=bar)
(?!)	not followed by	foo(?!bar)
(?<=)	preceded by, lookbehind	(?<=Rs)\d+
(?<!)	not preceded by	
\.	a literal dot	escapes the dot
(?i)	ignore case from here	

1. Flags are set outside the pattern in most languages: i ignore case, m multi-line so ^ and \$ match at each line, s so . also matches a newline, g find all matches.
2. Two warnings. Nested quantifiers such as (a+)+ can take exponential time on a failing input, which is a real denial-of-service class called catastrophic backtracking. And you cannot parse HTML with a regular expression; use a parser.

■ 52.15.2 Five patterns worth keeping

1. Match an IPv4 address, roughly:

```
| \b(?:\d{1,3}\.){3}\d{1,3}\b
```
2. It finds four groups of one to three digits separated by dots. It will also match 999.999.999.999, so validate the ranges afterwards in code. A regular expression that fully validates IPv4 is long and unreadable, and checking each number is under 256 in code is clearer.
3. Find the start of every log line with a timestamp:

```
| ^\d{4}-\d{2}-\d{2}[ T]\d{2}:\d{2}:\d{2}
```
4. This matches both 2026-08-13 14:05:09 and the ISO 8601 form with a T. Use it with `grep -E` to pick out real log lines and drop stack-trace continuation lines.
5. Match a quoted string, without running past the closing quote:

```
| "(?:[^\\"|\\\.])*"
```
6. The trick is `[^\\"|\\\.]`, which means any character that is not a quote and not a backslash, alternated with `\\.`, which means a backslash followed by anything. That handles escaped quotes inside the string.
7. Find a possible secret in a diff before you commit it:

```
| (?i)(api[_-]?key|secret|token|password)\s*[:=]\s*\S+
```
8. Run it with `git diff --staged | grep -E` before every commit. It produces false positives, which is the correct trade-off for this job.
9. Capture the status code and byte count from a common log format line:

```
| "\s(\d{3})\s(\d+|-)$
```
10. Group 1 is the HTTP status, group 2 is the response size or a dash. Pipe it through `awk` or `sed -E` to build a count by status code.

52.16 Keyboard shortcuts and editor basics

■ 52.16.1 Terminal

Keys	What it does
Cmd-T	new tab, macOS Terminal
Cmd-N	new window, macOS
Cmd-K	clear scrollbar, macOS
Ctrl-Shift-T	new tab, Linux terminals
Ctrl-Shift-C, Ctrl-Shift-V	copy, paste, Linux
Ctrl-A then D	detach from a tmux session
Ctrl-A then C	new tmux window
Ctrl-A then N	next tmux window

1. The tmux prefix is Ctrl-B by default; Ctrl-A is a very common reconfiguration and a convention rather than a default.

■ 52.16.2 Shell line editing

1. The shortcuts in section 52.9.6 are Emacs-style bindings, which is the default in bash and zsh.
2. If you prefer vi bindings, run `set -o vi`. Then Escape puts you in command mode and the vim movement keys work on the command line.
3. `Ctrl-R` then typing searches history backwards. Press `Ctrl-R` again to go further back. `Ctrl-G` cancels.

■ 52.16.3 Enough vim to edit a file and get out

1. vim has modes. That is the whole thing people find confusing. You start in normal mode, where letters are commands, not text.

Key	What it does
i	insert before the cursor
a	insert after the cursor
o	open a new line below
Escape	leave insert mode
h j k l	left, down, up, right
0	start of line
\$	end of line
gg	top of file
G	bottom of file
:42	go to line 42
/text then Enter	search forward
n	next match
x	delete one character
dd	delete the whole line
yy	copy the whole line
p	paste after the cursor
u	undo
Ctrl-R	redo
:w	write the file
:q	quit
:wq	write and quit
:q!	quit and throw away changes

2. The five you actually need, in order: press Escape to be sure you are in normal mode. Press i to type. Press Escape again. Type `:wq` and press Enter to save and leave. Type `:q!` and press Enter to leave without saving.
3. If a git command drops you into an editor you did not expect, that is vim, because it is the default `core.editor` on many systems. Change it with `git config --global core.editor "nano"` if you would rather.
4. nano is the friendly alternative. `Ctrl-O` writes, `Ctrl-X` exits, and it prints the shortcuts along the bottom of the screen.

52.17 What to do when you are stuck

■ 52.17.1 The debugging method

1. **Reproduce it.** A bug you cannot trigger on purpose cannot be fixed, only guessed at. Write down the exact steps.
2. **Read the actual error.** Not the summary. The first line and the deepest line of the stack.
3. **Establish what is true.** Write down three things you have proved and how you proved them. Write down three things you are assuming.
4. **Check the assumptions first.** Most bugs live there. The version you think you are running, the file you think you are editing, the environment variable you think is set.
5. **Bisect.** Cut the problem in half. Does the failure happen with half the input, half the config, half the code. `git bisect` does this over history automatically.
6. **Change one thing at a time.** Two changes at once means you learn nothing from the result.
7. **Look at the boundary.** Most faults sit where two systems meet: your code and a library, your machine and the network, your process and the filesystem.
8. **Ask what changed.** If it worked yesterday, something moved. A deployment, a certificate, a DNS record, a dependency update, a disk filling up.
9. **Explain it out loud** to a person or an object. Saying it in order forces the gap into view. This is called rubber-duck debugging, and it works because it makes you state your assumptions.
10. **Take a break.** After ninety minutes with no progress, stop. Returning with fresh attention beats another hour of the same.
11. **Write down the fix** and why it worked. The same problem will come back to you or to somebody else.

■ 52.17.2 How to read an error message

1. Read the **first** line and the **last** line before anything in between. The first says what went wrong. The last is often where it went wrong.
2. Find the **first line that mentions your own code.** Everything above it is usually library internals.
3. Separate the **error type** from the **message** from the **location**. `FileNotFoundException` is the type. The path is the message. The line number is the location.
4. Look for a number: an exit code, an `errno`, a status code, a signal number. Those are searchable and precise.
5. Common exit codes: 0 success, 1 general error, 2 misuse of a shell builtin, 126 found but not executable, 127 command not found, 130 interrupted by Ctrl-C, 137 killed by signal 9, often the out-of-memory killer.
6. Common `errno` values: 2 `ENOENT` no such file, 13 `EACCES` permission denied, 32 `EPIPE` broken pipe, 98 `EADDRINUSE` address already in use, 110 `ETIMEDOUT` connection timed out, 111 `ECONNREFUSED` connection refused.
7. Note what the error does **not** say. An error that says “connection refused” tells you something answered. An error that says “timed out” tells you nothing answered. Those are different problems.

■ 52.17.3 The minimal reproduction

1. Copy the failing thing into a new, empty directory or file.
2. Delete half of it. Does it still fail. If yes, delete half of what is left. If no, put it back and delete the other half.
3. Repeat until removing anything makes the failure go away.
4. What remains is the reproduction. It is usually five to twenty lines.
5. Remove your credentials, your company's names and your real data. Replace them with `example.com` and the documentation addresses from section 52.4.3.
6. Half the time the bug becomes obvious during this process, and you never need to ask anyone. That is not wasted effort; that is the method working.

■ 52.17.4 Searching effectively

1. Search the **exact error text**, in quotes, with your own paths, names and numbers removed.
2. Add the technology and the version: `postgres 16`, not `postgres`.
3. Add the year if the technology moves fast, or restrict the results to the last year. Answers about a 2019 version of a fast-moving tool are often wrong now.
4. Search the project's own issue tracker before the general web. The people who wrote the code discuss it there.
5. Read the official documentation for the exact version you are running. Not the latest, the one you have.
6. When an answer says "just disable the check", read why the check exists before doing it.
7. Prefer answers that explain the mechanism. An answer that gives you a command with no reason will not help you next time, and may not be safe.

■ 52.17.5 Asking a question that gets answered

1. Give these seven things, in this order, and you will get an answer.
2. **What you are trying to do**, in one sentence, at the level of the goal and not the current attempt.
3. **What you did**, as exact commands or code that someone else could run.
4. **What you expected** to happen.
5. **What actually happened**, pasted verbatim, including the full error, as text and not as a picture.
6. **Your environment**: operating system and version, tool versions, and how it was installed.
7. **What you have already tried** and what each attempt ruled out. This is the single line that most changes the quality of the answers, because it stops people suggesting things you have done.
8. **A minimal reproduction**, from section 52.17.3.
9. Two things not to do. Do not ask "does anyone know about X"; just ask the question. And do not describe the problem you invented while trying to solve the real one, without saying what the real one is; that is the most common reason a thread goes nowhere.
10. If you solve it yourself before anyone replies, post the answer. Somebody with the same problem will find it.

52.98 Common wrong ideas

1. Wrong: a failed ping means the host is down. Right: it means ICMP did not come back. Very many hosts drop ICMP deliberately and serve HTTPS perfectly.
2. Wrong: * * * at the end of a traceroute proves the fault is at that hop. Right: it proves those routers did not send ICMP time-exceeded messages, which is common and often deliberate.
3. Wrong: a timeout and a connection refused are both just failures. Right: refused means something answered and said no; a timeout means nothing answered at all. They point at different causes.

4. Wrong: private addresses in a traceroute mean something is misconfigured. Right: ISPs number their own cores privately as normal practice, which is why the reader saw 172.31, 172.26 and 172.16 addresses.
5. Wrong: `git rev-parse origin/main` tells you where the remote is. Right: it tells you where the remote was at your last fetch. Only `git ls-remote` asks the server.
6. Wrong: a disconnect during a push means the push did not happen. Right: the disconnect happened while reading the reply, so it says nothing about whether the write landed. Re-query and find out.
7. Wrong: 1 GB and 1 GiB are the same. Right: they differ by 7.4 per cent, and the gap grows with every step up the scale.
8. Wrong: MB/s and Mb/s are the same. Right: they differ by a factor of eight. A 100 Mbit/s line delivers about 12 MB/s at best.
9. Wrong: a green tick on a branch means your commit passed CI. Right: it means some run passed for something on that branch. Check the run's head SHA against your own.
10. Wrong: hashing a password with SHA-256 is secure storage. Right: SHA-256 is far too fast. Use Argon2id, scrypt or bcrypt with the parameters in section 52.13.3.

52.99 Chapter summary in 20 lines

1. This chapter is for looking things up, not for reading through.
2. Learn the latency ladder as shape, not as digits: cache in nanoseconds, memory in hundreds of nanoseconds, storage in microseconds, disks and networks in milliseconds.
3. Scaled to human time at one nanosecond per second, a cross-continent round trip is several years and a fifteen-second timeout is several centuries.
4. About one millisecond of round trip per hundred kilometres of fibre is a rule you can do in your head, and it is physics.
5. Learn 2^{10} , 2^{20} and 2^{30} , and the three that cause bugs: 2^{31} , 2^{32} and 2^{53} .
6. Decimal and binary prefixes differ by a percentage that grows with scale: 2.4 per cent at kilo, 7.4 at giga, 20.9 at yotta.
7. One hex digit is four bits and two are one byte. That is the only reason hexadecimal exists in computing.
8. UTF-8 costs one byte for English, two for most European scripts, three for Devanagari and East Asian scripts, four for emoji.
9. The seven OSI layers are the vocabulary; the four TCP/IP layers are what actually runs. Both statements are true together.
10. The private ranges are 10.0.0.0/8, 172.16.0.0/12 and 192.168.0.0/16, from RFC 1918, and the middle one reaches to 172.31.
11. For every command, ask two questions: what does a pass prove, and what does it not prove. That second question is the whole method.
12. For "I cannot reach a site", work upward: link, DNS, TCP, TLS, HTTP, content. Each pass eliminates everything below it.
13. Refused, unreachable and silent are three different failures with three different causes, and only the third costs you a full timeout.
14. Report a fault to an ISP in protocol terms with a control test, and never accuse anyone; the evidence supports a silent drop and does not name a party.
15. Almost every git command works offline, because the whole history is in the `.git` directory on your machine.

16. Git failures fall into five families: transport, authentication, scope, server-side rejection and local. Naming the family is most of the fix.
17. After any failed push, ask the server what it now believes with `git ls-remote` before doing anything else.
18. Quote your variables, start scripts with `set -euo pipefail`, and never pipe an unknown URL into a shell.
19. A magic number identifies a file; the extension only suggests one.
20. When stuck: reproduce, read the real error, separate what is proved from what is assumed, change one thing at a time, and write down the fix.

Master Timeline and Glossary

53.0 How to use this chapter

1. This is the last chapter, and it is the only one built for looking things up rather than reading straight through.
2. Every other chapter in this book teaches one topic twice: once in plain words, once in the engineer's words. This chapter holds the index to all of them.
3. Because it is a reference, it does not use the six-block shape that the rest of the book uses. It is a timeline, three smaller timelines, a long glossary, and two closing pages.
4. Section 53.1 is the master timeline of computing, from clay tokens around 3000 BCE to the state of things in 2026. Three columns: the year, what happened, and why it mattered.
5. Section 53.2 is a timeline of programming languages, with who made each one and what problem it was built for.
6. Section 53.3 is a timeline of standards and protocols: the written-down agreements that let machines from different makers work together.
7. Section 53.4 is the glossary. It is the main body of this chapter. It is alphabetical, one letter per heading, and it is meant to cover every term used anywhere in the 53 chapters.
8. Every glossary line has exactly three parts, separated by dashes: the term, then the plain meaning in one short sentence, then the technical meaning with the precise definition.
9. Read the plain meaning if you just want to follow a conversation. Read the technical meaning if you have to write it down, argue about it, or build it.
10. Section 53.5 is honest advice on what to do next. Section 53.6 compresses the whole book into exactly 100 numbered lines.
11. A word about dates. Where a thing has several defensible dates, we pick one and say which event it is: invented, first working, published, standardized or shipped. Those can be years apart.
12. Where experts genuinely disagree about a date, we say "about" and give the range. The Antikythera mechanism is the clearest case: published estimates cluster between 150 and 100 BCE.
13. Anything in this chapter dated 2025 or 2026 is recent enough that you should check it again before quoting it. Everything before about 2020 is settled history.
14. Two small conventions used throughout. BCE means before the common era, so the numbers count down. "c." is short for the Latin circa and means "about".

53.1 The master timeline of computing

The table below has one row per event. It is one continuous list in year order. Ancient dates are approximate by nature; modern ones are exact.

Year	Event	Why it mattered
c. 3000 BCE	Sumerian clay tokens	First stored count outside a head
c. 2700 BCE	Sumerian counting board	Ancestor of every abacus
c. 2000 BCE	Babylonian base-60 tables	Reusable answers, written down
c. 1900 BCE	Babylonian place value	Position of a digit carries value
c. 1550 BCE	Rhind papyrus copied	Oldest surviving arithmetic manual
c. 500 BCE	Chinese counting rods	Positional arithmetic with sticks
c. 300 BCE	Euclid writes the Elements	A procedure you can follow blindly
c. 300 BCE	Salamis counting tablet	Oldest surviving counting board
c. 100 BCE	Antikythera mechanism	Geared model of the sky, 30+ gears
c. 100 CE	Roman hand abacus	Calculation becomes portable
c. 499 CE	Aryabhata's Aryabhatiya	Indian decimal place value written
628 CE	Brahmagupta's rules for zero	Zero becomes a number, not a gap
c. 820 CE	Al-Khwarizmi on calculation	Gives us "algorithm" and "algebra"
c. 1200 CE	Chinese suanpan in wide use	Fast decimal arithmetic for trade
1202	Fibonacci's Liber Abaci	Arabic numerals reach Europe
1614	Napier publishes logarithms	Multiplying becomes adding
1617	Napier's bones described	Portable multiplication aid
1622	Oughtred's slide rule	Analogue calculation for 350 years
1623	Schickard's calculating clock	First known geared calculator
1642	Pascal builds the Pascaline	Geared adder with automatic carry
1673	Leibniz's stepped reckoner	First machine to multiply directly
1703	Leibniz publishes on binary	Base 2 arithmetic written down
1725	Bouchon's punched-tape loom	Holes in paper steer a machine
1728	Falcon's punched-card loom	Cards replace fragile tape
1801	Jacquard shows loom in Paris	Pattern separated from mechanism
1804	Jacquard head patented	The program becomes a thing you own
1822	Babbage's difference engine	Machine-made mathematical tables
1837	Cooke-Wheatstone telegraph	Messages faster than horses
1837	Analytical Engine designed	Mill, store, cards: a real computer
1838	Morse and Vail show their code	Letters become dots and dashes
1843	Lovelace publishes Note G	First published algorithm for a machine
1844	Washington to Baltimore line	Telegraph proven over distance

Year	Event	Why it mattered
1847	Boole's Mathematical Analysis	Logic written as algebra
1854	Boole's Laws of Thought	AND, OR and NOT get their rules
1858	First transatlantic cable works	Continents linked, then it failed
1866	Permanent Atlantic cable laid	The first reliable global network
1876	Bell patents the telephone	Sound itself travels on wires
1877	Edison's phonograph	Sound recorded and played back
1878	First telephone exchange	Switching, not point-to-point wires
1887	Hertz produces radio waves	Signals without any wire
1889	Hollerith patent 395,782	Counting by electricity and holes
1890	US census tabulated by machine	First mass data processing job
1896	Tabulating Machine Company	The firm that becomes IBM
1897	Thomson identifies the electron	The carrier of charge is named
1900	Hilbert lists 23 problems	Sets the century's maths agenda
1901	Marconi's transatlantic signal	Radio crosses an ocean
1904	Fleming's thermionic valve	First electronic one-way device
1906	De Forest's audion triode	Electronic amplification is possible
1911	CTR formed by merger	Punched cards become an industry
1924	CTR renamed IBM	Sixty years of dominance begin
1925	Bell Telephone Laboratories	Research lab behind much of this book
1928	The Entscheidungsproblem posed	Can proof itself be mechanized
1931	Godel's incompleteness theorems	Some true things cannot be proved
1936	Turing's On Computable Numbers	Defines what a computer can ever do
1936	Church's lambda calculus	A second, equivalent model of computing
1937	Shannon's relay thesis at MIT	Boolean algebra meets real wires
1937	Stibitz builds the Model K	Binary adder from relays, on a table
1938	Zuse's Z1 in a Berlin flat	Mechanical binary programmable machine
1939	Hewlett-Packard founded	The garage startup pattern begins
1940	Stibitz demonstrates remotely	First computing over a telegraph line
1941	Zuse's Z3 runs	First working program-driven computer
1942	Atanasoff-Berry Computer works	Electronic binary arithmetic, no program
1943	Colossus Mark 1 at Bletchley	First large-scale electronic computer

Year	Event	Why it mattered
1944	Harvard Mark I dedicated	US sequence-controlled calculator
1945	First Draft on the EDVAC	Stored-program design written down
1945	Bush's As We May Think	Imagines linked documents, the memex
1946	ENIAC shown to the press	Electronic speed becomes public news
1947	Transistor at Bell Labs	The end of the vacuum tube begins
1948	Manchester Baby runs a program	First stored program actually executed
1948	Shannon's theory of communication	Information gets a unit and a limit
1948	Wiener publishes Cybernetics	Feedback and control as one subject
1949	EDSAC enters regular service	Subroutines and a real user service
1950	Turing's imitation game paper	The question of machine thinking framed
1951	Ferranti Mark 1 delivered	First commercially sold computer
1951	UNIVAC I accepted by the census	Computing enters US government work
1952	Hopper's A-0 translator	The idea of a compiler appears
1952	UNIVAC predicts the election	Computers enter everyday speech
1953	IBM 701 shipped	IBM enters electronic computing
1953	Core memory in Whirlwind	Fast, reliable random-access memory
1954	Silicon transistor at TI	Silicon beats germanium on heat
1956	IBM 350 RAMAC disk drive	Random access to five megabytes
1956	Dartmouth workshop names AI	The field gets its name
1957	Fortran compiler delivered	Programming above the machine
1957	Sputnik launched	Panic that funds ARPA and the space race
1957	Eight leave Shockley	Fairchild, and then Silicon Valley
1958	Kilby demonstrates a circuit on one chip	Components without separate wires
1958	ARPA founded	The agency that funds the internet
1959	Noyce's planar integrated circuit	Chips can be made in quantity
1959	COBOL specified by CODASYL	Business data processing standardized
1959	DEC PDP-1 announced	Interactive computing begins
1960	ALGOL 60 report published	Block structure and formal grammar

Year	Event	Why it mattered
1960	Baran begins work at RAND	Networks that survive damage
1961	CTSS time-sharing demonstrated	Many users share one machine
1962	Licklider heads ARPA's IPTO	Funding aimed at networked computing
1962	Spacewar on the PDP-1	The first widely copied video game
1963	ASCII published	One agreed number per letter
1963	Sutherland's Sketchpad	Interactive graphics and constraints
1964	IBM System/360 announced	One family, one instruction set
1964	BASIC written at Dartmouth	Beginners can write programs
1964	Engelbart's first mouse	Pointing becomes an input method
1965	Moore's law article published	The industry gets a roadmap
1965	Davies coins the word packet	Data is chopped into labelled pieces
1965	DEC PDP-8 at \$18,500	The minicomputer era opens
1966	Taylor funds the ARPANET	The project is actually paid for
1968	Intel founded	The chip giant begins
1968	Engelbart's demo in San Francisco	Mouse, windows, hypertext, video call
1969	RFC 1 published	The open standards habit begins
1969	ARPANET's first message, 29 Oct	Two computers talk across a country
1969	Unix begun at Bell Labs	The operating system family that won
1969	AMD founded	A second source for chips
1970	Xerox PARC founded	Where the modern desktop was invented
1970	Codd's relational model paper	Data as tables you can query
1970	Intel 1103 DRAM shipped	Semiconductor memory beats magnetic core
1971	Intel 4004 announced	A whole processor on one chip
1971	Tomlinson sends network email	The @ sign is chosen as a separator
1971	IBM ships the floppy disk	Removable storage for everyone
1971	Project Gutenberg begins	Text made free and machine-readable
1972	C language at Bell Labs	Portable systems programming
1972	Atari's Pong released	Video games become a business
1972	ARPANET demonstrated publicly	Doubters are convinced
1973	Xerox Alto working	Screen, mouse, windows, network, all at once
1973	Metcalf's Ethernet memo	Local networks over one shared cable

Year	Event	Why it mattered
1973	Norway and UK join ARPANET	The network becomes international
1974	Cerf and Kahn's protocol paper	Networks of networks: the internet idea
1974	Intel 8080 released	The chip the hobbyists could buy
1975	Altair 8800 on sale	Personal computing starts in kit form
1975	Microsoft founded	Software becomes a separate industry
1975	MOS 6502 sold at \$25	Cheap CPU for home computers
1976	Apple founded	The other half of the home computer story
1976	Diffie and Hellman's paper	Secrets agreed over an open line
1976	Cray-1 delivered	Vector supercomputing arrives
1977	Apple II, PET and TRS-80	Computers you buy ready to use
1977	RSA public-key algorithm	Signatures and key exchange with maths
1977	Three-network TCP test	The internet idea proven end to end
1978	Intel 8086 released	The x86 line that still runs today
1978	TCP is split into TCP and IP	The thin waist of the internet appears
1978	Kernighan and Ritchie's C book	One small book teaches a generation
1979	VisiCalc released	The first application worth buying a computer for
1979	Usenet created	Global discussion with no owner
1979	Motorola 68000 released	The CPU behind the first Macs and Amigas
1980	Ethernet Blue Book published	Three firms agree one local network
1980	Sinclair ZX80 sold in the UK	Computers under 100 pounds
1981	IBM PC model 5150 announced	The business standard, and clones
1981	RFC 791 and RFC 793 published	IPv4 and TCP written down properly
1981	Xerox Star launched	The desktop metaphor goes on sale
1982	Sun Microsystems founded	Workstations and networked Unix
1982	Commodore 64 released	Best-selling single computer model ever
1982	SMTP defined in RFC 821	Email gets one agreed delivery protocol
1983	TCP/IP flag day, 1 January	The old protocol switched off overnight
1983	DNS proposed in RFC 882	Names stop living in one shared file

Year	Event	Why it mattered
1983	IEEE 802.3 Ethernet standard	Ethernet becomes vendor-neutral
1983	GNU project announced	Free software as an organized movement
1983	Apple Lisa launched	A graphical interface reaches the market
1984	Macintosh launched, 24 January	Graphical computing becomes affordable
1984	Cisco founded	Routing becomes a product
1984	ISO 7498 publishes the OSI model	Seven layers, the teaching vocabulary
1985	Windows 1.0 released	Microsoft enters graphical computing
1985	IEEE 754 floating point published	Every machine rounds the same way
1985	symbolics.com registered, 15 March	The first .com domain name
1985	ARM1 first works at Acorn	The CPU design now in every phone
1985	NSFNET begins	The research backbone that becomes the internet
1986	First IETF meeting	The internet's standards body forms
1987	Perl 1.0 released	Text processing and system glue
1987	RFC 1034 and 1035 published	DNS as it still works today
1987	Toshiba presents NAND flash	The storage in every phone and SSD
1987	IBM VGA introduced	640x480 becomes the baseline display
1988	The Morris worm, 2 November	First internet-wide security incident
1988	NSFNET upgraded to T-1	A 1.544 Mbit/s national backbone
1988	IRC written in Finland	Real-time text chat, still running
1989	Berners-Lee's web proposal	Linked documents over the internet
1989	RFC 1122 host requirements	What every internet host must do
1989	GNU General Public Licence v1	Copyleft in a legal document
1990	ARPANET decommissioned	The original network retires quietly
1990	First web server runs at CERN	info.cern.ch answers requests
1990	Windows 3.0 released	Windows finally sells in volume
1991	Linux kernel announced, 25 August	A free Unix-like kernel appears
1991	Web software released publicly	Anyone can run a server or a browser
1991	Python 0.9.0 released	Readability as a design goal
1991	Unicode 1.0 published	One number per character, all scripts

Year	Event	Why it mattered
1991	PGP released	Strong encryption in ordinary hands
1991	First GSM call made	Digital mobile telephony begins
1992	UTF-8 designed on a placemat	Unicode that does not break old software
1992	JPEG published as a standard	Photographs become small enough to send
1993	Mosaic browser released	Images inline, and the web grows fast
1993	CERN puts the web in public domain	No fee, no permission, no owner
1993	Intel Pentium released	The superscalar x86 era
1993	Doom released, 10 December	3D games and shareware distribution
1993	MP3 standardized in MPEG-1	Music files small enough to share
1994	Netscape founded	The web becomes an industry
1994	W3C founded	The web gets a standards body
1994	Linux 1.0 released	Free Unix reaches production quality
1994	Amazon founded	Retail moves online
1995	Netscape IPO, 9 August	The dot-com boom psychology begins
1995	NSFNET switched off, 30 April	The internet becomes commercial
1995	Windows 95 released, 24 August	The graphical PC becomes the default
1995	Java, JavaScript, PHP and Ruby	Four lasting languages in one year
1995	India's public internet, 15 August	VSNL opens dial-up to the public
1996	USB 1.0 published	One connector to replace many
1996	RFC 1918 private addresses	10.x, 172.16.x and 192.168.x reserved
1996	HTTP/1.0 written down, RFC 1945	The web's protocol described at last
1997	IEEE 802.11 published	Wireless local networking standardized
1997	HTTP/1.1 published, RFC 2068	Reused connections and virtual hosts
1997	Deep Blue beats Kasparov	Search plus hardware beats a champion
1998	Google founded, 4 September	Search becomes the front door
1998	ICANN incorporated	Names and numbers get a caretaker
1998	XML 1.0 published	Machine-readable structured text
1998	IPv6 specified in RFC 2460	128-bit addresses defined
1998	Bluetooth SIG founded	Short-range wireless gets an owner

Year	Event	Why it mattered
1999	Napster launched	Peer-to-peer file sharing at scale
1999	802.11b and the Wi-Fi name	Wireless becomes a consumer product
1999	TLS 1.0 published, RFC 2246	SSL becomes an open standard
1999	Nvidia GeForce 256	The word GPU enters common use
2000	NASDAQ peaks, 10 March	5,048.62, then a long fall
2000	USB 2.0 published	480 Mbit/s makes USB storage practical
2000	GPS accuracy degradation ended	Civil GPS becomes ten times better
2000	DDR SDRAM standardized	Two transfers per clock in main memory
2001	Wikipedia launched, 15 January	Reference work written by everyone
2001	Mac OS X 10.0 released	A Unix core under a consumer desktop
2001	Windows XP released	The PC desktop for a decade
2001	iPod released	Portable digital music goes mainstream
2001	Agile Manifesto published	A named alternative to big up-front plans
2001	IBM POWER4 has two cores	Multicore processors begin
2002	The Bezos API mandate	Teams must talk only through interfaces
2003	AMD Opteron ships x86-64	64-bit on ordinary hardware
2003	PCI Express 1.0 published	Serial lanes replace parallel buses
2003	Skype released	Voice calls over the public internet
2003	Steam launched	Games delivered without discs
2004	Facebook launched, 4 February	Social networking at national scale
2004	Firefox 1.0 released	Browser competition returns
2004	Gmail beta, 1 April	Applications move into the browser
2004	Ubuntu 4.10 released	Linux packaged for ordinary users
2005	BitKeeper licence withdrawn	The trigger for writing git
2005	Git's first commit, 7 April	Distributed version control done right
2005	YouTube founded	Video becomes a normal web object
2005	Dual-core desktop chips ship	The clock speed race ends
2006	Amazon S3 launched, 14 March	Storage rented by the gigabyte-month
2006	Amazon EC2 beta, 25 August	Servers rented by the hour
2006	Twitter launched	Short public messages at scale
2006	Hadoop released	Batch processing across cheap machines

Year	Event	Why it mattered
2007	iPhone announced, 9 January	The pocket computer with a real browser
2007	CUDA released	GPUs become general-purpose compute
2007	Android announced, 5 November	An open phone platform for everyone else
2007	Netflix begins streaming	Video moves from post to packets
2008	Bitcoin white paper, 31 October	Money without a central ledger keeper
2008	Chrome released, 2 September	Fast JavaScript and per-tab isolation
2008	GitHub launched	Code hosting becomes social
2008	First Android phone ships	The two-platform phone world begins
2008	App Store opens, 10 July	Software distribution through one gate
2008	USB 3.0 published	5 Gbit/s over a compatible connector
2009	Bitcoin genesis block, 3 January	The chain actually starts
2009	Node.js released	JavaScript on the server
2009	Go announced, 10 November	Simple concurrency for server software
2009	IEEE 802.11n published	MIMO takes Wi-Fi past 100 Mbit/s
2010	iPad released	Tablets become a product category
2010	Bluetooth 4.0 adds Low Energy	Coin-cell devices join the network
2010	Stuxnet discovered	Software as a weapon against machinery
2010	OpenStack launched	Open-source infrastructure clouds
2011	IANA runs out of IPv4, 3 February	The address shortage becomes real
2011	IBM Watson wins Jeopardy	Statistical language systems go public
2011	Siri ships on the iPhone 4S	Voice assistants reach the mainstream
2011	Smartphones outsell PCs	The centre of computing moves
2012	AlexNet wins ImageNet	Deep learning on GPUs beats everything
2012	World IPv6 Launch, 6 June	IPv6 turned on permanently by big sites
2012	Raspberry Pi released	A 35-dollar computer for learning
2012	DDR4 standard published	Higher density at lower voltage
2013	Docker released, March	Containers become easy to use
2013	Snowden disclosures begin, June	Encryption everywhere becomes the norm

Year	Event	Why it mattered
2013	IEEE 802.11ac published	Gigabit Wi-Fi in the 5 GHz band
2014	Kubernetes announced, June	Cluster orchestration gets a standard
2014	Heartbleed disclosed, 7 April	One buffer bug affects half the web
2014	Swift announced	Apple replaces Objective-C
2014	USB Type-C specified	A reversible connector for everything
2015	HTTP/2 published, RFC 7540	Binary framing and multiplexed streams
2015	Kubernetes 1.0 and the CNCF	Container orchestration becomes neutral
2015	Let's Encrypt begins issuing	Free automated certificates for all
2015	Rust 1.0 released, 15 May	Memory safety without a garbage collector
2015	TensorFlow released	Machine learning frameworks go public
2016	AlphaGo beats Lee Sedol, March	Search plus learning solves Go
2016	Mirai botnet DDoS, 21 October	Insecure home devices break big services
2016	Bluetooth 5.0 published	Four times the range for Low Energy
2016	PyTorch released	Define-by-run makes research faster
2017	Attention Is All You Need, June	The transformer architecture published
2017	WannaCry ransomware, 12 May	Unpatched machines at national scale
2017	PCI Express 4.0 published	16 GT/s per lane
2018	Meltdown and Spectre, 3 January	Speculation leaks data across boundaries
2018	GDPR takes effect, 25 May	Data protection with real penalties
2018	TLS 1.3 published, RFC 8446	Fewer round trips, forward secrecy only
2018	GPT-1 and then BERT	Pretraining plus fine-tuning wins in NLP
2018	Microsoft agrees to buy GitHub	Open source and big vendors converge
2019	GPT-2 released in stages	Staged release becomes a debate
2019	Wi-Fi 6 certification opens	OFDMA brings order to crowded air
2019	PCI Express 5.0 published	32 GT/s per lane
2019	USB4 specification published	Thunderbolt's tunnelling becomes open
2020	GPT-3 shows in-context learning	Scale alone changes what a model can do
2020	Apple M1 ships, November	ARM reaches the desktop with real speed

Year	Event	Why it mattered
2020	DDR5 standard published, July	4800 MT/s and on-module regulation
2020	Remote work at global scale	Video and cloud tools become essential
2021	GitHub Copilot preview, June	Code completion from a language model
2021	Log4Shell disclosed, 9 December	One logging library, global emergency
2021	IEEE 802.11ax approved	Wi-Fi 6 becomes a full standard
2022	PCI Express 6.0 published	PAM4 signalling and forward error correction
2022	HTTP/3 published, RFC 9114	HTTP over QUIC, on top of UDP
2022	The Chinchilla paper, March	Data, not just parameters, sets quality
2022	Stable Diffusion released, August	Image generation with open weights
2022	ChatGPT released, 30 November	Language models reach the general public
2023	GPT-4 released, 14 March	Multimodal input and much stronger results
2023	Llama and Llama 2 released	Open-weight models become serious
2023	Claude released, 14 March	A second major assistant family
2023	EU AI Act agreed, December	The first broad legal framework for AI
2024	Wi-Fi 7 certification, 8 January	320 MHz channels and multi-link operation
2024	Nvidia Blackwell announced	208 billion transistors in two dies
2024	Bluetooth 6.0 published	Channel sounding measures true distance
2024	El Capitan tops the TOP500	About 1.74 exaflops at Livermore
2024	Unicode 16.0 published	154,998 characters defined
2024	EU AI Act in force, 1 August	Obligations start phasing in
2025	PCI Express 7.0 specification	128 GT/s per lane, no products yet
2025	Reasoning models become normal	Models spend compute at answer time
2025	2 nm class production starts	Gate-all-around transistors in volume
2026	Agentic tools in daily use	Models call tools and run multi-step work
2026	Long contexts are routine	Whole codebases fit in one request
2026	On-device inference is common	Small models run on phones and laptops

53.2 Timeline of programming languages

The year given is the year the language first worked or was first released, not the year it was designed or the year it became popular. Those can differ by a decade.

Year	Language	Creator	What it was for
1949	Short Code	Mauchly and Schmitt	Readable arithmetic on UNIVAC
1952	Autocode	Alick Glennie	First compiler, Manchester Mark 1
1952	A-0	Grace Hopper	Assembling reusable subroutines
1956	IPL	Newell, Shaw, Simon	Lists and symbols for early AI
1957	FORTRAN	John Backus, IBM	Scientific and numerical work
1958	ALGOL 58	International committee	Publishing algorithms clearly
1958	LISP	John McCarthy	Symbolic computing and AI
1959	COBOL	CODASYL committee	Business records and reports
1960	ALGOL 60	Naur, Backus and others	Block structure, formal grammar
1962	APL	Kenneth Iverson	Whole-array mathematics
1962	Simula I	Dahl and Nygaard	Simulating real-world systems
1964	BASIC	Kemeny and Kurtz	Teaching students to program
1964	PL/I	IBM	One language for all workloads
1967	Simula 67	Dahl and Nygaard	Classes and objects, the first time
1967	Logo	Papert and colleagues	Teaching children with a turtle
1970	Pascal	Niklaus Wirth	Teaching structured programming
1970	Forth	Charles Moore	Small stack-based control systems
1972	C	Dennis Ritchie	Writing Unix portably
1972	Prolog	Colmerauer and Roussel	Rules and logical deduction
1972	Smalltalk	Alan Kay's team, PARC	Objects, messages, live interfaces
1973	ML	Robin Milner	Proofs, with inferred types
1975	Scheme	Sussman and Steele	A tiny, clean Lisp
1977	awk	Aho, Weinberger, Kernighan	One-line text processing
1979	Bourne shell	Stephen Bourne	Gluing Unix commands together
1979	SQL, first product	Chamberlin and Boyce	Asking questions of tables

Year	Language	Creator	What it was for
1980	Ada	Ichbiah for the US DoD	Long-lived safety-critical systems
1983	C++	Bjarne Stroustrup	Objects with no speed penalty
1984	Verilog	Moorby and Gateway	Describing hardware, not software
1984	MATLAB, commercial	Cleve Moler	Matrix and signal mathematics
1984	Objective-C	Cox and Love	Smalltalk-style objects over C
1985	PostScript	Warnock and Geschke	Telling a printer what a page is
1986	Erlang	Armstrong at Ericsson	Phone switches that never stop
1987	Perl	Larry Wall	Reports, text and system glue
1987	VHDL	US DoD project	Hardware description, IEEE 1076
1989	Bash	Brian Fox for GNU	A free, extended Bourne shell
1990	Haskell	Academic committee	Pure, lazy functional research
1991	Python	Guido van Rossum	Readable general-purpose code
1991	Visual Basic	Microsoft	Building Windows apps quickly
1993	Lua	Ierusalimschy and team	Small language embedded in apps
1993	R	Ihaka and Gentleman	Statistics and data graphics
1995	Java	James Gosling, Sun	One binary on many machines
1995	JavaScript	Brendan Eich, Netscape	Small scripts inside web pages
1995	PHP	Rasmus Lerdorf	Pages built on the server
1995	Ruby	Yukihiro Matsumoto	Programming that feels pleasant
1996	OCaml	INRIA team	ML with objects and speed
2000	C#	Anders Hejlsberg, Microsoft	Applications on .NET
2003	Scala	Martin Odersky	Objects and functions on the JVM
2005	F#	Don Syme, Microsoft	Functional programming on .NET
2007	Clojure	Rich Hickey	A Lisp with immutable data
2009	Go	Griesemer, Pike, Thompson	Simple, fast server programs
2011	Dart	Google	Web apps, later Flutter
2012	Elixir	Jose Valim	Erlang's reliability, nicer syntax

Year	Language	Creator	What it was for
2012	TypeScript	Anders Hejlsberg, Microsoft	Types added to JavaScript
2012	Julia	Bezanson and colleagues	Fast numerical computing
2014	Swift	Chris Lattner, Apple	Safer apps for Apple platforms
2014	Solidity	Gavin Wood and others	Contracts running on Ethereum
2015	Rust 1.0	Graydon Hoare, Mozilla	Safety without a garbage collector
2016	Kotlin 1.0	JetBrains	Concise, safer code for Android
2016	Zig	Andrew Kelley	C's job with fewer surprises
2023	Mojo	Chris Lattner, Modular	Python-like code for AI hardware

53.3 Timeline of standards and protocols

A standard is a document. It says what a thing must do so that two products made by strangers will work together. The number after the name is the document you can look up.

Year	Standard	What it defined
1963	ASCII, ASA X3.4	7-bit codes for 128 characters
1967	ASCII revision	Lower case and control codes settled
1969	RFC 1	The RFC document series itself
1974	Cerf-Kahn TCP paper	Internetworking between networks
1980	RFC 768, UDP	Send a datagram, no promises
1980	Ethernet Blue Book, DIX	10 Mbit/s over one shared cable
1981	RFC 791, IPv4	32-bit addresses and the IP header
1981	RFC 792, ICMP	Error and diagnostic messages
1981	RFC 793, TCP	Ordered, reliable byte streams
1982	RFC 821, SMTP	How mail moves between servers
1982	RFC 826, ARP	IP address to MAC address on a LAN
1983	IEEE 802.3	Ethernet as a vendor-neutral standard
1983	RFC 882 and 883	The first DNS design
1984	ISO 7498, OSI model	Seven named layers for teaching
1985	IEEE 754	Binary floating point, all machines alike
1985	RFC 959, FTP	File transfer with a control channel
1986	ISO 9660	The CD-ROM filesystem

Year	Standard	What it defined
1987	RFC 1034 and 1035	DNS as still used today
1988	IEEE 802.1D	Spanning tree, loop-free bridging
1989	RFC 1122 and 1123	What every internet host must do
1990	IEEE 1076, VHDL	Hardware description as a standard
1991	Unicode 1.0	One code point per character
1992	ITU T.81, JPEG	Lossy image compression
1993	RFC 1459, IRC	Real-time chat rooms
1993	ISO/IEC 11172-3, MP3	Perceptual audio compression
1993	RFC 1519, CIDR	Prefix lengths replace address classes
1993	UTF-8 in the X/Open standard	Unicode as bytes, ASCII-compatible
1994	RFC 1738, URLs	The shape of a web address
1995	SSL 3.0	Encrypted web sessions, now obsolete
1996	RFC 1918	Private address ranges for local use
1996	RFC 1945, HTTP/1.0	Request line, headers, body
1996	USB 1.0	12 Mbit/s, one connector, hot plug
1997	RFC 2068, HTTP/1.1	Keep-alive, host header, chunking
1997	IEEE 802.11	Wireless LAN at 1 and 2 Mbit/s
1997	RFC 2131, DHCP	Automatic address assignment
1998	RFC 2460, IPv6	128-bit addresses, simpler header
1998	RFC 2373, IPv6 addressing	Address types and text notation
1999	RFC 2246, TLS 1.0	SSL becomes an IETF standard
1999	RFC 2616, HTTP/1.1	The version everyone implemented
1999	IEEE 802.11b	11 Mbit/s at 2.4 GHz
1999	IEEE 802.11a	54 Mbit/s at 5 GHz, OFDM
1999	Bluetooth 1.0	Short-range personal wireless links
1999	IEEE 802.1Q	VLAN tags inside Ethernet frames
2000	USB 2.0	480 Mbit/s high speed
2000	JEDEC JESD79, DDR	Data on both clock edges
2001	RFC 3168, ECN	Congestion signalled, not dropped
2003	IEEE 802.11g	54 Mbit/s at 2.4 GHz
2003	PCI Express 1.0	2.5 GT/s serial lanes
2003	JEDEC DDR2	4n prefetch, lower voltage
2003	WPA, then WPA2 in 2004	Wi-Fi encryption that actually works
2004	Bluetooth 2.0 + EDR	About 3 Mbit/s over the same radio

Year	Standard	What it defined
2005	RFC 4271, BGP-4	How networks tell each other routes
2006	RFC 4291, IPv6 addressing	The current IPv6 address rules
2006	RFC 4443, ICMPv6	Errors and neighbour discovery for v6
2006	RFC 4346, TLS 1.1	Fixes for CBC attacks
2007	PCI Express 2.0	5 GT/s per lane
2007	JEDEC DDR3	8n prefetch, 1.5 V
2008	RFC 5246, TLS 1.2	SHA-256 and AEAD cipher suites
2008	RFC 5321, SMTP	The current mail transfer standard
2008	IEEE 754-2008	Decimal formats and fused multiply-add
2008	USB 3.0	5 Gbit/s SuperSpeed, extra wires
2009	IEEE 802.11n	MIMO, 40 MHz, frame aggregation
2009	Bluetooth 3.0 + HS	Wi-Fi used for the bulk transfer
2010	Bluetooth 4.0	Low Energy, GATT, coin-cell devices
2010	PCI Express 3.0	8 GT/s, 128b/130b encoding
2011	RFC 6265, cookies	How browsers store and send cookies
2011	RFC 6455, WebSocket	A two-way channel over one HTTP port
2012	RFC 6598, shared space	100.64.0.0/10 for carrier NAT
2012	RFC 6749, OAuth 2.0	Delegated access without passwords
2012	JEDEC DDR4	1.2 V, bank groups, higher density
2013	IEEE 802.11ac	80 and 160 MHz, 256-QAM, MU-MIMO
2014	RFC 7230 to 7235	HTTP/1.1 rewritten as six documents
2014	USB Type-C 1.0	A reversible 24-pin connector
2014	Bluetooth 4.2	Privacy, longer packets, IPv6 support
2015	RFC 7540, HTTP/2	Binary frames, streams, header compression
2015	RFC 7519, JWT	A signed token you can read
2016	Bluetooth 5.0	Four times the range, twice the speed
2017	IEEE 754-2019 work begins	Refinement of the 2008 revision
2017	PCI Express 4.0	16 GT/s per lane
2017	USB 3.2	20 Gbit/s using two lanes
2018	RFC 8446, TLS 1.3	One round trip, forward secrecy only
2018	RFC 8200, IPv6	IPv6 promoted to full internet standard
2019	PCI Express 5.0	32 GT/s per lane

Year	Standard	What it defined
2019	USB4	Tunnelling, 40 Gbit/s, Type-C only
2019	WPA3 required for new Wi-Fi	Individual encryption, better handshake
2020	JEDEC DDR5	4800 MT/s, on-module power regulation
2021	RFC 9000, QUIC	Reliable streams on top of UDP
2021	IEEE 802.11ax, Wi-Fi 6	OFDMA, 1024-QAM, target wake time
2022	RFC 9110 to 9114	HTTP semantics, and HTTP/3 over QUIC
2022	PCI Express 6.0	64 GT/s, PAM4, forward error correction
2022	USB4 Version 2.0	80 Gbit/s, and 120 Gbit/s one way
2024	Wi-Fi 7 from IEEE 802.11be	320 MHz, 4096-QAM, multi-link operation
2024	Bluetooth 6.0	Channel sounding for true distance
2024	Unicode 16.0	154,998 characters across 168 scripts
2025	PCI Express 7.0	128 GT/s per lane, on paper first

53.4 The glossary

Every line has the same three parts: the term, the plain meaning, then the technical meaning. Where a word means two different things in two fields, both senses are given as separate lines.

■ 53.4.1 A

1. **A record** — the DNS entry holding an IPv4 address — a resource record of type A mapping a name to a 32-bit address; AAAA does the same for IPv6.
2. **ABI** — the binary rulebook two compiled parts must share — application binary interface: calling convention, register use, struct layout, symbol naming.
3. **Abstraction** — hiding detail behind a simpler idea — a layer offering a stable interface while the implementation beneath is free to change.
4. **Activation** — a number flowing through a network as it runs — a layer's output for one input, alive only during the pass and not part of the model.
5. **Activation function** — the bend that stops a network being one straight line — an elementwise nonlinearity such as ReLU, GELU or SwiGLU.
6. **ADC** — turns a real signal into numbers — analogue-to-digital converter, sampling a voltage at a fixed rate and quantizing to a fixed bit depth.
7. **Address space** — every address a program is allowed to name — the range of addresses a process can generate, commonly 2^{48} bytes of user space on 64-bit systems.
8. **AES** — the normal way to scramble bulk data — Advanced Encryption Standard, 128-bit block cipher with 128, 192 or 256-bit keys, FIPS 197, 2001.
9. **Agent** — a model that acts instead of only answering — a loop where a model picks a tool call, the tool runs, the result returns, until a stop condition.
10. **Aliasing** — false patterns from sampling too slowly — signal components above half the sample rate folding back as lower, wrong frequencies.

11. **Alignment** (memory) — putting data at tidy addresses — placing an object at an address that is a multiple of its size, required or faster on most architectures.
12. **Alignment** (AI) — making a model behave as intended — the work of getting model behaviour to match stated human intent, values and constraints.
13. **Allocator** — the code that hands out memory — the runtime or kernel component that finds, records and returns memory blocks to callers.
14. **Alpha channel** — how see-through a pixel is — a per-pixel opacity value, usually 8 bits, used when compositing layers.
15. **ALU** — the part that does the sums — arithmetic logic unit, a combinational block performing add, subtract, bitwise and shift operations and setting flags.
16. **Amdahl's law** — the slow part limits your speedup — speedup is bounded by $1/(s + p/N)$ for serial fraction s over N processors.
17. **Ampere** — how much electricity flows per second — the SI unit of current, one coulomb of charge per second.
18. **Amplitude** — how big a wave is — the peak deviation of a signal from its resting value; in audio it maps to loudness.
19. **Analogue** — smoothly varying, not stepped — a signal that may take any value in a continuous range, unlike a digital signal with discrete levels.
20. **Anti-aliasing** — smoothing jagged edges — MSAA, FXAA, TAA and similar methods that add or reuse samples to reduce sampling artefacts.
21. **Anti-cheat** — software that catches players who cheat — combined client integrity checks, server-authoritative rules and statistical detection.
22. **Anycast** — one address, many machines — announcing the same prefix from several sites so each client reaches the topologically nearest one.
23. **Apex domain** — the bare name with no www — the zone's own name, such as example.com, which cannot hold a CNAME under standard DNS rules.
24. **API** — an agreed way for programs to ask each other for things — the endpoints, functions, arguments and guarantees one piece of software offers another.
25. **Argon2** — a password hash built to be slow and greedy for memory — winner of the 2015 Password Hashing Competition, with time, memory and parallelism costs.
26. **ARM** — the processor family in nearly every phone — a RISC architecture licensed as designs by Arm Ltd, first silicon working in 1985.
27. **ARP** — finding a neighbour's hardware address — Address Resolution Protocol, RFC 826, broadcasting for the MAC address owning an IPv4 address on the link.
28. **ARPANET** — the network the internet grew out of — the ARPA-funded packet network, first message 29 October 1969, retired 1990.
29. **Artifact** — a file a build makes and keeps — a stored pipeline output such as a binary, image or test report, retained for later jobs or download.
30. **ASCII** — numbers for English letters — a 7-bit character set from 1963 with 128 code points, 95 printable and 33 control codes.
31. **ASLR** — moving things so attackers cannot guess addresses — address space layout randomization of stack, heap and library bases at load time.
32. **Assembler** — turns readable instructions into machine code — a translator producing one machine instruction per mnemonic and resolving labels and directives.
33. **Assembly language** — machine code you can read — a notation with one mnemonic per instruction, plus labels, macros and assembler directives.
34. **AST** — a program drawn as a tree — abstract syntax tree, the parser's output, with nodes for

expressions and statements and no punctuation.

35. **Asynchronous** — start now, collect the answer later — an operation returning before completion, signalling later by callback, event, future or poll.
36. **Atomic** — all at once or not at all — an operation no observer can see half-finished, enforced by hardware instructions, locks or transactions.
37. **Attention** — letting each word look at the others — a weighted sum of value vectors, weighted by the scaled dot product of one query with every key.
38. **Attenuation** — a signal weakening with distance — loss of power along a path, measured in decibels, from resistance, absorption or spreading.
39. **Authoritative server** — the machine holding the real answer for a name — a DNS server answering from its own zone data rather than from cache.
40. **Autonegotiation** — two ports agreeing a speed by themselves — Ethernet link partners exchanging capability pulses and choosing the best shared speed and duplex.
41. **Autonomous system** — one network under one routing policy — an AS with a 16 or 32-bit number that announces its prefixes to neighbours using BGP.
42. **Availability** — how much of the time it works — uptime as a fraction; 99.9 percent permits about 43 minutes of downtime per month.
43. **Availability zone** — one isolated site inside a cloud region — a data centre with independent power and cooling, linked to its region at low latency.
44. **AVX** — wide maths instructions on x86 chips — Advanced Vector Extensions, SIMD sets using 256-bit registers, or 512-bit in AVX-512.

■ 53.4.2 B

1. **Backpressure** — telling the sender to slow down — a flow-control signal propagated upstream when a consumer cannot keep up.
2. **Backpropagation** — working out which weight caused which mistake — reverse-mode automatic differentiation applying the chain rule from the loss back to every parameter.
3. **Bandwidth** — how much can flow per second — the data rate of a link in bits per second, distinct from latency, which is delay.
4. **Bandwidth throttling** — deliberately slowing traffic — rate limiting applied by policy at a network device, service or account level.
5. **Bandwidth-delay product** — how much data fits inside the wire — bandwidth multiplied by round-trip time, the amount that must be in flight to keep a link full.
6. **Bank** (memory) — one independently addressed section of a chip — a DRAM subdivision with its own row buffer, allowing one row open per bank.
7. **Bare repository** — a git repository with no working files — a repository containing only the object database and refs, normally used as a push target.
8. **Base model** — the raw model before it is taught manners — a network trained only on next-token prediction, not yet instruction-tuned or preference-tuned.
9. **Base station** — the mast your phone talks to — the mobile network's radio equipment serving one or more cells, called an eNodeB in LTE and gNodeB in 5G.
10. **Batch** — a handful of examples processed together — the group of samples whose gradients are averaged before one parameter update.
11. **bcrypt** — an old but sound password hash — a 1999 adaptive hash based on Blowfish, with a cost factor that raises work as hardware improves.
12. **Beamforming** — aiming a radio signal instead of shouting everywhere — controlling phase across several antennas so signals add in one direction and cancel elsewhere.

13. **Benchmark** — a test everyone runs so results can be compared — a fixed task and scoring rule; it measures the benchmark first and the world second.
14. **BGP** — how networks tell each other which routes they have — Border Gateway Protocol, RFC 4271, a path-vector protocol carrying prefixes and AS paths between autonomous systems.
15. **Bias** (AI) — the number added after the multiply — a per-unit learned constant added to the weighted sum before the activation function.
16. **Big-endian** — the biggest byte first — a byte order storing the most significant byte at the lowest address; network byte order is big-endian.
17. **Binary** — counting with only 0 and 1 — base-2 positional notation, where each place is worth twice the one to its right.
18. **Binary search** — halving the haystack each time — locating a value in sorted data in $O(\log n)$ comparisons by discarding half the range each step.
19. **Binning** — sorting finished chips by how good they turned out — testing dies and selling them at the highest speed and core count they pass.
20. **BIOS** — the old start-up firmware on PCs — the 16-bit firmware that initializes hardware and loads a 512-byte boot sector, superseded by UEFI.
21. **Bisect** — a binary search through history for the bad commit — git bisect, halving the commit range each test to find the first bad commit in $\log_2(n)$ steps.
22. **Bit** — one on-or-off — a binary digit, the smallest unit of information, value 0 or 1.
23. **Bit depth** — how many steps a sample can take — the number of bits per sample; 16-bit audio gives 65,536 levels and about 96 dB of dynamic range.
24. **Bit rot** — data quietly going bad — undetected corruption of stored bits from charge leakage, media decay or cosmic rays, caught only by checksums.
25. **BLE** — the low-power half of Bluetooth — Bluetooth Low Energy, introduced in version 4.0 in 2010, using 40 channels and short connection events.
26. **BLE GATT** — the rules for reading a small value over Bluetooth — Generic Attribute Profile, a table of services and characteristics addressed by handle and UUID.
27. **Blob** — git's word for a file's contents — a git object holding raw bytes, named by the SHA-1 or SHA-256 of a header plus the content.
28. **Block** (storage) — the smallest lump a drive reads or writes — a fixed-size unit, 512 bytes or 4096 bytes on disks, and typically 128 KiB to 4 MiB in NAND erase blocks.
29. **Blocking** — waiting instead of doing something else — a call that does not return until its work completes, holding the calling thread.
30. **Boolean algebra** — the maths of true and false — an algebra over $\{0,1\}$ with AND, OR and NOT, shown by Shannon in 1937 to describe switching circuits.
31. **Boot sector** — the very first block a machine reads from a disk — the first 512-byte sector, holding MBR partition entries and a small loader on legacy systems.
32. **Bootloader** — the small program that starts the real one — code that loads and hands control to a kernel, such as GRUB, systemd-boot or U-Boot.
33. **Bootstrapping** — a compiler built with itself — writing a compiler for a language in that same language, after first compiling it with another one.
34. **Boule** — the big silicon crystal a wafer is sliced from — a single-crystal ingot, typically 300 mm across, pulled from a melt by the Czochralski process.
35. **BPE** — cutting text into common chunks — byte-pair encoding, repeatedly merging the most frequent adjacent pair to build a fixed-size subword vocabulary.
36. **Branch** (CPU) — an instruction that may jump — a control-flow instruction whose target or direction may depend on a condition.

37. **Branch** (git) — a moving name for a line of work — a ref under refs/heads that points at one commit and moves forward as you commit.
38. **Branch prediction** — guessing which way a jump goes before knowing — hardware predicting direction and target so the pipeline keeps fetching; a wrong guess costs the pipeline depth.
39. **Bridge** — a device joining two network segments — a layer 2 device forwarding frames by learned MAC address; a switch is a multi-port bridge.
40. **BSSID** — the identity of one specific access point — the 48-bit MAC address of an access point's radio, unlike an SSID, which is a network name.
41. **Buffer** — a waiting area for data — memory holding data between a producer and a consumer running at different speeds.
42. **Buffer overflow** — writing past the end of a box — writing beyond an allocation's bounds, corrupting adjacent memory and often control data such as return addresses.
43. **Bufferbloat** — too much queueing makes everything feel slow — excessive buffering in network devices that inflates latency under load without preventing loss.
44. **Bus** — a shared set of wires — a set of conductors and rules carrying address, data and control signals between components.
45. **Byte** — eight bits, the usual unit of size — an octet, 8 bits, able to hold 256 distinct values.
46. **Bytecode** — halfway between source and machine code — a compact instruction set for a virtual machine, such as JVM bytecode or Python's .pyc format.

■ 53.4.3 C

1. **Cache** — a small fast copy of things you keep needing — memory holding recently or likely used data closer to the consumer than the original.
2. **Cache coherence** — keeping every core's copy honest — a protocol such as MESI ensuring all cores see one consistent value for each cache line.
3. **Cache hit** — the copy was already there — a request satisfied from the cache without going to the slower backing store.
4. **Cache line** — the block a cache moves as one unit — the unit of transfer between cache levels, 64 bytes on most current x86 and ARM designs.
5. **Cache miss** — the copy was not there — a request that must be served from the next level, costing that level's latency.
6. **Callback** — code you hand over to be run later — a function passed to another routine to be invoked when an event or completion occurs.
7. **Canary release** — trying a change on a few users first — routing a small share of traffic to a new version and watching error rates before wider rollout.
8. **Capability** — permission attached to a token, not a person — a transferable right to do a specific operation, held as an unforgeable reference.
9. **Capacitor** — a component that stores a little charge — two conductors separated by a dielectric, storing charge Q equal to capacitance C times voltage V .
10. **CDN** — copies of a site kept near users — content delivery network: caches in many locations, steered by DNS or anycast to reduce distance and origin load.
11. **Certificate** — a signed statement that a key belongs to a name — an X.509 document binding a public key to identifiers, signed by an issuer and valid between two dates.
12. **Certificate authority** — an organization browsers already trust — a CA whose root certificate ships in trust stores and which signs certificates after validating control of a name.
13. **Certificate pinning** — accepting only one specific certificate — a client refusing certificates other than pinned keys, ignoring the wider CA set.

14. **CGNAT** — your provider sharing one public address between many homes — carrier-grade NAT, usually using 100.64.0.0/10 from RFC 6598.
15. **cgroup** — a fence around how much a process may use — a Linux control group limiting and accounting CPU, memory, I/O and process counts for a set of tasks.
16. **Chain of trust** — a signed line from a root to your site — the verification path from a trusted root through intermediates to the leaf certificate.
17. **Check run** — one automated test result on a commit — a status object on a forge, attached to a specific commit SHA, with a conclusion such as success or failure.
18. **Checkout** — putting a commit's files into your folder — updating the working tree and HEAD to match a specified commit, branch or path.
19. **Checksum** — a small number that proves nothing got mangled — a value computed over data and compared after transfer or storage to detect accidental change.
20. **Cherry-pick** — copying one commit onto another branch — applying a single commit's diff elsewhere, creating a new commit with a new hash.
21. **Chinchilla** — the finding that models were trained on too little data — the 2022 DeepMind result giving compute-optimal token and parameter ratios.
22. **Chiplet** — a big chip built from several smaller ones — separate dies packaged together and joined by a high-speed interconnect, improving yield and mixing process nodes.
23. **Chunk** — a piece of a bigger thing sent on its own — a bounded portion of data transferred or processed separately, as in chunked transfer encoding.
24. **CIDR** — writing an address range as a prefix — Classless Inter-Domain Routing, RFC 1519, notation such as 192.168.0.0/24 giving address and prefix length.
25. **Cipher suite** — the exact set of algorithms a connection uses — the negotiated combination of key exchange, authentication, bulk cipher and MAC or AEAD mode.
26. **Circuit switching** — a dedicated path reserved for one call — reserving capacity end to end for the call's duration, unlike packet switching, which shares links.
27. **Client prediction** — the game moving you before the server replies — applying local input immediately and reconciling later against authoritative server state.
28. **Clock** — the machine's heartbeat — a periodic square wave defining the instants at which state elements sample their inputs.
29. **Clock domain** — a region sharing one clock — part of a chip driven by one clock, with synchronizers needed for signals crossing to another domain.
30. **Closure** — a function that remembers where it came from — a function value together with captured bindings from its defining scope.
31. **Cloud region** — a geographic cluster of data centres — a named location such as ap-south-1, containing several availability zones with independent failure domains.
32. **CMOS** — the way nearly all logic is built — complementary metal-oxide-semiconductor, pairing n-channel and p-channel FETs so steady states draw almost no current.
33. **CNAME** — a name that points to another name — a DNS record aliasing one name to another, after which resolution restarts at the target.
34. **Coalescing** — joining small pieces into one bigger one — combining adjacent free blocks, memory accesses or writes to reduce overhead.
35. **Codec** — the thing that squeezes and unsqueezes media — coder-decoder: the algorithm pair compressing and decompressing audio or video, such as AAC, H.264 or AV1.
36. **Codepoint** — the number that identifies a character — a Unicode scalar value from U+0000 to U+10FFFF, excluding the surrogate range.
37. **Cold start** — the first call being slow — the delay while a serverless platform allocates and initial-

izes an execution environment before running your code.

38. **Cold storage** — cheap storage you rarely read — archival tiers with low cost per gigabyte and retrieval delays measured in minutes to hours.
39. **Colour space** — the agreed meaning of a colour number — a defined set of primaries, white point and transfer function, such as sRGB, Display P3 or Rec. 2020.
40. **Commit** — a saved snapshot with a message — a git object naming a tree, zero or more parents, author, committer, timestamps and a message, identified by its hash.
41. **Compaction** — tidying storage by rewriting it — merging and rewriting data to reclaim space, as in log-structured stores and SSD garbage collection.
42. **Compiler** — turns source code into machine code — a program translating a whole source program into another language, usually machine code, before it runs.
43. **Compression** — making data smaller — encoding that reduces size, lossless if the original returns exactly, lossy if some information is discarded.
44. **Concurrency** — several things in progress at once — structuring work so tasks overlap in time; parallelism means they literally run at the same instant.
45. **Conflict** (git) — two edits to the same lines — a merge where the same region changed on both sides, leaving markers for a human to resolve.
46. **Constant folding** — doing the maths at compile time — a compiler optimization evaluating constant expressions during compilation.
47. **Container** — an isolated box for one program and its files — a process group isolated by kernel namespaces and limited by cgroups, sharing the host kernel.
48. **Container** (media) — the wrapper holding audio and video together — a file format such as MP4, MKV or WebM carrying encoded streams, timing and metadata.
49. **Contamination** — a model already saw the exam — benchmark test data appearing in training data, inflating scores without matching ability.
50. **Context switch** — the CPU swapping one task for another — saving one thread's registers and state, then loading another's, costing roughly one to a few microseconds.
51. **Context window** — how much a model can read at once — the maximum number of tokens a model may attend over in one request, including its own output.
52. **Continuous delivery** — every good build is ready to ship — an automated pipeline that keeps the main branch in a deployable state, with release as a decision.
53. **Continuous integration** — merging often, tested every time — the practice of integrating work frequently, with an automated build and test on every change.
54. **Control plane** — the part that decides — the systems computing routes, policy and configuration, as opposed to the data plane that moves packets.
55. **Cookie** — a small note a site asks your browser to keep — a name-value pair stored by the browser and returned on matching requests, defined by RFC 6265.
56. **Copy-on-write** — share until someone writes — mapping the same pages into several users and duplicating a page only when one of them modifies it.
57. **Core** — one complete processor inside a chip — an independent set of execution units, registers and L1 caches able to run its own instruction stream.
58. **Coroutine** — a function that can pause and resume — a routine with suspendable execution state, allowing cooperative multitasking without OS threads.
59. **CORS** — a site giving permission for another site to read it — Cross-Origin Resource Sharing: response headers letting a browser relax the same-origin policy.
60. **CPU** — the part that follows the instructions — central processing unit, the general-purpose pro-

cessor fetching, decoding and executing instructions.

61. **CPU-bound** — limited by thinking, not waiting — a workload whose completion time is set by processor throughput rather than I/O.
62. **CRC** — a strong checksum for detecting damage — cyclic redundancy check, polynomial division over GF(2); CRC-32 protects Ethernet frames.
63. **Cross-compilation** — building on one machine for another — producing binaries for a target architecture or OS different from the build host.
64. **Cryptographic hash** — a fingerprint of any data — a one-way function producing a fixed-size digest, where finding collisions is computationally infeasible.
65. **CSMA/CA** — listen before you transmit, and back off — Carrier Sense Multiple Access with Collision Avoidance, the Wi-Fi access method with random backoff.
66. **CSRF** — a site tricking your browser into using your login — cross-site request forgery, defeated by anti-forgery tokens and SameSite cookies.
67. **CSS** — the rules that decide how a page looks — Cascading Style Sheets: selectors and declarations applied by cascade, specificity and inheritance.
68. **Culling** — not drawing what nobody can see — discarding geometry outside the view frustum, facing away, or hidden behind other objects.
69. **Current** — the flow of electricity — the rate of charge flow, measured in amperes; one ampere is one coulomb per second.
70. **Czochralski** — the way a silicon crystal is grown — dipping a seed crystal into molten silicon and slowly pulling and rotating it to form a single-crystal boule.

■ 53.4.4 D

1. **DAC** — turns numbers back into a real signal — digital-to-analogue converter, reconstructing a voltage from samples at a fixed rate.
2. **Daemon** — a program that runs quietly in the background — a long-lived process with no controlling terminal, usually started at boot.
3. **Datagram** — a message sent with no promises — a self-contained packet delivered without connection setup, ordering or retransmission.
4. **dBm** — signal strength on a logarithmic scale — power relative to one milliwatt; -50 dBm is strong Wi-Fi and -85 dBm is marginal.
5. **DDR** — memory that moves data on both clock edges — double data rate SDRAM; DDR5, standardized 2020, starts at 4800 MT/s.
6. **Dead code** — code that can never run — instructions unreachable on any path, normally removed by the compiler.
7. **Deadlock** — two tasks each waiting for the other — a cycle of hold-and-wait dependencies where no participant can proceed.
8. **Debouncing** — ignoring a switch's noisy chatter — filtering multiple contact transitions into one clean event, typically over 5 to 50 ms.
9. **Decibel** — a way to write huge ratios in small numbers — ten times the base-10 logarithm of a power ratio; 3 dB is roughly double.
10. **Decode (AI)** — writing the answer one token at a time — the autoregressive generation phase, one token per forward pass, memory-bandwidth bound.
11. **Decoder-only** — the transformer shape used by chat models — a stack of masked self-attention blocks with no separate encoder.
12. **Deep learning** — networks with many stacked layers — machine learning using multi-layer neural networks trained by gradient descent.

13. **Default route** — where to send anything you have no rule for — the 0.0.0.0/0 entry, or ::/0 for IPv6, in a routing table.
14. **Defragmentation** — putting a file's pieces back together — rearranging blocks so files occupy contiguous space, useful on disks and pointless on SSDs.
15. **Delta compression** — storing only what changed — encoding an object as a difference against a similar one, as git does inside packfiles.
16. **Demand paging** — loading pages only when touched — bringing a page into memory on its first access, signalled by a page fault.
17. **Dependency** — something your code needs to work — an external library, service or tool required to build or run software.
18. **Dependency injection** — passing in what a thing needs — supplying collaborators from outside rather than constructing them internally.
19. **Detached HEAD** — you are on a commit, not on a branch — HEAD holding a commit hash directly, so new commits belong to no branch.
20. **Deterministic lockstep** — every machine simulates the same thing — sending only inputs and relying on identical simulation on all clients.
21. **DHCP** — the network hands you an address automatically — Dynamic Host Configuration Protocol, RFC 2131, using the DORA exchange to lease settings.
22. **Die** — one chip cut from a wafer — a single rectangle of processed silicon containing a complete circuit.
23. **Dielectric** — the insulating filling in a capacitor — a non-conducting material that polarizes in a field and raises capacitance.
24. **Diffie-Hellman** — agreeing a secret over an open line — key exchange where each side combines its private value with the other's public value.
25. **Diode** — a one-way valve for electricity — a PN junction conducting when forward biased above about 0.7 V in silicon.
26. **Directory** — a folder holding names — a filesystem object mapping names to inode numbers or file records.
27. **Dirty bit** — a mark saying this copy changed — a flag showing a page or cache line differs from the backing store and must be written back.
28. **Disk image** — a file holding a whole drive's contents — a byte-for-byte copy of a block device, including partition table and filesystems.
29. **Distributed system** — several machines pretending to be one — a system whose components run on networked machines and coordinate by message passing.
30. **Distro** — one packaged version of Linux — a distribution bundling a kernel, libraries, package manager and defaults, such as Debian or Fedora.
31. **DMA** — devices moving data without bothering the CPU — direct memory access, where a controller transfers to or from memory and interrupts on completion.
32. **DNS** — the phone book turning names into addresses — a distributed hierarchical database of resource records, RFC 1034 and 1035.
33. **DNS resolver** — the helper that does the lookups for you — a recursive server that queries root, TLD and authoritative servers and caches results.
34. **Docker** — the tool that made containers easy — a container engine with an image format, build file and registry workflow, released 2013.
35. **Docker image** — a frozen filesystem plus start instructions — a layered, content-addressed bundle of filesystem layers and configuration metadata.
36. **DOM** — the page as a tree the code can change — Document Object Model, the browser's live

object tree built from parsed HTML.

37. **Doping** — adding impurities to make silicon useful — introducing donors such as phosphorus or acceptors such as boron to make n-type or p-type material.
38. **DPI** — dots per inch on paper — printer resolution; PPI is the screen equivalent, pixels per inch.
39. **DPO** — training from preferences without a reward model — direct preference optimization, fitting the policy directly to pairs of preferred and rejected answers.
40. **DRAM** — the main memory that needs constant refreshing — dynamic RAM storing a bit as charge on a capacitor, refreshed roughly every 32 or 64 ms.
41. **Draw call** — one order sent to the graphics card — a command to render a batch of geometry with one state and shader set.
42. **Driver** — the code that speaks a device's language — kernel or user-space software translating generic requests into device-specific commands.
43. **DROP** — silently binning a packet — a firewall action discarding a packet with no reply, so the sender only sees a timeout.
44. **Duplex** — whether both ends can talk at once — full duplex allows simultaneous send and receive; half duplex allows only one direction at a time.
45. **Dynamic linking** — libraries joined at start-up, not build time — resolving symbols at load or first use, sharing one library copy across processes.

■ 53.4.5 E

1. **eBPF** — running safe little programs inside the kernel — an in-kernel virtual machine with a verifier, used for tracing, networking and security.
2. **ECC (memory)** — memory that corrects its own small errors — error-correcting code memory, typically SECDED, fixing single-bit and detecting double-bit errors.
3. **ECC (crypto)** — strong keys that are short — elliptic curve cryptography; a 256-bit curve key is roughly as strong as a 3072-bit RSA key.
4. **ECMP** — spreading traffic over several equally good paths — equal-cost multipath, hashing a flow's five-tuple to pick one of several next hops.
5. **Edge case** — the odd input that breaks things — a condition at the boundary of valid input, often untested.
6. **Edge computing** — doing work near the user instead of far away — running compute at points of presence close to clients to cut latency.
7. **Elasticity** — capacity that grows and shrinks with demand — automatic scaling of resources in response to load, with matching cost changes.
8. **ELF** — the executable format on Linux — Executable and Linkable Format, with a header, program headers for loading and section headers for linking.
9. **Embedding** — a meaning turned into a list of numbers — a learned dense vector whose geometry places related items close together.
10. **Emulation** — one machine pretending to be another — software reproducing another system's instruction set and devices closely enough to run its software.
11. **Encapsulation (networks)** — wrapping one message inside another — placing a higher-layer unit into a lower-layer payload with its own header.
12. **Encoder** — the half that reads rather than writes — a transformer stack producing representations of an input without generating tokens.
13. **Endianness** — which end of a number comes first — byte order in memory; little-endian stores the least significant byte at the lowest address.
14. **Endpoint** — one address a service answers on — a specific URL and method combination, or a

network address plus port.

15. **Entropy** — how surprising the data is — the average information per symbol in bits, the floor for lossless compression.
16. **Environment variable** — a setting passed to a program at start — a name-value pair inherited through the process environment, such as PATH or HOME.
17. **Ephemeral port** — the temporary port your side uses — a short-lived source port, usually from 32768 to 60999 on Linux, chosen per connection.
18. **Epoch** (training) — one full pass through the data — one complete presentation of the training set to the learner.
19. **Epoch** (time) — the moment counting starts — the Unix epoch, 00:00:00 UTC on 1 January 1970, the zero point for time_t.
20. **Error budget** — the amount of failure you are allowed — the difference between 100 percent and an SLO, spendable on risky changes.
21. **Etching** — cutting the pattern into the wafer — removing material chemically or with plasma where photoresist does not protect it.
22. **Ethernet** — the wired local network everyone uses — IEEE 802.3 framing and access rules, from 10 Mbit/s in 1983 to 800 Gbit/s today.
23. **EUV** — the light used to print the smallest features — extreme ultraviolet lithography at 13.5 nm wavelength, in production since 2019.
24. **Eventual consistency** — everyone agrees, given a moment — a model where replicas converge if updates stop, without guaranteeing immediate agreement.
25. **Exception** — an error that jumps out of normal flow — a signalled condition transferring control to a handler and unwinding the stack.
26. **Exit code** — the number a program leaves behind — a process's status, 0 for success by convention and 1 to 255 for failure.
27. **Exponent** — the part of a float that sets the scale — the biased power-of-two field in IEEE 754, 8 bits in binary32 and 11 in binary64.
28. **Extension** — the bit after the dot in a filename — a naming convention, not a guarantee; the real type comes from content or magic numbers.

■ 53.4.6 F

1. **Fan-out** — how many things one thing drives — the number of inputs a single output feeds, limiting speed in logic and load in messaging.
2. **Fast-forward** — the branch just slides forward — a merge where the target is an ancestor of the source, so the ref simply moves, creating no commit.
3. **Fault tolerance** — carrying on despite broken parts — designing so component failure degrades service instead of stopping it.
4. **Feature flag** — a switch that turns a feature on or off — configuration allowing behaviour to change at runtime without redeploying.
5. **Fetch** (git) — download new objects but change nothing — updating remote-tracking refs and objects without touching your branches or working tree.
6. **FIFO** — first in, first out — a queue discipline, or a named pipe file created with mkfifo.
7. **File descriptor** — the small number a program uses to name an open file — a per-process index into the kernel's open file table; 0, 1 and 2 are stdin, stdout, stderr.
8. **File handle** — the object behind an open file — the kernel structure holding the file's position, mode and reference count.
9. **Filesystem** — the way files are laid out on a device — the on-disk structures and rules holding

names, metadata and data blocks, such as ext4, APFS or NTFS.

10. **Fine-tuning** — extra training on your own examples — continued training of a pretrained model on a smaller task-specific dataset.
11. **FinFET** — a transistor with a fin sticking up — a 3D transistor whose gate wraps a thin silicon fin, in production from 2011 to about the 3 nm class.
12. **Firewall** — a guard deciding which packets may pass — a device or kernel subsystem filtering traffic by rules over addresses, ports, state and content.
13. **Firmware** — software living in the device itself — code stored in non-volatile memory on a device, run before or beneath the operating system.
14. **Firmware update** — replacing the software inside a device — writing new code to a device's flash, usually with A/B slots and a signature check.
15. **Fixed timestep** — the game's physics ticks at one steady rate — advancing simulation in constant increments regardless of frame time, with interpolation for display.
16. **Flash memory** — storage that keeps data with no power — floating-gate or charge-trap cells holding charge, erased in blocks and written in pages.
17. **Flip-flop** — a circuit that remembers one bit — an edge-triggered storage element capturing its input at a clock edge.
18. **Floating point** — a number with a moving decimal point — a sign, exponent and fraction encoding under IEEE 754, trading precision for range.
19. **Flow control** — stopping a fast sender flooding a slow receiver — TCP's advertised receive window, or the equivalent at other layers.
20. **Flush** — pushing buffered data out now — forcing pending writes from a buffer to the next level, such as fsync to storage.
21. **Fork (process)** — making a copy of the running program — the Unix call creating a child process with a copied address space, usually copy-on-write.
22. **Fork (repository)** — your own copy of someone's project — a server-side clone under your account, with its own refs and pull-request relationship.
23. **Forward proxy** — a middleman your client chooses — a server making requests on a client's behalf, often for policy or caching.
24. **Forward secrecy** — yesterday's traffic stays safe if today's key leaks — using ephemeral key exchange so long-term key compromise cannot decrypt past sessions.
25. **Fragment (IP)** — a packet cut up to fit — an IP packet split to fit a link's MTU, reassembled at the destination.
26. **Frame (network)** — the layer 2 envelope — the Ethernet or Wi-Fi unit with MAC addresses, payload and a frame check sequence.
27. **Frame (graphics)** — one complete picture — one full rendered image; at 60 Hz the frame budget is 16.67 ms.
28. **Frame budget** — the time you have for one picture — the per-frame time allowance, 16.67 ms at 60 Hz and 6.94 ms at 144 Hz.
29. **Frame rate** — pictures per second — displayed frames per second; smoothness also depends on frame time consistency, not the average alone.
30. **Framebuffer** — the memory holding the picture to be shown — a region of memory holding pixel values scanned out to a display.
31. **Free software** — software you may run, study, change and share — software distributed with the four freedoms, usually under a copyleft licence such as the GPL.
32. **Frequency** — how many cycles per second — cycles per second in hertz; a 4 GHz clock has a period of 250 picoseconds.

33. **FTL** — the SSD's private map of where data really is — flash translation layer, mapping logical block addresses to physical pages and handling wear and garbage collection.
34. **Full-duplex** — talking and listening at the same time — simultaneous bidirectional transmission on separate paths or with echo cancellation.
35. **Function call** — jumping into a named block and coming back — transferring control with arguments and a return address, following the ABI's calling convention.
36. **Fuzzing** — throwing random rubbish at a program to break it — automated testing with mutated or generated inputs, watching for crashes and assertion failures.

■ 53.4.7 G

1. **Game loop** — read input, update, draw, repeat — the cycle sampling input, advancing simulation and rendering, once per frame.
2. **Gamma** — the curve between number and brightness — a nonlinear transfer function matching encoding to perception, roughly 2.2 for sRGB.
3. **Garbage collection** — memory tidied up automatically — a runtime reclaiming unreachable objects, by tracing or reference counting.
4. **Gate** (logic) — a tiny circuit applying one logical rule — a circuit implementing AND, OR, NOT, NAND, NOR or XOR over binary inputs.
5. **Gate** (transistor) — the leg that switches the flow — the control terminal whose voltage forms or removes the channel between source and drain.
6. **Gateway** — the way out of your local network — the router a host sends to when the destination is not on its own subnet.
7. **GATT** — how Bluetooth devices expose small values — Generic Attribute Profile, a hierarchy of services, characteristics and descriptors addressed by handle.
8. **GDDR** — memory built for graphics cards — graphics DDR SDRAM tuned for very high bandwidth with wide buses and high clock rates.
9. **Gigabit** — a thousand million bits — 10^9 bits; note that 1 Gbit/s is 125 MB/s before protocol overhead.
10. **GIL** — only one thread runs Python bytecode at a time — CPython's global interpreter lock, serializing bytecode execution across threads.
11. **Git** — the version control system almost everyone uses — a content-addressed distributed VCS created by Linus Torvalds in April 2005.
12. **Golden image** — the trusted base copy you build from — a validated machine or container image used as the starting point for deployments.
13. **Goodput** — the useful data rate, not the raw one — application-level throughput after headers, retransmissions and protocol overhead.
14. **Goroutine** — a very cheap thread in Go — a lightweight task multiplexed onto OS threads by the Go runtime scheduler.
15. **GPIO** — a pin you can set high or low yourself — general-purpose input/output, a configurable digital pin on a microcontroller or board.
16. **GPT** (partition) — the modern partition table — GUID Partition Table, part of UEFI, supporting large disks and 128 partitions by default.
17. **GPT** (model) — a generative pretrained transformer — a decoder-only transformer trained to predict the next token.
18. **GPU** — the chip built for many small sums at once — a processor with thousands of simple lanes, built for throughput on parallel work.
19. **Graceful degradation** — losing features instead of falling over — designing so partial failure re-

duces function rather than causing an outage.

20. **Gradient clipping** — stopping an update from being too big — rescaling gradients whose norm exceeds a threshold, to keep training stable.
21. **Gradient descent** — walking downhill on the error — updating parameters against the gradient of the loss, scaled by the learning rate.
22. **GraphQL** — the client asks for exactly the fields it wants — a query language and runtime with one endpoint, a typed schema and client-shaped responses.
23. **Ground** — the reference point voltages are measured from — the common return path defined as zero volts in a circuit.
24. **gRPC** — fast structured calls between services — a remote procedure call framework using Protocol Buffers over HTTP/2, with streaming support.
25. **Guard clause** — checking the bad case first and leaving — an early return that removes nesting from the main path.
26. **GUI** — pointing at pictures instead of typing commands — a graphical user interface with windows, icons, menus and a pointer.

■ 53.4.8 H

1. **Hallucination** — a model stating something untrue with confidence — fluent output not grounded in training data or provided context.
2. **Handover** — your phone moving to the next mast without dropping — transferring an active connection between cells while keeping the session alive.
3. **Handshake** — the greeting that sets up a connection — the exchange establishing parameters, such as TCP's SYN, SYN-ACK, ACK.
4. **Hard link** — two names for the same file — a second directory entry pointing at the same inode, with a shared link count.
5. **Hash table** — a lookup that is fast because it computes where to look — a map using a hash of the key to index buckets, average $O(1)$ lookup.
6. **HBM** — memory stacked right next to the processor — high bandwidth memory, stacked DRAM dies on an interposer, giving terabytes per second.
7. **HDD** — a drive with spinning magnetic platters — a hard disk with rotating platters and moving heads, giving milliseconds of seek latency.
8. **HDR** — brighter brights and darker darks — high dynamic range imaging with wider luminance range, usually with a PQ or HLG transfer function.
9. **HEAD** — where you are in the repository right now — a ref pointing to the current branch, or directly to a commit when detached.
10. **Header** — the label on the front of a message — the fixed or structured prefix carrying addressing and control information before the payload.
11. **Heap** — memory you ask for and give back yourself — the region for dynamic allocation, managed by the allocator rather than by scope.
12. **Heat sink** — metal that carries heat away — a finned metal block spreading and radiating heat from a package to moving air or liquid.
13. **Hertz** — cycles per second — the SI unit of frequency, one cycle per second.
14. **Hexadecimal** — counting in sixteens — base-16 notation using 0 to 9 and A to F, where one digit encodes exactly four bits.
15. **Hit rate** — how often the cache had it — the fraction of requests served from cache, the main determinant of average latency.
16. **Hop** — one router along the way — a single forwarding step; traceroute reveals hops by increasing

the TTL.

17. **Hotfix** — an urgent small change — a minimal patch shipped outside the normal release cycle to fix a live problem.
18. **HTML** — the markup that says what parts a page has — HyperText Markup Language, a tree of elements the browser parses into the DOM.
19. **HTTP** — the rules browsers and servers use to talk — a request-response protocol with methods, status codes and headers, now RFC 9110.
20. **HTTPS** — HTTP inside an encrypted tunnel — HTTP carried over TLS, normally on port 443, giving confidentiality, integrity and server authentication.
21. **Huffman coding** — short codes for common symbols — an optimal prefix-free code built from symbol frequencies, used inside DEFLATE and JPEG.
22. **Hyperparameter** — a setting you choose before training — a value not learned by gradient descent, such as learning rate, batch size or layer count.
23. **Hyper-threading** — one core pretending to be two — simultaneous multithreading, running two instruction streams over one core's execution resources.
24. **Hypervisor** — software that runs whole machines inside one machine — a layer creating and scheduling virtual machines, type 1 on bare metal or type 2 on a host OS.

■ 53.4.91

1. **IaaS** — renting raw machines and networks — infrastructure as a service, where you manage the OS and everything above it.
2. **IAM** — who is allowed to do what — identity and access management: principals, policies, roles and permission evaluation.
3. **ICMP** — the network's error and echo messages — the control protocol carrying unreachable, time exceeded and echo, RFC 792.
4. **Idempotent** — doing it twice changes nothing more — an operation whose repeated application has the same effect as one application.
5. **Idle** — doing nothing on purpose — a scheduler state with no runnable task, usually entering a low-power CPU state.
6. **IEEE 754** — the rule that makes floating point the same everywhere — the 1985 standard defining binary32, binary64, rounding modes, infinities and NaN.
7. **Image** (container) — a frozen filesystem plus start-up settings — a layered, content-addressed bundle of layers and configuration.
8. **IMEI** — the serial number identifying a phone itself — a 15-digit equipment identity, distinct from the SIM's subscriber identity.
9. **Immutable** — it cannot be changed after it is made — a value or object whose state is fixed at creation, simplifying sharing and caching.
10. **Impedance** — how much a component resists an alternating signal — the complex ratio of voltage to current; speakers are commonly 4 or 8 ohms.
11. **Index** (git) — the staging area between edits and a commit — a binary file listing paths, modes and blob hashes for the next commit.
12. **Inductor** — a coil that resists sudden changes in current — a component storing energy in a magnetic field, with voltage proportional to di/dt .
13. **Inference** — using a trained model to get an answer — the forward pass only, with no gradients and no parameter updates.
14. **Infrastructure as code** — servers described in files, not clicked into existence — declarative resource definitions kept in version control and applied by a tool.

15. **init** — the first process the kernel starts — PID 1, which starts services and adopts orphaned processes.
16. **Inode** — the record holding a file's facts — a filesystem structure with mode, owner, times, size and block pointers, but not the name.
17. **Instruction pipeline** — several instructions in progress at once — overlapping fetch, decode, execute and write-back stages to raise throughput.
18. **Instruction set** — the list of operations a CPU understands — the ISA: opcodes, registers, addressing modes and the binary encoding.
19. **Instruction tuning** — teaching a model to follow requests — supervised fine-tuning on instruction-and-response pairs.
20. **Integer overflow** — a number too big for its box — a result exceeding the type's range, wrapping in unsigned types and undefined for signed C.
21. **Integration test** — checking that the parts work together — a test exercising several components and their real interfaces.
22. **Interface (network)** — one connection point on a machine — a NIC or virtual device with its own MAC address, addresses and statistics.
23. **Intermediate representation** — the compiler's private middle language — an IR such as LLVM IR, easier to optimize than source or machine code.
24. **Interpreter** — runs source code directly, line by line — a program executing a source or bytecode representation without producing a native binary.
25. **Interrupt** — a device tapping the CPU on the shoulder — an asynchronous signal causing the CPU to jump to a handler and return.
26. **Interrupt latency** — how long before the handler starts — the delay from signal assertion to the first handler instruction.
27. **IOMMU** — an address translator for devices — hardware mapping and restricting device DMA addresses, essential for safe passthrough.
28. **IP address** — the number that identifies a machine on a network — a 32-bit IPv4 or 128-bit IPv6 address, assigned to an interface, not a device.
29. **IPC (CPU)** — instructions finished per clock tick — instructions per cycle, the other half of performance beside frequency.
30. **IPC (software)** — how two programs talk — inter-process communication by pipes, sockets, shared memory or message queues.
31. **IPv4** — the old 32-bit address scheme — RFC 791 addressing, about 4.3 billion addresses, exhausted at IANA in 2011.
32. **IPv6** — the 128-bit replacement — RFC 8200 addressing with 2^{128} addresses, no header checksum and no router fragmentation.
33. **IXP** — a building where networks meet and swap traffic — an internet exchange point with a shared switch fabric for peering.

■ 53.4.10 J

1. **JavaScript** — the language that runs inside web pages — a dynamically typed, event-driven language standardized as ECMAScript.
2. **JIT** — compiling while the program runs — just-in-time compilation of hot paths to native code, guided by runtime profiles.
3. **Jitter** — how much the delay wobbles — variation in packet delay, more damaging than average latency for voice and games.
4. **Job (CI)** — one unit of work in a pipeline — a set of steps run on one runner, with its own environment and result.
5. **Job control** — putting a command in the background — shell management of process groups with foreground, background and stopped states.
6. **Journaling** — writing down the plan before doing it — a filesystem log of intended metadata changes, replayed after a crash.
7. **JSON** — a simple text format for structured data — JavaScript Object Notation: objects, arrays, strings, numbers, booleans and null.
8. **JWT** — a signed token you can read yourself — JSON Web Token, RFC 7519, a base64url header, payload and signature joined by dots.

■ 53.4.11 K

1. **Kernel (OS)** — the part of the system with full power over the machine — the code running in privileged mode, owning scheduling, memory and devices.
2. **Kernel (maths)** — the small window slid over data — a filter matrix applied by convolution across an image or signal.
3. **Kernel mode** — the privileged half of the processor — the state allowing all instructions and address ranges, entered by trap or interrupt.
4. **Kernel panic** — the system giving up — an unrecoverable kernel error that halts the machine rather than risk corruption.
5. **Key (attention)** — what each token offers to be matched against — a projected vector compared with queries to produce attention weights.
6. **Key derivation** — turning a password into a proper key — a KDF such as PBKDF2, scrypt or Argon2 stretching a secret into key material.
7. **Key exchange** — agreeing a secret without posting it — a protocol such as Diffie-Hellman letting both sides derive a shared key.
8. **Keyframe** — a video frame that stands alone — an intra-coded frame decodable without reference to others, the seek point in a stream.
9. **Kill** — telling a process to stop — sending a signal such as SIGTERM to request exit or SIGKILL to force it.
10. **Kilobyte** — a thousand bytes — 1000 bytes in SI usage; 1024 bytes is a kibibyte, KiB.
11. **Knowledge cutoff** — the date a model's reading stops — the point beyond which pretraining data was not collected.
12. **Kubernetes** — the system that keeps containers running — a container orchestrator with a declarative API and reconciling controllers.
13. **KV cache** — remembering earlier keys and values so they are not redone — stored per-layer key and value tensors for tokens already processed.

■ 53.4.12 L

1. **Lag compensation** — the server rewinding time to judge your shot — re-evaluating a hit against the world state the shooter actually saw.
2. **Latch** — a memory circuit that follows while enabled — a level-sensitive storage element, unlike an edge-triggered flip-flop.
3. **Latency** — the waiting time before something starts — the delay between cause and effect, measured end to end and reported as percentiles.
4. **LBA** — numbering blocks straight through — logical block addressing, a linear block number replacing cylinder, head and sector.
5. **LCD** — a screen where a backlight shines through gates — liquid crystal display, twisting crystals to control light per subpixel.
6. **Learning rate** — how big a step training takes — the scale factor on the gradient, the most sensitive hyperparameter.
7. **Least privilege** — give only the rights actually needed — restricting each principal to the minimum permissions for its task.
8. **Lexer** — the part that cuts source code into words — the tokenizer producing a stream of tokens from characters.
9. **LFS** — keeping big files out of git's history — Large File Storage, replacing large files with pointers and storing content separately.
10. **Library** — reusable code you call — a packaged collection of functions linked statically or loaded dynamically.
11. **Linked list** — items each pointing at the next — a sequence of nodes with pointers, cheap to insert and slow to index.
12. **Linker** — joins compiled pieces into one program — the tool resolving symbols, laying out sections and producing an executable or shared object.
13. **Little-endian** — the smallest byte first — byte order storing the least significant byte at the lowest address, as x86 and ARM do.
14. **Load balancer** — spreading requests across servers — a device or service distributing connections by round robin, least connections or hashing.
15. **Loader** — the code that puts a program into memory — the kernel or dynamic loader mapping segments, resolving symbols and jumping to the entry point.
16. **localhost** — the name a machine uses for itself — the hostname resolving to 127.0.0.1 and ::1, never leaving the machine.
17. **Locality** — recently or nearby data is likely used again — temporal and spatial locality, the reason caches work.
18. **Lock** — one at a time, please — a synchronization primitive giving exclusive access to shared state.
19. **LOD** — simpler models for distant objects — level of detail, swapping meshes or textures by screen size to save work.
20. **Log** — the running record of what happened — an append-only stream of events used for debugging, audit and recovery.
21. **Logic gate** — a tiny circuit applying one rule — a combinational circuit implementing a Boolean function of its inputs.
22. **Logit** — the raw score before it becomes a probability — the unnormalized output per vocabulary entry, fed to softmax.
23. **Loopback** — the machine talking to itself — the virtual interface for 127.0.0.0/8 and ::1, never leaving the host.
24. **LoRA** — training a small add-on instead of the whole model — low-rank adaptation, learning two

small matrices whose product updates a frozen weight.

25. **Loss function** — the score that says how wrong the model is — the objective minimized in training, typically cross-entropy for language models.
26. **Lossless** — nothing is thrown away — compression from which the exact original bytes can be restored, as in FLAC, PNG and gzip.
27. **Lossy** — some detail is thrown away for size — compression discarding information judged imperceptible, as in JPEG, MP3 and H.264.
28. **LRU** — throw out what was used longest ago — least recently used, a common cache replacement policy.
29. **LTE** — the fourth generation mobile standard — 3GPP Long Term Evolution, an all-IP radio network using OFDMA downlink.

■ 53.4.13 M

1. **MAC** (crypto) — a tag proving a message was not altered — message authentication code, such as HMAC, computed with a shared secret key.
2. **MAC address** — the hardware name of a network port — a 48-bit link-layer address, the first 24 bits identifying the manufacturer.
3. **Mach-O** — the executable format on macOS — Apple's binary format, with load commands and support for fat binaries holding several architectures.
4. **Magic number** — the few bytes at the start that say what a file is — a fixed signature such as 0x7F ELF or PK for zip, used by the file command.
5. **Malloc** — asking for memory while running — the C library call returning a pointer to an uninitialized block of the requested size.
6. **MBR** — the old partition table in the first sector — master boot record, four primary partitions and a 2 TiB limit.
7. **Memory leak** — memory taken and never given back — allocated memory that stays reachable but unused, growing the process footprint.
8. **Merge** — joining two lines of work — a commit with two or more parents, combining changes since the merge base.
9. **Merge base** — the last commit both branches share — the best common ancestor used as the reference point in a three-way merge.
10. **Merge queue** — testing changes in the order they will land — a forge feature building each pull request against the real future main branch.
11. **mergeStateStatus** — a forge's summary of whether a merge is possible — GitHub's field with values such as CLEAN, BLOCKED, BEHIND, DIRTY or UNKNOWN.
12. **MESI** — the four states a cache line can be in — modified, exclusive, shared, invalid: the coherence protocol keeping cores consistent.
13. **Metadata** — data about the data — attributes such as size, times, type and permissions, held separately from content.
14. **Microkernel** — a tiny kernel with drivers outside it — a design keeping only scheduling, memory and IPC privileged, with services in user space.
15. **Microservice** — a small service that does one job — an independently deployable service with its own data and interface.
16. **Middleware** — code sitting between request and handler — a chain of components processing requests before or after the application.
17. **Migration** (data) — changing the shape of stored data — a versioned script altering schema or contents, applied in order and recorded.

18. **MIMO** — several antennas sending several streams — multiple input multiple output, using spatial paths to multiply capacity.
19. **Mipmap** — smaller pre-made copies of a texture — a chain of half-size texture levels selected by screen footprint to avoid shimmering.
20. **Mixture of experts** — only part of the model runs per token — a layer routing each token to a few expert subnetworks, so active parameters are fewer than total.
21. **MMU** — the hardware that translates addresses — memory management unit, walking page tables to map virtual to physical addresses.
22. **Mode (file)** — the permission bits on a file — the 12-bit field holding owner, group and other permissions plus setuid, setgid and sticky.
23. **Model card** — the label describing what a model is and is not — a document stating intended use, training data summary, evaluations and limitations.
24. **Modulation** — changing a wave so it carries data — varying amplitude, frequency or phase to encode symbols on a carrier.
25. **Monolithic kernel** — one big kernel with drivers inside — a design running services and drivers in kernel mode, as Linux does.
26. **Monorepo** — everything in one repository — a single repository holding many projects, with shared tooling and atomic cross-project changes.
27. **Moore's law** — transistors per chip keep doubling — Gordon Moore's 1965 observation, revised in 1975 to a doubling roughly every two years.
28. **MOSFET** — the switch nearly all chips are made from — metal-oxide-semiconductor field-effect transistor, whose gate voltage forms a channel.
29. **Mount** — attaching a filesystem into the tree — making a device or remote share visible at a directory path.
30. **Mount point** — the directory where a filesystem appears — the path at which a filesystem's root is grafted into the namespace.
31. **MTU** — the biggest packet a link will carry — maximum transmission unit, 1500 bytes on standard Ethernet.
32. **Multicast** — one send, many listeners — delivery to a group address, where the network duplicates packets only where paths diverge.
33. **Multi-head attention** — several attention views at once — running attention in parallel subspaces and concatenating the results.
34. **Multiplexing** — many conversations over one link — interleaving several logical streams on one physical or transport channel.
35. **Mutation testing** — checking that tests would notice a bug — deliberately altering code to see whether the test suite fails.
36. **Mutex** — a lock only one holder may take — mutual exclusion primitive with owner tracking, blocking other threads until released.

■ 53.4.14 N

1. **Namespace** (Linux) — a private view of a system resource — a kernel feature isolating mounts, PIDs, network stacks, users or hostnames per process group.
2. **NaN** — the float that means “not a number” — an IEEE 754 value produced by invalid operations, unequal even to itself.
3. **NAND flash** — the storage in phones and SSDs — non-volatile memory of series-connected cells, written per page and erased per block.
4. **NAT** — many private machines behind one public address — network address translation, rewriting addresses and ports and tracking the mapping.
5. **Netcode** — the part of a game that handles the network — the synchronization design: tick rate, prediction, interpolation and reconciliation.
6. **Netmask** — which part of an address is the network — a bit mask marking the prefix, written as 255.255.255.0 or as /24.
7. **Network interface** — the port a machine uses to reach a network — a physical or virtual device with a MAC address and its own addresses.
8. **Neural network** — layers of weighted sums with bends between them — a differentiable function of stacked linear maps and nonlinearities, fitted by gradient descent.
9. **Next hop** — the router to hand this packet to — the neighbouring address a routing table entry sends matching traffic to.
10. **Nginx** — a common web server and reverse proxy — an event-driven server handling many connections with few processes.
11. **Nibble** — half a byte — four bits, exactly one hexadecimal digit.
12. **NIC** — the network card — network interface controller, handling framing, checksums and often offloads.
13. **Node** (compute) — one machine in a cluster — a host contributing CPU, memory and storage, managed by the cluster’s scheduler.
14. **Node** (process) — the transistor generation name — a marketing label such as 5 nm or 3 nm, no longer matching any physical dimension.
15. **Nonce** — a number used exactly once — a value ensuring freshness or uniqueness, never repeated under one key.
16. **Non-volatile** — it remembers with the power off — storage retaining state without power, unlike DRAM and SRAM.
17. **Normalization** (AI) — keeping numbers in a sensible range — layer or RMS normalization rescaling activations to stabilize training.
18. **Notification** (interrupt) — see interrupt — an asynchronous event delivered to software rather than polled for.
19. **NTP** — how machines agree what time it is — Network Time Protocol, disciplining clocks to within milliseconds over the internet.
20. **Null pointer** — a pointer deliberately pointing at nothing — the reserved address zero, whose dereference traps on most systems.
21. **NUMA** — memory that is closer to some cores than others — non-uniform memory access, where latency depends on which node owns the memory.
22. **NVMe** — the protocol built for flash, not for disks — a command set over PCIe with deep parallel queues and very low overhead.
23. **NVRAM** — small memory that survives a reboot — non-volatile RAM used for firmware settings and boot variables.
24. **Nyquist** — sample at least twice the highest frequency — the sampling theorem requiring a rate

above twice the signal bandwidth to avoid aliasing.

■ 53.4.15 O

1. **OAuth** — letting an app act for you without your password — a delegation framework issuing scoped access tokens, RFC 6749.
2. **Object file** — compiled code not yet joined up — a relocatable binary with sections, symbols and relocation entries.
3. **Observability** — being able to tell what a system is doing — the ability to answer new questions from existing logs, metrics and traces.
4. **OFDM** — splitting a channel into many narrow lanes — orthogonal frequency division multiplexing, used by Wi-Fi, LTE, 5G and DSL.
5. **Ohm's law** — push equals flow times resistance — $V = IR$, relating voltage, current and resistance in a linear element.
6. **OLED** — a screen where each dot makes its own light — organic light-emitting diode panels with no backlight, giving true black.
7. **Opcode** — the number that says which operation — the field of an instruction encoding selecting the operation to perform.
8. **Opcode fusion** — merging two instructions into one operation — a CPU front-end optimization combining common instruction pairs.
9. **Open weights** — the trained numbers are published — a model whose parameters are downloadable, which is not the same as open training data.
10. **Orchestration** — deciding what runs where — automated placement, scaling and recovery of workloads across a cluster.
11. **Origin** — the default name for where you cloned from — the conventional remote name git creates for the source repository.
12. **Origin server** — the machine holding the real content — the source a CDN fetches from when it has no valid cached copy.
13. **Orphan** (git) — an object nothing points to — an unreachable object, removable by garbage collection after its grace period.
14. **Oscillator** — the circuit that makes the ticking — a crystal or ring circuit producing a periodic reference signal.
15. **OSI model** — seven named layers for teaching — ISO 7498, from physical up to application, useful as vocabulary, not as an implementation.
16. **Out-of-order** — doing ready work first, then tidying up — executing instructions as operands become available, retiring them in program order.
17. **Overclocking** — running a chip faster than rated — raising frequency and often voltage beyond specification, at the cost of heat and stability.
18. **Overfitting** — memorizing the answers instead of learning — fitting noise in training data, shown by training loss falling while validation loss rises.
19. **Overlay network** — a network built on top of another — virtual links tunnelled over an existing network, as with VXLAN or WireGuard.
20. **Overprovisioning** — spare flash the drive keeps hidden — reserved capacity that improves garbage collection and endurance.

■ 53.4.16 P

1. **PaaS** — you bring the code, they run everything else — platform as a service, managing runtime, scaling and patching for you.
2. **Packaging** (chips) — putting the die in something you can solder — attaching a die to a substrate with bumps or wires and encapsulating it.
3. **Packet** — one labelled chunk of data — a network-layer unit of header plus payload, routed independently.
4. **Packet loss** — a packet that never arrives — discard caused by congestion, errors or policy, inferred from missing acknowledgements.
5. **Packfile** — many git objects compressed into one file — a container storing objects with delta compression, plus an index for lookup.
6. **Page** — the unit memory is managed in — a fixed-size block of virtual memory, usually 4 KiB, mapped to a physical frame.
7. **Page fault** — the page was not in memory — a trap when a virtual page has no valid mapping, handled by loading or allocating.
8. **Page table** — the map from virtual to physical pages — a multi-level structure walked by the MMU, cached in the TLB.
9. **Parameter** (AI) — one learned number in the model — a single weight or bias updated by training and stored in the model file.
10. **Parity** — one extra bit to spot an odd error — a bit making the count of ones even or odd, detecting single-bit errors.
11. **Parser** — the part that works out the structure — the component turning tokens into a syntax tree by grammar rules.
12. **Partition** — one labelled region of a drive — a contiguous block range described by an MBR or GPT entry.
13. **Pass@k** — did any of k attempts pass — a benchmark metric giving credit if at least one of k samples is correct.
14. **Passphrase** — a long password made of words — a secret chosen for entropy through length rather than symbol variety.
15. **Patch** — a file describing a change — a unified diff with context lines, applicable to matching source.
16. **PATH** — the list of folders the shell searches — an environment variable of directories scanned in order for a command name.
17. **Payload** — the actual content, minus the wrapping — the data a protocol carries, excluding headers and trailers.
18. **PCIe** — the fast lanes connecting chips inside a computer — PCI Express, point-to-point serial lanes; gen 5 runs 32 GT/s per lane.
19. **PCM** — sound stored as plain numbers — pulse-code modulation, uncompressed samples at a fixed rate and bit depth.
20. **PE** — the executable format on Windows — Portable Executable, with a DOS stub, COFF header and sections such as .text and .rdata.
21. **Peering** — two networks exchanging traffic directly — a bilateral agreement to swap customer routes, often settlement-free.
22. **Permission** — what you are allowed to do to a file — access bits or ACL entries checked by the kernel on open.
23. **Persistent storage** — data that outlives the process — storage surviving restarts, unlike memory or a container's writable layer.

24. **Phase** — where a wave is in its cycle — angular offset in degrees or radians, the basis of phase-shift keying.
25. **Photolithography** — printing the circuit pattern with light — projecting a mask image onto photoresist to define features on a wafer.
26. **Photoresist** — the light-sensitive coating on a wafer — a polymer whose solubility changes on exposure, defining where etching happens.
27. **Piconet** — a small group of Bluetooth devices working together — one primary device and up to seven active secondaries sharing a hopping pattern.
28. **Ping** — asking a host whether it is there — sending ICMP echo requests and timing the replies.
29. **Pipe** — the output of one command becoming the input of the next — a kernel buffer joining one process's stdout to another's stdin.
30. **Pipeline (CPU)** — instructions in a production line — overlapping instruction stages so one finishes per cycle in the ideal case.
31. **Pixel** — one dot of the picture — the smallest addressable element of a raster image or display.
32. **Plist** — the settings file format on Apple systems — a property list, in XML or binary form, holding key-value configuration.
33. **PN junction** — where p-type meets n-type silicon — the boundary forming a depletion region and conducting in only one direction.
34. **Pod** — the smallest deployable unit in Kubernetes — one or more containers sharing a network namespace, address and storage volumes.
35. **Pointer** — a value that holds an address — a variable containing the memory address of another object.
36. **Polling** — asking repeatedly instead of being told — checking a status in a loop rather than waiting for an interrupt or event.
37. **Port** — the number identifying which program on a machine — a 16-bit endpoint identifier in TCP and UDP headers.
38. **Positional encoding** — telling the model where each word sits — added or rotated information giving order to otherwise position-blind attention.
39. **POSIX** — the portable Unix rulebook — IEEE 1003 standards defining system calls, shell and utilities.
40. **PPI** — how tightly packed the dots are — pixels per inch of a display, about 460 on current high-end phones.
41. **Precision** — how finely a number can be written — the count of significant bits or digits a format can represent.
42. **Prefetch** — fetching before it is asked for — hardware or software loading data into cache ahead of predicted use.
43. **Prefill** — reading the whole prompt in one go — the parallel forward pass over input tokens that fills the KV cache, compute bound.
44. **Pretraining** — the long first training on huge text — self-supervised next-token training that produces a base model.
45. **Primary key** — the column that identifies a row — a unique, non-null identifier for a table's rows.
46. **Privilege escalation** — getting more power than you were given — an exploit raising a principal's permissions beyond its intended level.
47. **Process** — one running program with its own memory — an address space, one or more threads, and a table of open file descriptors.
48. **Profiling** — measuring where the time actually goes — sampling or instrumenting a program to attribute cost to code paths.

- 49. **Prompt injection** — hidden text telling a model to misbehave — untrusted content in a model's context that overrides intended instructions.
- 50. **Propagation delay** — the time a gate takes to change its output — the interval from input transition to a valid output, tens of picoseconds today.
- 51. **Protocol** — the agreed rules for a conversation — the message formats, ordering and state machine two parties follow.
- 52. **Proxy** — a middleman making requests for you — a server that terminates one connection and opens another on the client's behalf.
- 53. **PTY** — a fake terminal for a program that expects one — pseudo-terminal, a master and slave pair providing terminal semantics without hardware.
- 54. **Pull request** — asking for your branch to be merged — a forge object linking a source branch, target branch, review and checks.
- 55. **Push** — sending your commits to a remote — uploading objects and asking the remote to update refs, refused if it is not a fast-forward.
- 56. **PWM** — a switch flicked fast to fake a level — pulse-width modulation, varying duty cycle to control average power.

■ 53.4.17 Q

- 1. **QAM** — packing more bits into each radio symbol — quadrature amplitude modulation; 1024-QAM carries 10 bits per symbol.
- 2. **Quantization** — using coarser numbers to save space — reducing weight precision, for example FP16 to INT8 or 4-bit, with a small accuracy cost.
- 3. **Query** (attention) — what one token is looking for — a projected vector compared against every key to produce attention weights.
- 4. **Queue** — a line of waiting work — a FIFO structure decoupling producers from consumers.
- 5. **QUIC** — a fast transport built on UDP — RFC 9000, giving streams, encryption and connection migration without head-of-line blocking.
- 6. **Quorum** — enough members agreeing to decide — a majority of replicas required for a consistent read or write.
- 7. **Quota** — a cap on how much you may use — an enforced limit on storage, requests or resources per account or user.

■ 53.4.18 R

- 1. **Race condition** — the answer depends on who gets there first — a bug where behaviour depends on the unsynchronized timing of concurrent access.
- 2. **RAG** — letting a model read documents before answering — retrieval-augmented generation, injecting retrieved passages into the prompt.
- 3. **RAID** — several drives acting as one, for speed or safety — striping, mirroring or parity across disks; RAID is not a backup.
- 4. **RAM** — the fast memory that forgets when power stops — volatile random-access memory holding running code and data.
- 5. **Rebase** — replaying your commits on a new base — creating new commits with the same changes but new parents and new hashes.
- 6. **Refactoring** — tidying code without changing behaviour — a behaviour-preserving transformation improving structure or clarity.
- 7. **Reflog** — git's private diary of where refs pointed — a local log of ref updates, letting you recover from a bad reset.

8. **Refresh rate** — how often the screen redraws — display updates per second in hertz, commonly 60, 120 or 144.
9. **Register** — the CPU's own handful of tiny stores — a named storage location inside the core, accessed in a fraction of a cycle.
10. **Registry** (containers) — the shop images are pulled from — a service storing and serving container images by name and digest.
11. **Registry** (Windows) — the central settings database — a hierarchical store of keys and values used by Windows and its applications.
12. **Regularization** — stopping the model memorizing — techniques such as weight decay, dropout or early stopping that limit overfitting.
13. **REJECT** — refusing a packet and saying so — a firewall action sending an ICMP unreachable or TCP RST, so the sender fails fast.
14. **Remote** — a named repository somewhere else — a stored URL plus fetch and push refsspecs, such as origin.
15. **Remote-tracking ref** — your last known idea of a remote branch — a local ref under refs/remotes updated only by fetch or push.
16. **Replication** — keeping copies on more than one machine — maintaining synchronized data on several nodes for durability or read scaling.
17. **Repository** — the whole project with all its history — a directory containing the object database, refs and configuration.
18. **Resistance** — how much a material fights the flow — the ratio of voltage to current, in ohms, dissipating power as heat.
19. **Resolution** — how many dots the picture has — the pixel count of an image or display, such as 1920 by 1080.
20. **Resolver** — the helper that does DNS lookups for you — a recursive server querying the hierarchy and caching results by TTL.
21. **REST** — using plain HTTP methods on named resources — an architectural style with stateless requests and uniform verbs over URLs.
22. **Reverse proxy** — a middleman in front of the servers — a server accepting client requests and forwarding them to backends.
23. **RFC 1918** — the address ranges reserved for private use — 10.0.0.0/8, 172.16.0.0/12 and 192.168.0.0/16, never routed on the internet.
24. **Ring buffer** — a fixed queue that wraps around — a circular array with head and tail indices, overwriting or blocking when full.
25. **RLHF** — training a model on what people preferred — reinforcement learning from human feedback, optimizing against a learned reward model.
26. **Root server** — the servers at the top of DNS — the 13 named root identities serving the root zone, reached by anycast.
27. **Rootkit** — malware that hides itself in the system — code subverting the kernel or firmware to conceal its own presence.
28. **RoPE** — encoding position by rotating the vectors — rotary position embedding, applying a position-dependent rotation to queries and keys.
29. **Round-trip time** — how long there and back takes — the delay from sending to receiving the acknowledgement, driving TCP behaviour.
30. **Router** — the box that forwards between networks — a device choosing an outgoing interface by longest-prefix match on the destination.
31. **Routing table** — the list of where to send what — the forwarding entries of prefix, next hop,

interface and metric.

32. **RSA** — an old public-key algorithm based on big numbers — a scheme whose security rests on the difficulty of factoring; keys are 2048 bits or larger.
33. **RST** — a rude end to a TCP connection — a reset flag telling the peer to abandon the connection immediately.
34. **Runner** — the machine that executes a CI job — an agent that claims jobs from a queue and reports results back.

■ 53.4.19 S

1. **SaaS** — you just use the website — software as a service, run entirely by the provider with no infrastructure for you.
2. **Salt** — a random extra ingredient in a password hash — a unique per-password value stored alongside it, defeating precomputed tables.
3. **Same-origin policy** — one site cannot read another's data — the browser rule isolating documents by scheme, host and port.
4. **Sampling** (AI) — choosing the next word from the odds — drawing from the model's output distribution, shaped by temperature and top-p.
5. **Sampling rate** — how many measurements per second — samples per second; CD audio uses 44,100 Hz.
6. **Sandbox** — a restricted area a program cannot escape — an isolation mechanism limiting a process's syscalls and resources.
7. **SATA** — the older cable standard for drives — Serial ATA, 6 Gbit/s in revision 3, with one command queue.
8. **Scaling laws** — bigger models and more data give predictable gains — empirical power-law relations between compute, data, parameters and loss.
9. **Scheduler** — decides which task runs next — the kernel component choosing runnable threads by policy and priority.
10. **Scope** (OAuth) — the exact list of things a token may do — a string set attached to a token limiting the operations it authorizes.
11. **SDK** — the tools you need to build for a platform — a software development kit of libraries, headers, tools and samples.
12. **Sector** — the smallest addressable piece of a disk — 512 bytes traditionally, 4096 bytes on Advanced Format drives.
13. **Segment** — TCP's unit of data — the transport-layer unit with sequence numbers, flags and payload.
14. **Semantic versioning** — the version number tells you what changed — MAJOR.MINOR.PATCH, where a major bump means a breaking change.
15. **Semaphore** — a counter that limits how many may proceed — a synchronization primitive with wait and signal operations.
16. **Semiconductor** — a material between a conductor and an insulator — a solid such as silicon whose conductivity is controlled by doping, field or light.
17. **Serialization** — turning objects into bytes to send or store — encoding structures into a byte stream, reversed by deserialization.
18. **Serverless** — you write the function, not the server — a model where the platform runs code on demand and bills by invocation and duration.
19. **Session** — the memory of who you are between requests — server or token state associating requests with an authenticated user.

20. **SHA-256** — a common cryptographic fingerprint — a hash producing a 256-bit digest, used in TLS, git and signing.
21. **Shader** — a small program the GPU runs per vertex or pixel — GPU code for stages such as vertex, fragment or compute.
22. **Sharding** — splitting data across several databases — partitioning by key so each shard holds a subset of the rows.
23. **Shebang** — the first line saying which interpreter to use — the two bytes `#!` plus a path, read by the kernel when running a script.
24. **Shell** — the program that reads your commands — a command interpreter handling expansion, redirection, pipelines and job control.
25. **Signal** (Unix) — a short message telling a process something happened — an asynchronous notification such as SIGINT, SIGTERM or SIGSEGV.
26. **Signal-to-noise ratio** — how loud the message is compared with the hiss — the power ratio of signal to noise, usually in decibels.
27. **SIM** — the card that identifies you to the mobile network — a smart card holding the IMSI and authentication key, or an eSIM profile.
28. **SIMD** — one instruction working on many numbers — single instruction multiple data, as in SSE, AVX and NEON.
29. **Single point of failure** — the one part whose loss stops everything — a component with no redundancy on the critical path.
30. **SLC to QLC** — how many bits are squeezed into one flash cell — single, multi, triple and quad-level cells, trading endurance and speed for density.
31. **Slice** — a view into part of an array — a reference with pointer, length and sometimes capacity, without copying.
32. **SLO** — the promise you hold yourself to — a service level objective, a target for a measured indicator over a window.
33. **SMTP** — how mail servers hand messages to each other — Simple Mail Transfer Protocol, RFC 5321, on ports 25, 465 or 587.
34. **Snapshot** — a frozen picture of data at one moment — a point-in-time copy, often made cheaply by copy-on-write.
35. **Socket** — the endpoint a program reads and writes a connection through — an OS object identified by address, port and protocol.
36. **Softmax** — turning scores into probabilities — exponentiating logits and dividing by their sum so the values total one.
37. **Spinlock** — waiting by looping instead of sleeping — a lock that busy-waits, correct only for very short critical sections.
38. **Spread spectrum** — deliberately smearing a signal over more bandwidth — modulating over a wide band to resist interference and interception.
39. **Sprite** — a small image drawn over the scene — a 2D bitmap composited into a frame, historically with dedicated hardware.
40. **SQL injection** — smuggling commands inside data — an attack where unescaped input becomes part of a database query.
41. **SRAM** — fast memory built from logic, used in caches — static RAM using six transistors per bit, needing no refresh.
42. **SSD** — storage with no moving parts — a solid-state drive of NAND flash plus a controller, with microsecond latency.
43. **SSH** — a secure way to log in to another machine — the Secure Shell protocol on port 22, with

host keys and public-key user authentication.

44. **SSID** — the name of a wireless network — the human-readable network identifier broadcast in beacons.
45. **SSRF** — tricking a server into fetching an internal URL — server-side request forgery, reaching private services from a trusted position.
46. **Stack** — the memory used for calls and locals — a LIFO region holding frames with return addresses, arguments and locals.
47. **Staging area** — what will go into the next commit — git's index, holding the exact content to be committed.
48. **Stateful firewall** — it remembers connections, not just packets — a filter tracking flow state so replies are allowed automatically.
49. **Static linking** — the library is baked into the binary — copying library code into the executable at build time.
50. **Streaming** — playing while it is still arriving — delivering media progressively rather than downloading it whole.
51. **Subnet** — a slice of an address range — a network defined by a prefix, sharing one broadcast domain in IPv4.
52. **Sub-pixel** — the red, green or blue part of a dot — one colour element of a pixel, exploitable for text rendering.
53. **Superscalar** — issuing several instructions each cycle — a core with multiple parallel execution ports and wide issue.
54. **Swap** — using disk when memory runs out — backing anonymous pages with storage so more can be committed than exists.
55. **Symbolic link** — a file that points at another path — a special file holding a path string, resolved at open time.
56. **System call** — a program asking the kernel to do something — the trap instruction and ABI by which user code enters the kernel.
57. **systemd** — the thing that starts everything on modern Linux — an init system and service manager with units, sockets and journal.

■ 53.4.20 T

1. **Tag** — a fixed name for one commit — a ref under refs/tags, lightweight or an annotated object with message and signature.
2. **TCP** — the protocol that makes sure everything arrives in order — a connection-oriented transport with sequence numbers, acknowledgements and retransmission.
3. **Tearing** — the picture split across two frames — a display artefact when the buffer swaps mid-scanout, fixed by vsync.
4. **Temperature** — how adventurous the model's word choice is — a divisor on logits before softmax; lower is more deterministic.
5. **Thread** — one line of execution inside a program — a schedulable flow with its own stack and registers, sharing the process address space.
6. **Threat model** — deciding who you are defending against — an explicit statement of assets, adversaries, capabilities and out-of-scope risks.
7. **Three-way handshake** — the greeting that opens a TCP connection — the SYN, SYN-ACK, ACK exchange establishing sequence numbers.
8. **Throughput** — how much work gets done per second — completed operations or bits per unit time, distinct from latency.

9. **Tick rate** — how often the game server updates the world — server simulation steps per second, often 20 to 128 in shooters.
10. **TLB** — a small cache of address translations — translation lookaside buffer, holding recent virtual-to-physical page mappings.
11. **TLD** — the last label of a domain name — the top-level domain such as com, org or in, delegated from the root zone.
12. **TLS** — the encryption under HTTPS — Transport Layer Security; version 1.3, RFC 8446, needs one round trip and requires forward secrecy.
13. **Token** — the small piece of text a model actually sees — a subword unit from the tokenizer's vocabulary, roughly 0.75 English words each.
14. **Tokenizer** — the tool that cuts text into tokens — the encoder mapping text to integer IDs, usually by byte-pair encoding.
15. **Top-p** — keep only the most likely words that add up to p — nucleus sampling, restricting choice to the smallest set whose probability exceeds p.
16. **Trace** (observability) — the story of one request across services — a tree of timed spans sharing one trace identifier.
17. **Traceroute** — showing the routers along the way — sending packets with increasing TTL and reading the ICMP time-exceeded replies.
18. **Trailing whitespace** — invisible spaces at the end of a line — characters that break diffs and comparisons without being visible.
19. **Transaction** — all of it or none of it — a group of operations with atomicity, consistency, isolation and durability.
20. **Transformer** — the design behind modern language models — a stack of self-attention and feed-forward blocks, from the 2017 paper Attention Is All You Need.
21. **Transistor** — an electrical tap — a semiconductor switch or amplifier; in CMOS logic, a field-effect transistor.
22. **Transpiler** — a compiler from one language to another readable one — a source-to-source translator, as TypeScript to JavaScript.
23. **Trap** — a deliberate jump into the kernel — a synchronous exception raised by an instruction, such as a system call.
24. **Trilateration** — finding a position from several distances — computing a location from ranges to known points, as GPS does.
25. **TRIM** — telling the drive which blocks are now rubbish — a command letting the filesystem mark blocks free so the SSD can erase them early.
26. **Truncation** — cutting data that does not fit — discarding bits, characters or tokens beyond a limit, often silently.
27. **Truth table** — every input combination and its output — an exhaustive listing of a Boolean function's behaviour.
28. **TTL (IP)** — a hop counter that stops loops — a header field decremented per router, triggering ICMP time exceeded at zero.
29. **TTL (DNS)** — how long an answer may be cached — the seconds a resolver may reuse a record before asking again.
30. **TTY** — the terminal a program is attached to — a kernel device providing line discipline, echo and job control.
31. **Tunnel** — one network carried inside another — encapsulating packets inside another protocol, as with VPNs and GRE.

32. **Two-factor authentication** — a password plus something else — requiring a second independent factor such as a code or hardware key.
33. **Two's complement** — how computers store negative numbers — inverting all bits and adding one, giving one zero and a range from $-2^{(n-1)}$ to $2^{(n-1)}-1$.
34. **Type system** — rules about what values may be combined — a static or dynamic discipline classifying values and rejecting invalid operations.

■ 53.4.21 U

1. **UDP** — send it and hope — a connectionless transport with no ordering, no retransmission and very little overhead.
2. **UEFI** — the modern replacement for the BIOS — firmware with its own boot manager, GPT support, drivers and optional Secure Boot.
3. **Unicode** — one number for every character in every script — a character set of code points from U+0000 to U+10FFFF, with 154,998 assigned in version 16.0.
4. **Unit test** — checking one small piece on its own — a fast, isolated test of a single function or class.
5. **Unreachable** — nothing can get there from here — an object with no path from a root, or a network with no route.
6. **Upstream** — the branch or project yours follows — the configured remote branch a local branch compares and pushes to.
7. **Uptime** — how long since the last restart — elapsed time since boot, not the same as availability.
8. **USB** — the connector that replaced all the others — Universal Serial Bus, from 12 Mbit/s in 1996 to 80 Gbit/s in USB4 Version 2.0.
9. **User mode** — the restricted half of the processor — the unprivileged state where a program cannot touch devices or kernel memory directly.
10. **User space** — everything outside the kernel — processes running unprivileged, reaching the kernel only by system calls.
11. **UTF-8** — Unicode written as bytes, ASCII still working — a variable-length encoding using one to four bytes per code point.
12. **UUID** — a name unique without asking anyone — a 128-bit identifier, usually version 4 random or version 7 time-ordered.

■ 53.4.22 V

1. **Value** (attention) — the content a token contributes when attended to — a projected vector summed with attention weights to form the output.
2. **Vector database** — storage that finds things by meaning — an index over embeddings supporting approximate nearest-neighbour search.
3. **Version control** — keeping every version and who changed what — a system recording snapshots, authorship and lineage of files.
4. **Vertex** — one corner of a shape — a point with position and attributes, processed by the vertex stage.
5. **Virtual machine** — a whole fake computer inside a real one — an isolated guest with its own kernel, scheduled by a hypervisor.
6. **Virtual memory** — every program thinks it owns the whole address space — per-process address translation through page tables, with protection and paging.
7. **Virtualization** — one machine pretending to be several — hardware-assisted isolation of guests, using extensions such as VT-x or AMD-V.
8. **VLAN** — several separate networks over one set of wires — IEEE 802.1Q tagging, giving separate broadcast domains on shared links.

9. **Voice coil** — the coil that moves a speaker cone — a wire coil in a magnetic gap, driven by current to move the diaphragm.
10. **Volatile** (memory) — it forgets when power stops — storage requiring power to retain state, as DRAM and SRAM do.
11. **Voltage** — electrical push — potential difference in volts, the work per unit charge between two points.
12. **Volume** — storage attached to a container or machine — a named block or filesystem mount whose lifetime is separate from the workload.
13. **VPN** — a private tunnel across a public network — an encrypted tunnel giving remote hosts an address inside a protected network.
14. **Vsync** — waiting for the screen before swapping the picture — synchronizing buffer swaps to the display refresh to avoid tearing.
15. **Vulnerability** — a weakness someone can exploit — a flaw allowing an attacker to violate a security property, often tracked by CVE number.

■ 53.4.23 W

1. **Wafer** — the thin silicon disc chips are made on — a 300 mm polished slice cut from a boule, carrying hundreds of dies.
2. **Watchdog** — a timer that reboots a stuck system — hardware or software resetting the system if not periodically reset by software.
3. **Wear levelling** — spreading writes so no cell dies early — an SSD controller policy distributing program and erase cycles across blocks.
4. **Webhook** — the server calls you when something happens — an HTTP POST sent by a service to a URL you registered.
5. **WebSocket** — a two-way channel over one web connection — RFC 6455, upgrading an HTTP connection to a persistent frame-based channel.
6. **Weight** — one number that scales an input — a learned multiplier in a layer's matrix, the bulk of a model's parameters.
7. **Wi-Fi** — wireless local networking — IEEE 802.11 standards, branded by generation, currently up to Wi-Fi 7 from 802.11be.
8. **Word** (CPU) — the natural size the machine works in — the register and native operand width, 64 bits on current mainstream CPUs.
9. **Workflow** — the file describing an automated pipeline — a declarative definition of triggers, jobs and steps for a CI system.
10. **Working set** — the pages a program actually needs right now — the memory touched over a recent interval, the amount that must stay resident.
11. **Working tree** — the actual files you can see and edit — the checked-out files in your directory, separate from the index and object store.
12. **WPA2** — the Wi-Fi encryption most networks still use — 802.11i security with AES-CCMP and a four-way handshake.
13. **WPA3** — the newer Wi-Fi encryption — security using SAE key exchange, resisting offline dictionary attacks on the passphrase.
14. **Write amplification** — the drive writing more than you asked — the ratio of physical NAND writes to host writes, driven by garbage collection.

■ 53.4.24 X

1. **x86** — the instruction set in most PCs — Intel's CISC architecture from the 1978 8086, extended to 64 bits as x86-64 in 2003.

2. **XDR** — the widest brightness range a display claims — extreme dynamic range, a marketing name for HDR panels with high peak luminance.
3. **XML** — structured text with tags — a markup language for machine-readable data, standardized in 1998.
4. **XOR** — true when the inputs differ — the exclusive-or Boolean function, the core of parity, adders and simple ciphers.
5. **XSS** — injecting script into someone else's page — cross-site scripting, where untrusted input is rendered as executable script.

■ 53.4.25 Y

1. **Y2K** — the year 2000 date problem — the failure risk from two-digit year fields, largely averted by remediation before 2000.
2. **YAML** — an indentation-based configuration format — a superset of JSON where structure comes from indentation, common in CI and Kubernetes.
3. **Yield** — the share of chips that come out working — the fraction of dies on a wafer passing test, the main driver of chip cost.

■ 53.4.26 Z

1. **Zero trust** — trust nothing just because it is inside the network — an architecture authenticating and authorizing every request regardless of network position.
2. **Zero-day** — an attack for which no fix exists yet — a vulnerability exploited before the vendor has released a patch.
3. **Zombie process** — a finished process nobody has collected — a terminated child whose exit status has not yet been reaped by its parent.
4. **Zone** (DNS) — one slice of the name tree under one authority — a portion of the namespace served by one set of authoritative servers.

53.5 Where to go next

1. Understanding comes from doing. You did not learn to ride a bicycle by reading about balance, and this is the same.
2. Pick the one layer in this book that annoyed you most because you did not quite get it. Go there first. Discomfort is a good compass.
3. Build the smallest possible version of something you used today. A shell that runs one command. A web server that returns one line. A tiny assembler.
4. Then break it on purpose. Unplug the network mid-transfer. Fill the disk. Send a malformed header. You learn more from the failure than the success.
5. Read real source code, not just tutorials. Start with something small and old: a `coreutils` command, a toy compiler, an early version of a database.
6. Read the actual specifications. RFCs are shorter and clearer than their reputation. So is the IEEE 754 summary. So is the git object format.
7. Learn one tool that shows you the truth: a packet capture tool, a debugger, a profiler, or `strace`. One of these changes how you think permanently.
8. When something breaks, write down what you observed before you write down what you think it means. Keep those two columns separate. That is diagnosis.
9. Do not chase every new framework. The layers under them barely change. The person who knows the layers can pick up any framework in a week.

10. Teach it to someone. If you cannot explain it plainly, you have not finished learning it. That is the whole reason this book has a plain half.
11. Be sceptical of benchmark numbers, including ones you like. Ask what was measured, on what, by whom, and what was left out.
12. It is normal to forget most of the details. Keep this chapter. Remember the shape of the thing, and look the numbers up when you need them.
13. Nobody understands all of this at once, including the people who built it. Every expert you admire has a large map and a few deep holes.
14. You started with charge in a wire and finished with a language model. That is one continuous story, and you now know it end to end. Go and build.

53.6 The whole book in 100 lines

1. Everything starts with charge, a property of matter that pushes and pulls.
2. Voltage is push, current is flow, resistance is how hard the path fights back.
3. Ohm's law ties them together: voltage equals current times resistance.
4. Silicon is neither a good conductor nor a good insulator, and that is why it is useful.
5. Add tiny amounts of other elements and you get n-type and p-type silicon.
6. Join them and you get a junction that passes current in only one direction.
7. Add a third terminal and a small voltage controls a large flow. That is a transistor.
8. A transistor used as a switch is the only real trick in the whole machine.
9. Sand becomes a pure crystal, the crystal becomes a wafer, the wafer becomes chips.
10. Light prints the pattern, chemicals cut it, and the layers are built up in turn.
11. Not every die works, so yield quietly decides the price of everything.
12. Wire a few transistors one way and you get a gate: AND, OR, NOT, NAND.
13. NAND alone can build every other gate, and therefore every digital circuit.
14. Gates wired in a pattern add binary numbers without knowing what addition is.
15. Feed a gate's output back into its input and it holds a value. That is memory.
16. A clock decides when things may change, so signals have time to settle first.
17. Six transistors hold one bit quickly. That is SRAM, and it becomes cache.
18. One transistor and one capacitor hold one bit cheaply. That is DRAM, and it forgets.
19. Charge trapped on an isolated gate holds a bit with no power. That is flash.
20. Nothing in any of this knows what a number means.
21. Meaning is a convention. We agree that a pattern of bits stands for something.
22. Binary counts in twos. Hexadecimal writes four bits per digit for human eyes.
23. Negative numbers use two's complement, so one adder handles both signs.
24. Fractions use floating point, standardized as IEEE 754 in 1985, and it rounds.
25. Text is numbers too. ASCII gave 128 characters. Unicode gives over a million.
26. UTF-8 stores Unicode as bytes and leaves old ASCII files working unchanged.
27. Pictures are grids of pixels, and each pixel is three numbers for brightness.
28. A framebuffer holds those numbers, and the screen scans them out many times a second.
29. Sound is air pressure measured thousands of times a second and stored as numbers.
30. A converter turns those numbers back into a voltage that moves a coil and a cone.
31. A CPU fetches an instruction, decodes it, executes it, and writes the result.
32. It does this in a pipeline, so several instructions are in progress at once.
33. It guesses which way each branch will go, and it is usually right.
34. It runs work out of order and finishes it in order, to hide the waiting.
35. Memory is far slower than the core, so caches keep recent data close by.

36. A cache line is 64 bytes, and code that respects that runs several times faster.
37. Programs use virtual addresses, and hardware translates them through page tables.
38. That gives every process its own world and stops one program reading another's.
39. Storage is not memory. Storage keeps things when the power stops.
40. A hard disk seeks in milliseconds. A solid-state drive answers in microseconds.
41. Flash erases in big blocks, so drives shuffle data and hide where it really is.
42. Filesystems turn a flat array of blocks into names, folders and permissions.
43. Buses carry data between chips, and inside a computer the fast one is PCIe.
44. Firmware runs before any operating system and knows how to wake the machine.
45. Software is a pattern of bits held in the same memory as data. That is the big idea.
46. A compiler reads source text, works out what it means, and writes machine code.
47. It tokenizes, parses into a tree, checks meaning, optimizes, then emits code.
48. An interpreter skips the output file and carries out the meaning directly.
49. A linker joins the compiled pieces and a loader maps them into memory to run.
50. Languages are tools with opinions, each built for the problem of its own time.
51. An operating system shares one machine between many programs, safely.
52. The kernel is privileged. Your code is restricted and asks by system call.
53. A scheduler decides who runs next, thousands of times every second.
54. Drivers translate general requests into the exact language of one device.
55. The shell is only a program that reads your words and starts other programs.
56. Pipes join those programs so one program's output becomes another's input.
57. A file extension is a hint, not a fact. The bytes at the start are the fact.
58. An executable is a file with a header telling the loader how to start it.
59. Pressing a key sends a code that becomes an event that becomes a character.
60. A font renderer turns that character into pixels, composited into one frame.
61. A GPU exists because pictures need the same small sum done millions of times.
62. Thousands of simple lanes beat a few clever cores when the work is parallel.
63. A network is machines agreeing how to wrap, address and forward data.
64. Data is cut into packets so one big transfer cannot block everyone else.
65. Each layer adds a header and treats the layer above it as opaque payload.
66. An IP address names an interface. A MAC address names a port on one link.
67. Private addresses are reused everywhere, and NAT hides many machines behind one.
68. Routers forward by longest prefix match and know nothing of your conversation.
69. BGP is how independent networks tell each other which prefixes they can reach.
70. DNS turns names into addresses through a hierarchy of caches and authorities.
71. TCP adds sequence numbers, acknowledgements and retransmission to make a stream.
72. UDP adds almost nothing, which is exactly what real-time traffic wants.
73. Traceroute shows the path by sending packets that expire one hop further each time.
74. Silence is evidence. A timeout with no reply tells you what a refusal does not.
75. Diagnosis is separating what an observation proves from what it merely suggests.
76. Radio carries the same bits on a wave, shaped by modulation and shared by turns.
77. TLS wraps a connection in encryption, and a certificate chain proves who answered.
78. A firewall drops or rejects, a VPN tunnels, and a CDN moves content closer to you.
79. The web is documents fetched by HTTP, marked up in HTML, styled by CSS, moved by JavaScript.
80. An API is a promise about requests and answers, so machines can call machines.
81. Git stores snapshots, not differences, and names every object by its content hash.
82. A commit points at a tree and at its parents, and cannot change without changing its name.

83. Branches are only moving labels, which is why making one costs nothing.
84. Because the whole history is local, you can work fully with no network at all.
85. Merge joins two histories. Rebase rewrites yours onto a new base, with new hashes.
86. A forge adds accounts, review, permissions and automation on top of plain git.
87. Continuous integration runs your tests on a machine you do not own, against one exact commit.
88. Cloud is renting someone else's computers, with the hard parts already solved.
89. Containers isolate processes. Virtual machines isolate whole kernels.
90. Security is a threat model, least privilege, and honesty about what you cannot stop.
91. A game is a loop: read input, advance the world by a fixed step, draw, repeat.
92. Everything in that loop must fit the frame budget, or the player feels it.
93. Across a network the client guesses ahead, and the server has the final say.
94. Machine learning replaces rules you write with numbers fitted to examples.
95. A network of weighted sums and bends is trained by gradient descent on a loss.
96. Backpropagation works out which weight caused how much of the error.
97. A transformer lets every token look at every other token, all at once.
98. A language model only predicts the next token. Everything else follows from that.
99. It has no memory beyond its context, no access to truth, and no intent of its own.
100. From charge in a wire to a conversation with a machine, it is one continuous story, and you have now read it.

ABOUT THE AUTHOR

Shikhar Singh

Founder & Chairman

KedByte Technologies Private Limited

Shikhar Singh is the Founder & Chairman of KedByte Technologies Private Limited.

He wrote this book to solve a problem he kept meeting: capable people concluding they were not technical, when in truth nobody had ever shown them the bottom of the stack. His conviction is that computing has no genuinely hard idea in it, only a very long chain of simple ones, and that anybody who is walked along that chain in order can hold the whole of it in their head.

That conviction shapes the method used here. Explain it plainly, with a comparison and a worked example, so that it lands. Then explain it again in the exact professional vocabulary, with the real units and the real figures, so that it is usable. Say clearly where the plain version stops being true. Never let a reader carry away a confident misunderstanding.

Under his direction, KedByte Technologies Private Limited treats technical education as infrastructure rather than as a product feature: knowledge that should be transferable, verifiable, and free of the vocabulary barriers that keep capable people out of the field.

ABOUT THE PUBLISHER

KedByte Technologies Private Limited

KedByte Technologies Private Limited publishes technical work under the KedByte Press imprint.

The editorial standard applied to this volume is simple to state and difficult to meet. Every explanation must work twice: once for a reader who has never opened a terminal, and once for an engineer who needs the exact figure. Every claim that can be checked must be checked. Every figure that will go stale must carry a date. Where the field genuinely disagrees, both positions are given rather than one being quietly chosen.

Where this book uses real evidence, it uses it unaltered. The network trace in Part F, the failed pushes in Part G and the error messages quoted throughout are reproduced exactly as they were observed. Diagnosis is taught against ambiguous real data, because that is the only kind there is.

KEDBYTE

TECHNOLOGIES PRIVATE LIMITED

COLOPHON

This first edition of *How Computers Work* runs to nine parts and fifty-three chapters, and was set entirely from plain text.

The body text is set in TeX Gyre Pagella, a digital revival of Hermann Zapf's Palatino, chosen for long-form reading. Headings, tables and the KedByte identity are set in Poppins. Code, command output and diagrams are set in DejaVu Sans Mono, and every diagram in this book is drawn in plain ASCII so that it survives being copied anywhere.

The book was composed with pandoc and typeset with XeLaTeX on A4 stock. The single accent colour used on rules, chapter numbers and section headings is KedByte navy.
